PAGENUMBER1

CHAPTER 1
Population, Resources, Environment: Dimensions of the Human Predicament

It is clear that the future course of history will be determined by the rates at which people breed and die, by the rapidity with which nonrenewable resources are consumed, by the extent and speed with which agricultural production can be improved, by the rate at which the underdeveloped areas can industrialize, by the rapidity with which we are able to develop new resources, as well as by the extent to which we succeed in avoiding future wars. All of these factors are interlocked.

--Harrison Brown, 1954

Providing people with the ingredients of material wellbeing requires physical resources - land, water, energy, and minerals -- and the supporting contributions of environmental processes. Technology and social organization are the tools with which society transforms physical resources and human labor into distributed goods and services. These cultural tools are embedded in the fabric of the biological and geophysical environment; they are not independent of it.

As the number of people grows and the amounts of goods and services provided per person increase, the associated demands on resources, technology, social organization, and environmental processes become more intense and more complicated, and the interactions among these factors become increasingly consequential. It is the interactions -- technology with employment, energy with environment, environment and energy with agriculture, food and energy with international relations, and so on -- that generate many of the most vexing aspects of civilization's predicament in the last quarter of the twentieth century.

This book is about that predicament: about its physical underpinnings in the structure of the environment and the character of natural resources; about its human dimensions in the size, distribution, and economic condition of the world's population; about the impact of that population on the ecological systems of Earth and the impact of environmental changes on humanity; about the

technology, economics, politics, and individual behavior that have contributed to the predicament; and about the changes that might alleviate it.

THE ESSENCE OF THE PREDICAMENT

In a world inhabited in the mid- 1970s by a rapidly growing population of more than 4 billion people, a massive and widening gap in well-being separates a rich minority from the poor majority. The one-third of the world's population that lives in the most heavily industrialized nations (commonly termed developed countries -- DCs) accounts for 85 percent of the global personal income and a like fraction of the annual use of global resources. The people living in the less industrialized nations (often called less developed countries -LDCs) must apportion the remaining 15 percent of global income and resource use among two-thirds of the world's population. The result is an unstable prosperity for the majority of people in the DCs and frustrating, crushing poverty for the majority in the LDCs. Millions of the poorest -- especially infants and children -- have starved to death every year for decades; hundreds of millions have lived constantly, often consciously, almost always helplessly on the brink of famine and epidemic disease, awaiting only some modest quirk of an environment already stretched taut -- an earthquake, a flood, a drought -- to push them over that edge. The 1970s brought an apparent increase in such quirks -- 1972 and 1974 were years of flood, drought, and poor harvests. World food reserves plummeted, and millions more human beings were threatened by famine. Meanwhile, the entire population continued growing at a rate that would double the number of people in the world within 40 years.

The prosperity of the DCs - awesome by comparison with the poverty of the LDCs -- has been built on exploitation of the richest soils, the most accessible fossil fuels, and the most concentrated mineral deposits of the entire globe -- a one-time windfall. As they now struggle to maintain and even expand their massive consumption from a resource base of declining quality, the DCs by themselves appear to be taxing technology, social organization, and the physical environment beyond what they can long sustain. And the LDCs, as they try to follow the same path to economic development, find the bridges burned ahead of them. There will be no counterpart to the windfall of cheap resources that propelled the DCs into prosperity. A DC-style industrialization of the LDCs, based on the expensive resources that remain, is therefore probably foredoomed by enormous if not insurmountable economic and environmental obstacles.

The problems arising from this situation would be formidable even if the world were characterized by political stability, no population growth, widespread recognition of civilization's dependence on environmental processes, and a universally shared commitment to the task of closing the prosperity gap. In the real world, characterized by deep ideological divisions and territorial disputes, rapid growth of population and faltering food production, the popular illusion that technology has freed society from dependence on the environment, and the determined adherence of DC governments to a pattern of economic growth that enlarges existing disparities rather than narrowing them, the difficulties are enormously multiplied.

INTERACTIONS: RESOURCES, ECONOMICS, AND POLITICS

It takes water and steel to produce fuel, fuel and water to produce steel, fuel and water and steel to produce food and fiber, and so on. The higher the level of industrialization in a society, the more intimate and demanding are the interconnections among resources. Agriculture in the United States, Europe, and Japan, for example, uses far more fuel, steel, and mineral fertilizers per unit of food produced than does agriculture in India or Indonesia. The interconnections among resources also become more intense as the quality of the resource base diminishes; the

amount of fuel and metal that must be invested in securing *more* fuel and metal increases as exhaustion of rich deposits forces operations deeper, farther afield, and into leaner ores.

These tightening physical links among resources have their counterparts in economic and organizational ef-

fects. Scarcity or rising prices of one commodity generate scarcity and rising prices of others, thus contributing both directly and indirectly to inflation and often to unemployment. Massive diversion of investment capital and technical resources to meet the crisis of the moment -- attempting to compensate for lack of foresight with brute force applied too late -- weakens a system elsewhere and thus promotes crises in other sectors later. Apparent solutions seized in haste and ignorance cut off options that may be sorely missed when future predicaments arise.

International aspects add to the complexity -- and the dangers -- of these interactions. Money pours across international boundaries, collecting in those parts of the world where rich deposits of essential resources still remain. In resource-importing DCs, the pressure to redress the balance-of-payments imbalance becomes the dominant determinant of what is exported, subverting other goals. Resources of indeterminate ownership, such as fish stocks in oceans and seabed minerals, become the focus of international disputes and unregulated exploitation. And foreign policies bend and even reverse themselves to accommodate the perceived physical needs.

The interactions of resources, economics, and politics were displayed with compelling clarity in the worldwide petroleum squeeze of the mid-1970s. The consequences of a slowdown in the growth of petroleum production in the principal producing countries, accompanied by almost a quadrupling of the world market price, reverberated through all sectors of economic activity in DCs and LDCs alike. The prices of gasoline, jet fuel, heating oil, and electricity soared, contributing directly to inflation. Increased demand for petroleum substitutes such as coal drove the prices of those commodities up, thereby contributing indirectly to inflation, as well. Shortages of materials and services that are particularly dependent on petroleum for their production or delivery quickly materialized, feeding inflation and unemployment still further.

The impact of the energy crisis was especially severe on the already precarious world food situation. Indeed, rising food prices, following the poor harvests of 1972, were a major factor in the decision by the Organization of Petroleum Exporting Countries (OPEC) to raise oil prices. The strong and growing dependence of agriculture on energy -- especially petroleum -- soon made itself felt worldwide as an important contributor to further increases in food prices. This was especially so in developed countries (where agriculture is most highly mechanized), a few of which are the main sources of the exportable food supplies that determine world market prices. The largest exporter, the United States, has gratefully responded to increased foreign demand for its food exports, which has helped to pay for the nation's increasingly expensive oil imports (but which has also contributed to raising domestic food prices). This phenomenon -- the need to sell food abroad to pay for oil -- may have assured continued high-quality diets for nations like Japan that can still afford to buy, but it also reduced the amount of uncommitted food reserves in the

DCs that would be available to alleviate famines in LDCs too poor to buy the food they needed on the world market.

The most obvious consequence of the 1973 petroleum embargo and price rise on international political affairs was one intended by the oil-producing Arab states -- a sudden diminution of DC support for the Israeli position in Middle East territorial disputes. Some less obvious effects, however, may in the long run be more significant. The United States and several other DCs export military hardware as a major source of the foreign exchange they need to pay for imported raw materials; and the intensity with which the arms exporters hustle their wares in the international market is increasing as the oil-related balance-of-payments problem worsens. The result has been to support a spiraling arms race in LDCs, which is both a pathetic diversion of funds needed there to raise the standards of living and a profoundly destabilizing force operating against world peace. The export of nuclear reactors, likewise encouraged by the DCs' need to pay for imported raw materials, may also have disastrous effects. Although intended for production of electricity, these reactors also provide their LDC recipients with the materials needed to manufacture nuclear bombs. India's nuclear explosion in 1974 demonstrated for any remaining doubters that the spread of reactors can mean the spread of nuclear weapons. And it must be assumed that the distribution of such weapons into more

and more hands -- and into some of the most politically troubled regions of the world -- greatly increases the chances that they will be used.

INTERACTIONS: TECHNOLOGY, ENVIRONMENT, AND WELL-BEING

The relationship connecting technology, environment, and well-being would constitute a deep dilemma for civilization, even in the absence of the economic and political complexities just described. Simply stated, the dilemma is this: while the intelligent application of technology fosters human well-being directly, a reducible but not removable burden of environmental disruption by that technology undermines well-being. This negative burden includes the direct effects of technology's accidents and effluents on human life and health; the direct impact of accidents, effluents, preemption of resources, and transformation of landscapes on economic goods and services; and technology's indirect adverse impact on well-being via disruption of the vital services supplied to humanity by natural ecological systems. These free services -- including, among others, the assimilation and recycling of wastes -- are essential to human health and economic productivity. It is clearly possible to reach a point where the gain in well-being associated with (for example) producing more material goods does not compensate for the loss in well-being caused by the environmental damage generated by the technology that produced the goods. Beyond that point, pursuing increased prosperity merely by intensifying technological activity is counterproductive. Many people would argue that the United States has already passed that pivotal point.

The turning point where environmental costs begin to exceed economic benefits can be pushed back somewhat by using technologies that cause the least possible environmental damage. It cannot be pushed back indefinitely, however, because *no technology can be completely free of*

environmental impact. This flat statement -- implying that continued expansion of any technology will eventually lead to environmental costs exceeding its benefits -- is true on fundamental physical grounds. It means that environmental constraints will ultimately limit economic production -- the product of the number of people and the amount of economic goods and services that each person commands -- if nothing else limits it first.

Despite increased scientific attention to environmental problems in recent years, most of the potentially serious threats are only sketchily understood. For many such problems, it cannot be stated with assurance whether serious damage is imminent, many decades away, or indeed already occurring -- with the full consequences yet to manifest themselves. Much remains to be learned, for example, about the causation of cancer and genetic damage by low concentrations of nearly ubiquitous environmental contaminants, either alone or in combination: pesticide residues, combustion products, heavy metals, plasticizers, food additives, prescription and nonprescription drugs, and innumerable others.

The most serious and imminent peril of all may well prove to be civilization's interference with the "public service" functions of environmental processes. Agricultural production in a world already on the brink of famine depends intimately on the absence of major fluctuations in climate, on the chemical balances in soil and surface water that are governed by biological and geochemical nutrient cycles, on naturally occurring organisms for pollination of crops, and on the control of potential crop pests and diseases by natural enemies and environmental conditions. Agents of human disease and the vectors that transport those agents are also regulated in large part by climate, by environmental chemistry, and by natural enemies. Ocean fish stocks -- an important source of food protein -- depend critically on the biological integrity of the estuaries and onshore waters that serve as spawning grounds and nurseries. The environmental processes that regulate climate, build and preserve soils, cycle nutrients, control pests and parasites, help to propagate crops, and maintain the quality of the ocean habitat, are therefore absolutely essential to human well-being. Unfortunately, the side effects of technology are systematically diminishing the capacity of the environment to perform these essential services at the same time that the growth of population and the desire for greater affluence per capita are creating greater demand for them.

Nor can the public-service functions of the environment be safely replaced by technology if technology destroys them. Often the foresight, scientific knowledge, and technological skill that would be required to perform this substitution just do not exist. Where they do exist, the economic cost of an operation on the needed scale is almost invariably too high; and where the economic cost at first seems acceptable, the attempt to replace environmental services with technological ones initiates a vicious circle: the side effects of the additional technology disrupt more environmental services, which must be replaced with still more technology, and so on.

THE PROSPECTS: TWO VIEWS

The foregoing brief survey of the dimensions of the human predicament suggests a discouraging outlook for the coming decades. A continuing set of interlocking shortages is likely -- food,

energy, raw materials -- generating not only direct increases in human suffering and deprivation, but also increased political tension and (perversely) increased availability of the military wherewithal for LDCs to relieve their frustrations aggressively. Resort to military action is possible, not only in the case of LDCs unwilling to suffer quietly, but, with equal or greater likelihood, in the case of industrial powers whose high standard of living is threatened by denial of external resources. The probability that conflicts of any origin will escalate into an exchange of nuclear weapons, moreover, can hardly fail to be greater in 1985's world of perhaps fifteen or twenty nucleararmed nations than it has been in the recent world of five.

The growth of population -- very rapid in the LDCs, but not negligible in most DCs, either -- will continue to compound the predicament by increasing pressure on resources, on the environment, and on human institutions. Rapid expansion of old technologies and the hasty deployment of new ones, stimulated by the pressure of more people wanting more goods and services per person, will surely lead to some major mistakes -- actions whose environmental or social impacts erode well-being far more than their economic results enhance it.

This gloomy prognosis, to which a growing number of scholars and other observers reluctantly subscribes, has motivated a host of proposals for organized evasive action: population control, limitation of material consumption, redistribution of wealth, transitions to technologies that are environmentally and socially less disruptive than today's, and movement toward some kind of world government, among others. Implementation of such action would itself have some significant economic and social costs, and it would require an unprecedented international consensus and exercise of public will to succeed. That no such consensus is even in sight has been illustrated clearly by the diplomatic squabbling and nonperformance that have characterized major international conferences on the environment, population, and resources, such as the Stockholm conference on the environment in 1972, the Bucharest Conference on World Population in 1974, the Rome Food Conference in 1974, and the Conferences on the Law of the Sea in the early 1970s.

One reason for the lack of consensus is the existence and continuing wide appeal of a quite different view of civilization's prospects. This view holds that humanity sits on the edge of a technological golden age; that cheap energy and the vast stores of minerals available at low concentration in seawater and common rock will permit technology to produce more of everything and to do it cheaply enough that the poor can become prosperous; and that all this can be accomplished even in the face of continued population growth. In this view -- one might call it the cornucopian vision -- the benefits of expanded technology almost always greatly outweigh the environmental and social costs, which are perceived as having been greatly exaggerated, anyway. The vision holds that industrial civilization is very much on the right track, and that more of the same -- continued economic growth -with perhaps a little luck in avoiding a major war are all that is needed to usher in an era of permanent, worldwide prosperity. [1]

[1]Outstanding proponents of this view include British economist Wilfred Beckerman (*Two cheers for the affluent society*, St. Martin's Press, London, 1974): British physicist John Maddox (*The doomsday syndrome*, McGraw-Hill, New York, 1972); and American futurologist Herman Ka hn (*The next 200 years*, with William Brown and Leon Martel, William Morrow, New York, 1976).

Which view of civilization's prospects is more accurate is a question that deserves everyone's scrutiny. It cannot be decided merely by counting the "experts" who speak out on either side and then weighing their credentials. Rather, the arguments must be considered in detail -- examined, dissected, subjected to the test of comparison with the evidence around us. This is an ambitious task, for the issues encompass elements of physics, chemistry, biology, demography, economics, politics, agriculture, and a good many other fields as well. One must grapple with the arithmetic of growth, the machinery of important environmental processes, the geology of mineral resources, the potential and limitations of technology, and the sociology of change. It is necessary to ponder the benefits and shortcomings of proposed alternatives as well as those of the status quo; and it is important to ask where burdens of proof should lie.

Does civilization risk more if the cornucopians prevail and they are wrong? or if the pessimists prevail and they are wrong? Could an intermediate position be correct, or are perhaps even the pessimists too optimistic? What is the most prudent course in the face of uncertainty? Making such evaluations is, of course, a continuing process, subject to revision as new arguments, proposals, and evidence come to light. What is provided in the following chapters is a starting point: a presentation of essential principles, relevant data, and (we think) plausible analyses that bear on the predicament of humanity.

Brown, Harrison. 1954. *The challenge of man's future*. Viking, New York. A landmark in the literature of the human predicament, perceptively elucidating the interactions of population, technology, and resources. Brown alerted a generation of scholars and policy-makers to the seriousness of impending problems and has worked tirelessly in national and international scientific circles to mobilize the talent to help solve them.

Ehrlich, Paul R.; Anne H. Ehrlich; and John P. Holdren. 1973. *Human ecology*. W. H. Freeman and Company, San Francisco. A predecessor of this book, providing capsule introductions to many of the topics expanded upon here.

National Academy of Sciences-National Research Council. 1969. *Resources and man*. Report of the Committee on Resources and Man of the National Academy of Sciences. W. H. Freeman and Company, San Francisco. A sober look at population, food, energy, minerals, and environment, together with forthright policy recommendations, by a group of experts both eminent and eloquent.

Osborn, Fairfield. 1948. *Our plundered planet*. Little, Brown, Boston. A prescient early plea for an integrated approach to the interlocking problems of population, resources, and environment.

Section I
Natural Processes and Human Well-Being

There is one ocean, with coves having many names;
a single sea of atmosphere, with no coves at all;
a thin miracle of soil, alive and giving life;
a last planet; and there is no spare.

-- David R. Brower

Prehistoric human beings earned a living from their surroundings in much the same way as many other animals did (and do): they sought out and preyed upon other organisms -- edible plants and killable animals -- that shared the environment, they drank water where they found it, and they took shelter in trees and caves. The geographical distribution, size, and well-being of the human population under these circumstances were influenced very strongly by the characteristics of the natural environment -- patterns of hot and cold, wet and dry, steep and flat, lush and sparse. These patterns of climate, topography, flora, and fauna were in turn the products of millions of centuries of interaction among natural geophysical and biological processes -- continental drift, mountain-building, erosion, sedimentation, the advance and retreat of glaciers, the rise and fall of the oceans, and the evolution and extinction of various kinds of organisms.

Before the advent of agriculture, most of the natural processes and systems that so strongly influenced the human condition were themselves not much influenced by what humans did; the interaction was largely a one-way street. Fire and stone implements apparently were used even by the forerunners of *Homo sapiens* well over a million years ago, and the wielders of those early tools certainly used them to affect their local environments, both intentionally and inadvertently. But it was agriculture, which began about 10,000 years ago, that marked the sharpest transition in the capacity of *Homo sapiens* to influence the physical environment on a large scale. From that beginning, which permitted specialization and a scale of social organization not possible among hunter-gatherers, arose a long series of technological and social developments that produced the agricultural and industrial civilizations that today virtually cover the globe.

That civilizations have transformed many aspects of the physical environment is beyond dispute. Indeed, the prevalence of "man-made" environments (such as cities) and intensively managed ones (such as wheat fields) makes it all too easy to suppose that such technological environments are now the only ones that matter. This supposition, which one could call the humanity-is-now-the-master-of-nature hypothesis, is partly responsible for the widespread underestimation of the seriousness of environmental problems. Regardless of such beliefs, civilizations and their technological environments continue to be embedded, as they always have been, in a larger nontechnological environment. This larger environment provides the raw materials with which technology must work, and its characteristics *together* with those of technology define the limits of what is possible at any given time.

Technology and natural environmental processes together - not technology alone -- have permitted the human population and its material consumption to reach their present levels. Today human beings continue to depend on the nontechnological environment for a variety of services that technology not only cannot replace, but without which many technological processes themselves would be nonfunctional or unaffordable. Many of these services are mentioned in Chapter 1 -- the regulation of climate, the management of soil and surface water, the environmental chemistry of nutrient cycling and control of contaminants, and the regulation of pests and disease, among others. To understand the nature and extent of humanity's dependence on these services, and the degree of their vulnerability to disruption by mismanagement and overload, one must investigate in detail the character of the physical and biological processes that provide them. We do so in the next three chapters: "The Physical World," discussing basic geological processes, the hydrologic cycle, and climate; "Nutrient Cycles," describing the major pathways by which carbon, nitrogen, phosphorus, and other essential nutrients move from the living to the nonliving environment and back again; and "Populations and Ecosystems," an introduction to the principles of population biology and ecology essential to an understanding of the structure and functions of biological communities. The details of the actual threats to these processes posed by the activities of contemporary human beings are taken up in Chapter 11.

CHAPTER 2
The Physical World

All the rivers run into the sea; yet the sea is not full.

--Ecclesiastes

The *biosphere* is that part of Earth where life exists. In vertical dimension it extends from the deepest trenches in the ocean floor, more than 11,000 meters (36,000 feet) [1] below sea level, to at least 10,000 meters (m) above sea level, where spores (reproductive cells) of bacteria and fungi can be found floating free in the atmosphere. By far most living things -- most of which depend directly or indirectly on the capture of solar energy by photosynthesis in plants and certain bacteria -- exist in the narrower region extending from the limit of penetration of sunlight in the clearest oceans, less than 200 meters from the surface, to the highest value of the permanent snow line in tropical and subtropical mountain ranges -- about 6000 meters, or 20,000 feet. (Everest, the highest mountain, rises almost 8900 meters above sea level.) By any definition, the biosphere is as a mere film in thickness compared to the size of the ball of rock on which it sits -- about like the skin of an apple, in fact. The radius of Earth is about 6370 kilometers (km), or 4000 miles (mi).

Of course, conditions within the thin envelope of the biosphere are influenced by physical processes taking place far outside it: by the energy emitted by the sun, 150

[1]Throughout this book physical dimensions are given in metric units, sometimes accompanied by the English equivalent to ease the transition for readers not completely accustomed to the metric system. For more precise conversion factors, see the tables inside the covers of the book.

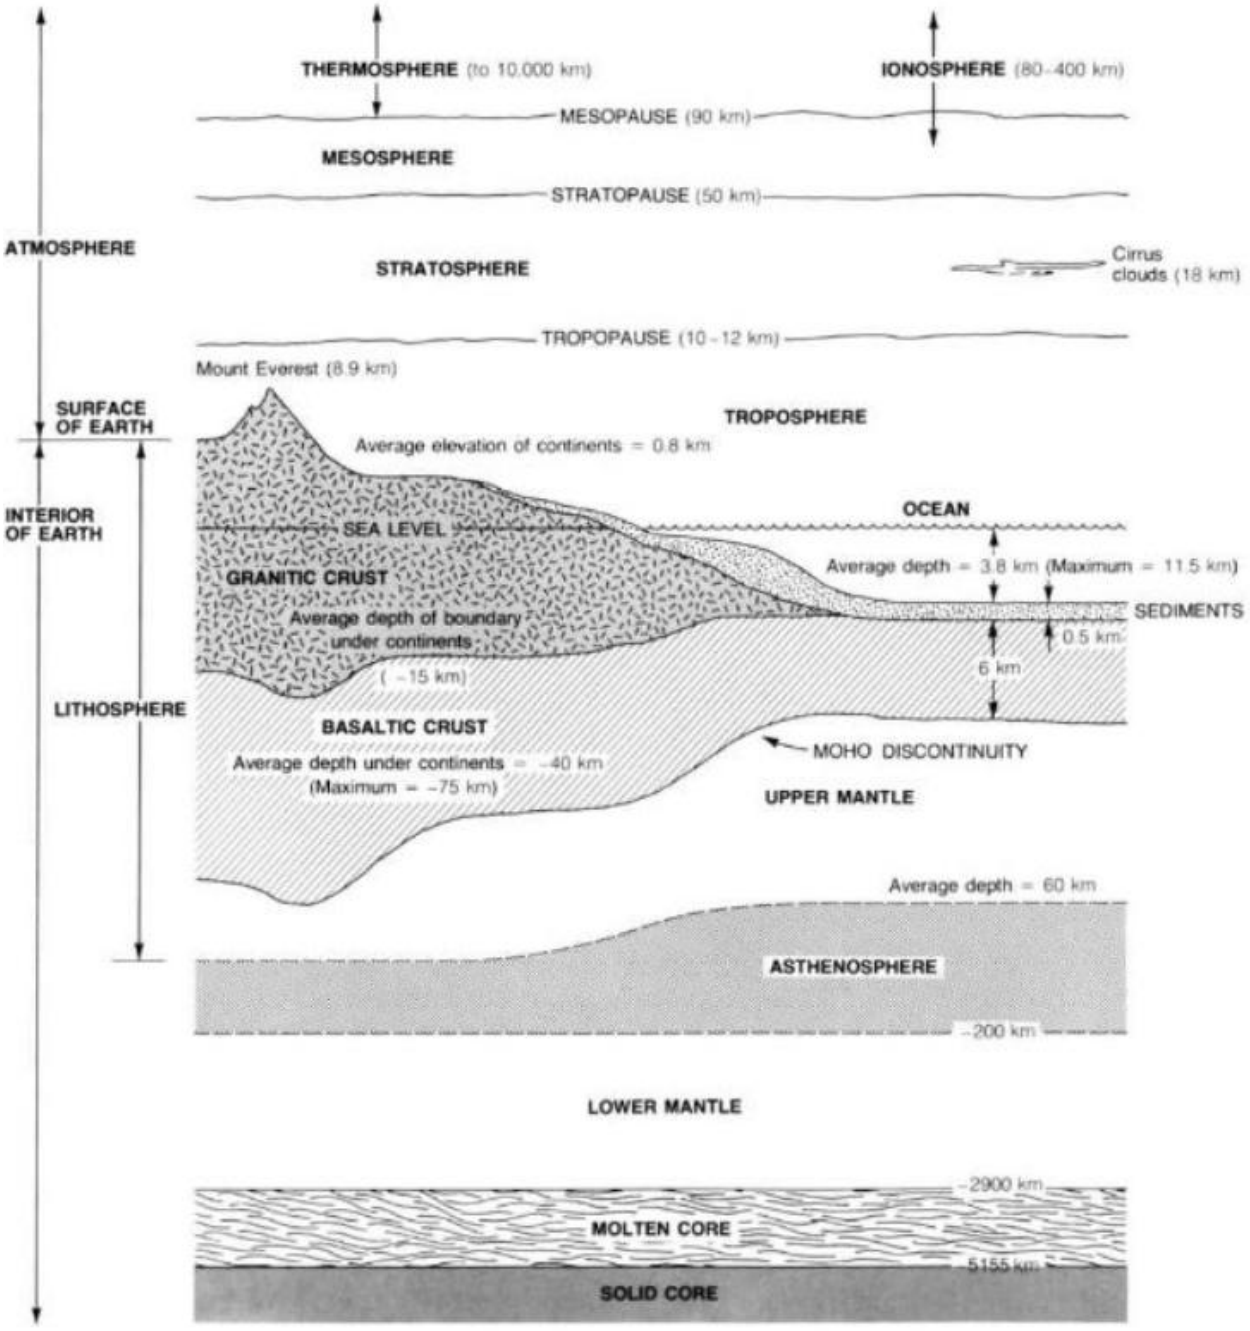

FIGURE 2-1 Vertical structure of the physical world. (Scales are greatly distorted.)

million kilometers away; by the tides originating in the relative motion and positions of Earth, sun, and moon (the distance from Earth to the moon averages about 380,000 km); by the presence of gases 20 to 400 km high in the atmosphere that screen out harmful components of incoming solar energy; by the constitution and structure of Earth's crust (to 40 km deep), which govern the availability of mineral nutrients at the surface and of metallic ores accessible to industrial civilization; by the behavior of the solid but plastically flowing [2] mantle (to 2900 km deep) on which the crustal plates "float" and move laterally; and by the motion of Earth's molten core (2900 to 5200 km deep), which produces the magnetic field that protects the planet's surface from bombardment by energetic, electrically charged particles from space. The vertical structure of Earth's atmosphere, surface, and interior is illustrated in Figure 2-1. The terminology used there for the various vertical divisions is explained in the following text, where the character of the atmosphere and Earth's interior are taken up in more detail.

In horizontal extent the biosphere covers the globe, although in the hottest deserts and coldest polar regions -- as at the highest elevations -- usually only dormant spores can be found. Earth's total surface area amounts to 510 million square kilometers (about 197 million mi^2), of which 71 percent is ocean and 29 percent land (see Table 2-1). The mass of all living organisms on Earth amounts to about 5 trillion metric tons, [3] threefourths of which consists of water. Under the reasonable assumption that living matter has about the same density as water [1 gram per cubic centimeter ($1 g/cm^3$)], this would mean that the living part of the biosphere was equivalent to a layer of material only I centimeter thick, covering the globe. (The range concealed in this average is from 0.0002 g of living material for each square centimeter of surface in the open ocean to 15 g or more for each square centimeter of surface in a tropical forest.)

TABLE 2-1 Surface Areas of the Globe

	Percentage of category	Area (million km^2)
TOTAL EARTH SURFACE		510
OCEANS		361

[2]*Plastic flow* in a solid refers to continuous deformation in any direction without rupture.

[3]A metric ton (MT) equals 1000 kilograms (kg), or 2205 pounds. One trillion (in scientific notation, 10^{12}) equals 1000 billion, or 1,000,000 million.

TABLE 2-2 Masses of Constituents of the Physical World

Constituent	Mass (trillion MT)
Living organisms (including water content)	8
Liquid fresh water, on surface	126
Atmosphere	5,140
Ice	30,000
Salts dissolved in oceans	49,000
Oceans	1,420,000
Earth's crust (average depth, 17 km)	24,000,000
Earth (total)	6,000,000,000

The relative masses of various constituents of the physical world are shown in Table 2-2.

To study the processes that operate in any subdivision of the physical world -- atmosphere, biosphere, Earth's crust -- one must know something about energy: what it is, how it behaves, how it is measured. For whenever and wherever anything is happening, energy in some form is involved; it is in many respects the basic currency of the physical world. An introduction to energy and the related concepts of work and power, along with the units in which these quantities can be measured, is provided in Box 2-1. Some feeling for how much energy is stored in and flows between various parts of the physical world is conveyed in Table 2-3.

EARTH'S SOLID SURFACE AND BELOW

The outermost layer of Earth's solid surface is called the crust. It ranges in thickness from about 6 kilometers beneath the ocean floor to as much as 75 kilometers below the largest mountain ranges. In essence, the crust floats on the denser *mantle* beneath it. (As is elaborated below, the crust and mantle are differentiated by the different compositions and densities of the rock they comprise.) As with icebergs on the sea, the more crust extends above the surface (as in a mountain range), the more bulk is hidden below. [4] This situation is made possible by the existence of a soft, yielding layer called the *asthenosphere* in the middle of the underlying

mantle. This layer's strength is low because the rock is near its melting point. The combination of the crust and the hard upper layer of the mantle is called the *lithosphere*, a term sometimes also employed in a more general sense to mean the entire solid part of Earth. Below the mantle, between the depths of 2900 and 5200 kilometers, lies Earth's *molten outer core*. This core consists largely of liquid iron (with some nickel) at a temperature of perhaps 2500° C; its properties and motion produce Earth's magnetic field.

TABLE 2-3 Energy Flow and Storage in the Physical World

	Energy or power
STORAGE	***Trillion MJ***
Energy released in a large volcanic eruption	100
Chemical energy stored in all living organisms	30,000
Energy released in a large earthquake	100,000
Chemical energy stored in dead organic matter	100,000
Heat stored in atmosphere	1,300,000
Kinetic energy of Earth's rotation on its axis	250,000,000,000
FLOWS	***Million Mw***
Tides	3
Heat flow from Earth's interior	32
Conversion of sunlight to chemical energy in photosynthesis	100
Conversion of sunlight to energy of motion of atmosphere	1,000
Sunlight striking top of atmosphere	172,000

[4]For more detailed treatment of this point and others in this section, see F. Press and R. Siever, *Earth*; and A. N. Strahler and A. H. Strahler, *Environmental geoscience*.

BOX 2-1 Work, Energy, and Power: Definitions, Disguises, and Units

Work is the application of a force through a distance. *Energy* is stored work. *Power* is the rate of flow of energy, or the rate at which work is done. All these concepts are more easily understood with the help of examples and some elaboration.

Work -- force multiplied by distance -- is done when a weight is lifted against the force of gravity (as with water carried upward in the atmosphere in the course of the hydrologic cycle), when mass is accelerated against the resistance of inertia (as with waves whipped up on the ocean by the wind) or when a body is pushed or pulled through a resisting medium (as with an aircraft moving through the atmosphere or a plow cutting through a field). The presence of distance in the concept of work means that work is done only if there is motion -- if you push on a stalled car and it doesn't budge, there is a force, but there is no work because there is no motion.

The foregoing are examples of *mechanical work* -- work involving the bulk (or *macroscopic*) motion of agglomerations of molecules. There are also various forms of *microscopic* work, such as *chemical work* and *electrical work*, which involve forces and motions on the scale of individual molecules, atoms, and electrons. To heat a substance is to do a form of microscopic work in which the individual molecules of the substance are made to move more rapidly about in all directions, without any bulk motion taking place. The demonstration that all these different manifestations of work are fundamentally the same can be found in treatises on physics and chemistry. [*]

If work has many guises, so must energy, which is only *stored* work. Work stored as the motion of a macroscopic object (for example, a speeding automobile or the Earth spinning on its axis) is called *mechanical energy* or *kinetic energy*. The latter term may be applied as well to the energy of motion of microscopic objects (such as, molecules, electrons). Work stored as the *disordered* motion of molecules -- that is, rotation, vibration, and random linear motion not associated with bulk motion of the substance -- is called *thermal energy* or *sensible heat* or (more commonly) just *heat*. Note that temperature and heat are not the same. Temperature is a measure of the intensity of the disordered motion of a typical molecule in a substance; the heat in a substance is the sum of the energies stored in the disordered motion of all its molecules. (The relation between temperature and energy is developed further in Box 2-3.)

Kinetic energy means something is happening; that is, the work is stored as motion. *Potential* or *latent* energy means something is "waiting" to happen. That is, the work is stored in the position or structure of objects that are subject to a force and a restraint; the force provides the potential for converting position or structure into kinetic energy, and the restraint is what keeps this from happening (at least temporarily). Each kind of potential energy is associated with a specific kind of force. Gravitational potential energy (an avalanche waiting to fall) and electrical potential energy (oppositely charged clouds waiting for a lightning stroke to surge between them) are associated with forces that can act between objects at large distances. Chemical potential energy (gasoline waiting to be burned, carbohydrate waiting to be metabolized) is associated with the forces that hold atoms together in molecules -- that is, with chemical bonds. Nuclear potential energy is due to the forces that hold protons and neutrons together in the nucleus -- the so-called strong force. Latent heat of vaporization (water vapor waiting to condense into liquid, whereupon the latent heat will be converted to sensible heat) and latent heat of fusion (liquid waiting to freeze into a solid, with the same result) are associated with the electrical forces between molecules in liquids and solids. The idea that potential energy is something "waiting" to happen needs only to be tempered by recognition that sometimes it can be a long wait -- the chemical potential energy in a piece of coal buried in Earth's crust, for example, may already have waited a hundred million years.

Electromagnetic radiation is a form of energy that does not fall neatly into any of the categories we have mentioned so far. It is characterized not (*Continued*)

[*]See, for example, R. Feynmann, R. Leighton, and M. Sands, *The Feymann lectures on physics*, Addison-Wesley, Reading, Mass., 1965.

Box 2-1 (*Continued*) in terms of the motion or position or structure of objects but in terms of the motion of electric and magnetic forces. [**] Light (visible electromagnetic radiation), radio waves, thermal (infrared) radiation, and X-rays are all closely related varieties of this particular form of energy. (See also Box 2-4.)

Albert Einstein theorized, and many experiments have subsequently verified, that any change in the energy associated with an object (regardless of the form of the energy) is accompanied by a corresponding change in mass. In this sense, mass and energy are equivalent and interchangeable, the formal expression of equivalence being Einstein's famous formula $E = mc^2$. (Here *E* denotes energy, *m* mass, and *c* the speed of light.) Because a small amount of mass is equivalent to a very large quantity of energy, a change in mass is only detectable when the change in energy is very large -- as, for example, in nuclear explosions.

Different professions use a bewildering array of units for counting work and energy. The metric system is prevailing, but so gradually that the literature of energy and environmental sciences will be littered for years to come by a needless profusion of archaic units. Since work has the dimensions of force times distance, and all energy can be thought of as stored work, it should be apparent that a single unit will suffice for all forms of energy and work. The most logical one is the *joule* (J), which is exactly the amount of work done in exerting the basic metric unit of force, 1 *newton* (N), over the basic metric unit of distance, 1 meter. [†] We shall use the joule and its multiples, the kilojoule (1000 J, or kJ) and the megajoule (1,000,000 J, or MJ), throughout this book.

Our only exception to the use of the joule is a concession to the enormous inertia of custom in the field of nutrition, where we reluctantly employ the *kilocalorie* (kcal). A kilocalorie is approximately the amount of thermal energy needed to raise the temperature of 1 kg of water by 1 degree Celsius (1° C); [††] this unit is often confusingly written as "calorie" in discussions of nutrition. Running the bodily machinery of an average adult human being uses about 2500 kcal -- about 10,000 kJ -- per day.)

Besides the erg (1 ten-millionth of a joule) and the calorie (1 thousandth of a kcal), the unit of energy most likely to be encountered by the reader elsewhere is the British thermal unit (Btu), which is approximately the amount of thermal energy needed to raise I pound of water by 1 degree Fahrenheit (1° F). A Btu is roughly a kilojoule.

In many applications one must consider not only *amounts* of energy but the *rate* at which energy flows or is used. The rate of energy flow or use is *power*. *Useful power* is the rate at which the flow of energy actually accomplishes work. The units for power are units of energy divided by units of time -- for example, British thermal units per hour, kilocalories per minute, and joules per second. One joule per second is a *watt* (w). A kilowatt (kw) is 1000 watts, and a megawatt (Mw) is 1,000,000 watts; these are the units we use for power in this book. These units are perfectly applicable to flows of nonelectric as well as electric energy, although you may be accustomed to them only in the context of electricity. Similarly, the kilowatt hour (kwh), denoting the amount of energy that flows in an hour if the rate (power) is 1 kilowatt, makes sense as a unit of energy outside the electrical context. A kilowatt hour is 3600 kilojoules. For example, we can speak of an automobile using energy (in this case, chemical energy stored in

gasoline) at a rate of 100 kilowatts (100 kilojoules of chemical energy per second). In an hour of steady driving at this rate of fuel consumption, the automobile uses 100 kJ/sec multiplied by 3600 sec (the number of seconds in an hour) or 360,000 kJ. The same quantity of energy used in a jumbo jetliner would produce a much larger power -say, 180,000 kw -- for a much shorter time (2 sec).

A complete set of conversion factors for units of energy and power appears just inside the covers of this book.

** A physicist might object at this point that it isn't always useful, or even possible, to discriminate between objects and fields of electric and magnetic force. This level of technicality will not be needed in this book.

† The units of force are units of mass multiplied by units of acceleration. One newton is a mass of 1 kg times an acceleration of 1 m per second (sec) per second (1 N = 1 kg·m/sec^2). One joule equals 1 newton-meter (1 J = 1 N-m = 1 kg·m^2/sec^2).

†† Zero and 100 on the Celsius, or centigrade, scale of temperature correspond to the freezing point and the boiling point of pure water. The conversion between Celsius (C) and Fahrenheit (F) is: degrees F = 1.8 x degrees C + 32.

Within the molten outer core is a *solid inner core*, also composed of iron and nickel, under enormous pressure.

Many of the characteristics of Earth's solid surface are the result of the operation of *tectonic processes*--the motion of great solid segments of the lithosphere, called *plates*, which slide about over the plastically flowing asthenosphere at a rate of a few centimeters per year. Operating over hundreds of millions of years, such motions have apparently produced displacements of thousands of kilometers. The now widely accepted theory of continental drift holds that the present arrangement of the continents arose in this way, beginning with the breakup of the single supercontinent Pangaea about 200 million years ago. [5]

Some of the main tectonic processes, as they continue to work today, are illustrated in Figure 2-2. At *divergent plate boundaries* on the ocean floor, such as the East Pacific and Mid-Atlantic Ridges, adjacent plates move apart and new crust is created in the gap by *magma* (molten rock which rises from below and then solidifies. This phenomenon is called seafloor spreading. At *convergent plate boundaries*, as along the western edge of South America, one plate may be driven beneath the other into the asthenosphere. Heat generated by the friction in these *subduction zones* melts some of the crustal rock to produce magma, which rises to feed volcanic activity at the surface. Deep-sea trenches, steep mountain ranges, and powerful earthquakes are other characteristics of these zones of violent collision between plates. At a third type of interface between plates, the plates slide past each other, moving parallel to the boundary. These *parallel-plate boundaries* are characterized by earthquakes with large surface displacements; the San Andreas Fault, which produced the great San Francisco earthquake of 1906, marks such a boundary. The principal plate boundaries are indicated on the map in Figure 2-3.

Many other geophysical processes operate simultaneously with the tectonic motions described above to govern the shape and composition of Earth's crust. These processes include mountain-building by uplifting of the crust, the wearing-away of exposed rock surfaces by the actions of wind, rain, ice, and chemical processes (together these effects are called *weathering*), the transport

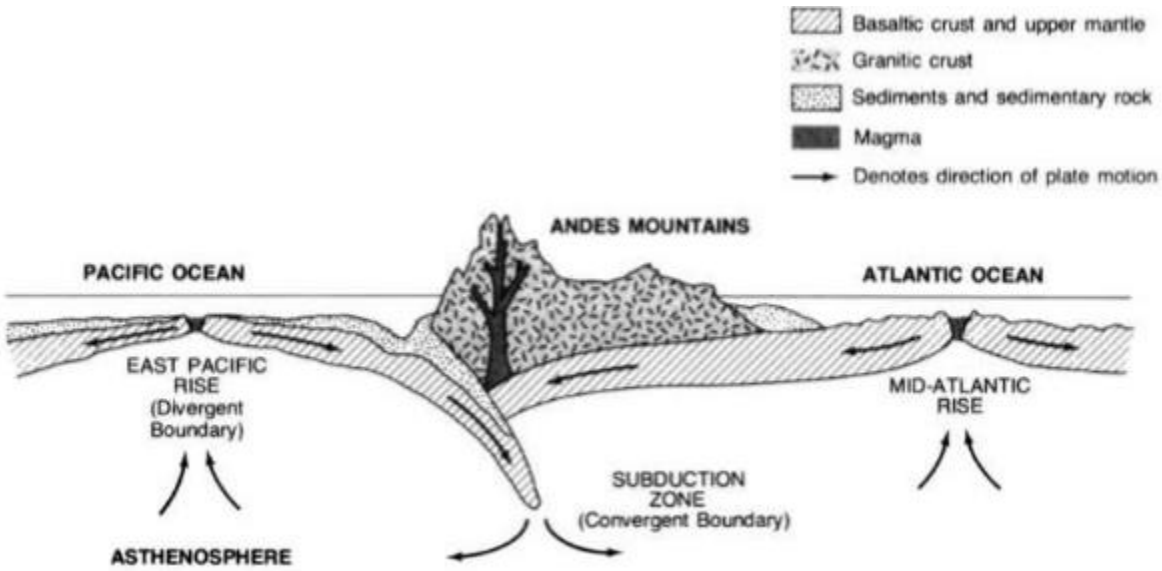

FIGURE 2-2 Tectonic processes and the Earth's surface. (From P. A. Rona, "Plate tectonics and mineral resources", *Scientific American*, July, 1973.)

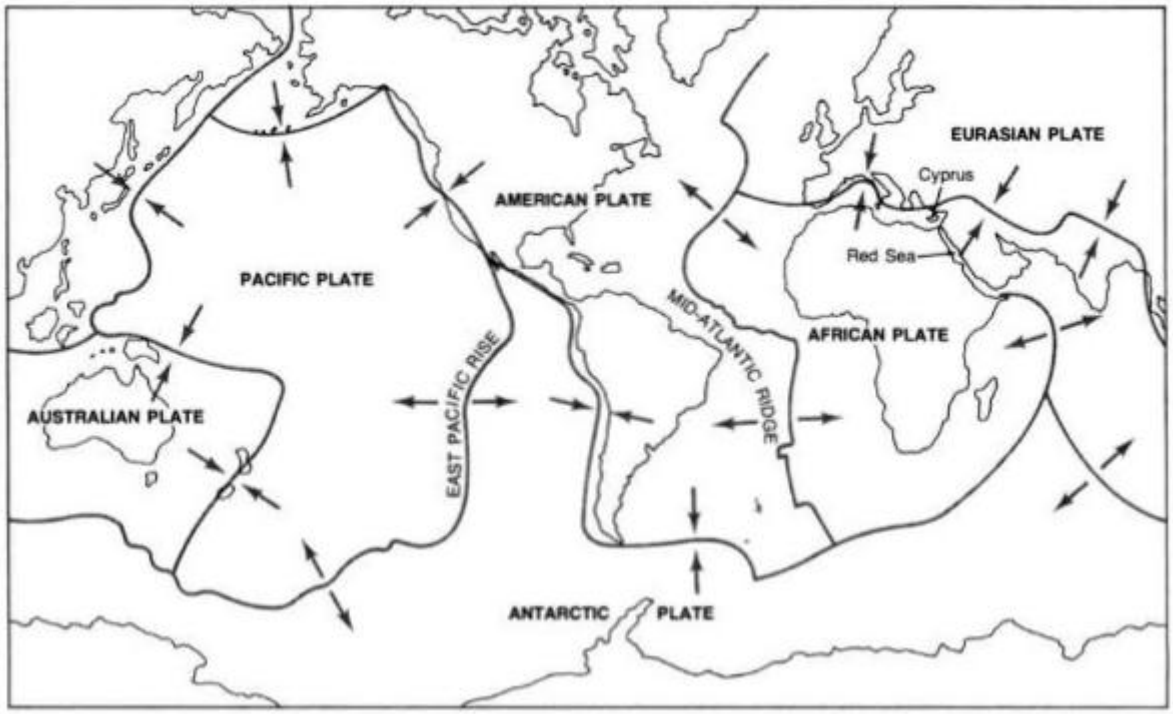

FIGURE 2-3 Six principal tectonic plates of the lithosphere.

of particles of rock and soil by water and wind (*erosion*), and the formation and transformation of new rocks from sedimentary material. The way in which these processes are linked together to produce the principal geological cycles is represented schematically in Figure 2-4.

Rock that is exposed at the surface of the crust is gradually weathered away by physical and chemical processes. The resulting particles are some of the raw materials for new soil (the formation of which also requires the action of living organisms), and some of the chemicals liberated from the rock become available to the biosphere as nutrients (see Chapter 3). Although the rock particles may sometimes be carried uphill by wind and ice, the predominant motion is downhill with the flow of water. Thus it happens over geologic spans of time (hundreds of thousands to millions of years) that large amounts of material are removed from the exposed rocky crust at high elevations and deposited on the lowlands and on the ocean floors. The accumulating weight of these sediments, consisting ultimately not only of rock fragments but also of dead plant and animal matter and chemicals precipitated out of seawater, contributes to sinking of the underlying crust and upper mantle. (Tectonic subsidence, the result of large-scale crustal motions, is more important in this sinking phenomenon than is the local accumulation of sediment weight, however. [6]) Simultaneously, crustal rise, or uplifting, under the lightened regions restores some of the loss of elevation produced by weathering and erosion. This process of sinking and uplifting is made possible by the capacity of the dense but soft (almost molten) asthenosphere to be deformed and, indeed, to flow. The folding

[6]Press and Siever, *Earth*, p. 479.

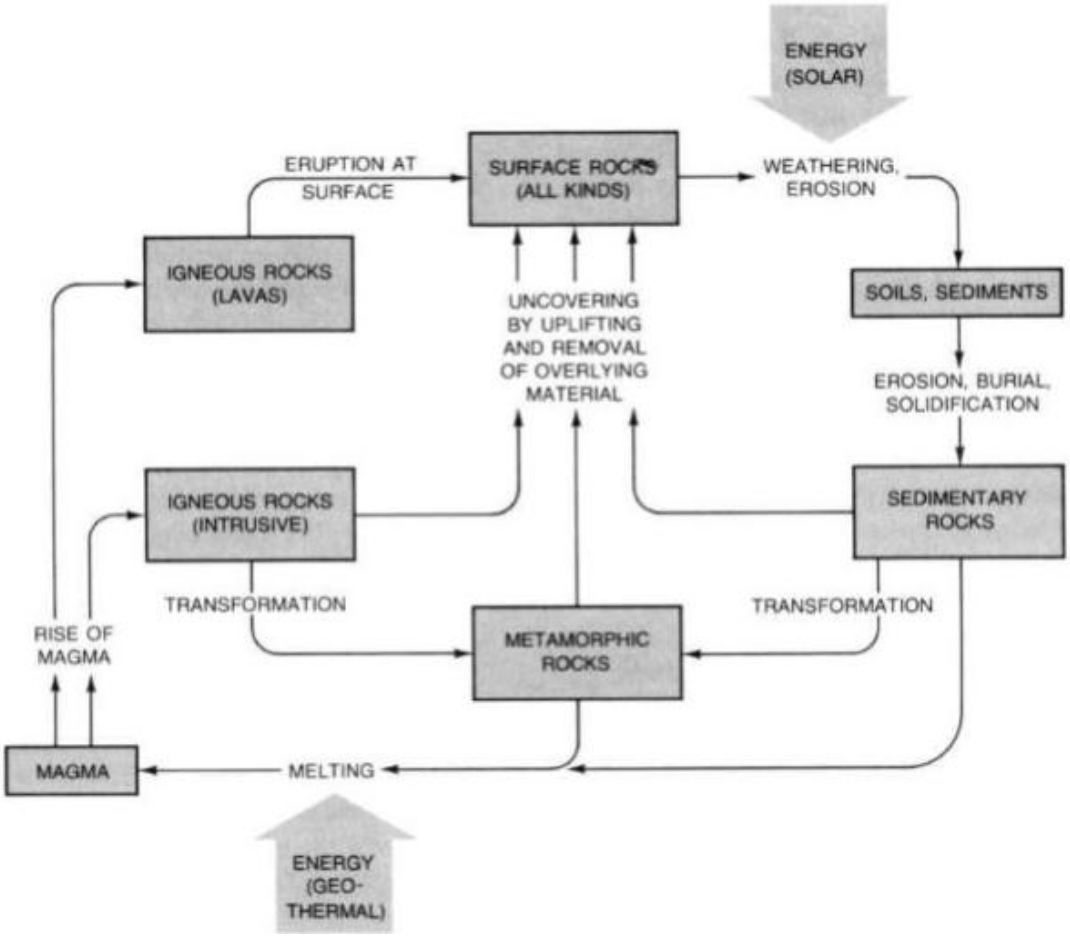

FIGURE 2-4 Geologic cycles. Intrusive igneous rocks are those that solidify from magma before reaching the surface, in contrast to extrusive igneous rocks (lava). Most sedimentation (deposition of sediments) takes place on the ocean floor. The time for material to complete a cycle is typically tens of millions to hundreds of millions of years.

and buckling of Earth's crust, which has produced much of the varied topography we see, is the combined result of the sinking-uplifting phenomenon just described and the continuous collision of the great lithospheric plates.

As layers of sediment become more deeply buried, they are subjected to temperatures and pressures high enough to initiate chemical and physical changes that transform the sediments into rock (called *sedimentary rocks*). Among the rocks formed in this way are shale, sandstone, limestone, and dolomite. Under some conditions, such as the particularly energetic geological environment where tectonic plates collide, further transformations under the action of heat and pressure produce *metamorphic rocks*, among which are slate and marble. The most abundant rocks in Earth's crust, however, are *igneous rocks* -- those formed by the cooling and solidification of magma. Repeated local melting, migration, and resolidification of the rock in Earth's crust and upper mantle have led over the eons to a general stratification, with the densest material on the bottom and less dense material above. Thus, the upper layer of the continental crust consists largely of *granitic* igneous rocks--rocks rich in the relatively light elements silicon and aluminum. The oceanic crust and the lower layer of the

continental crust (Figure 2-1) consist mainly of *basaltic* igneous rocks--somewhat denser material, containing substantial amounts of iron in addition to the lighter elements. The mantle below is *olivine* igneous rock, richer yet in iron and therefore denser than the overlying crust.

The average elemental composition of Earth's crust is given in Table 2-4. The predominance of the light elements is apparent: of the ten most abundant elements--accounting for 99 percent of the mass of the crust--only iron has an atomic number above 25. The crust comprises only about 0.4 percent of the mass of Earth, however. Essentially all the rest resides in the denser and vastly thicker mantle and core (Table 2-2). The composition of the entire planet (Table 2-5), reflects the predominance of iron in those inner layers. Of interest is that carbon, the basic building block of living

material, is not among the most abundant elements (it ranks fourteenth in crustal abundance, at 0.032 percent).

The energy that drives the great geological cycles has two distinct origins. Those parts of the cycles that take place on the surface--weathering, the formation of soil, erosion, the production of plant and animal matter that contributes to sediments--are powered by solar energy and its derivatives, wind and falling water. (The character of these energies is examined more closely later in this chapter.) The remaining geophysical processes (for example, the production and migration of magma and the inexorable motions of the tectonic plates) are driven by geothermal energy--heat that is produced beneath Earth's surface. It is thought that most of this heat results from the decay of radioactive isotopes that were already present when Earth was formed. [7] (The reader completely unfamiliar with the terminology and physics of radioactivity may wish to look ahead to Box 8-3.) The most important isotopes in this respect are uranium-238 (half-life 4.5 billion yr), thorium-232 (half-life 14 billion yr), and potassium-40 (half-life 1.3 billion yr). Notwithstanding the rather low concentration of these isotopes in Earth's crust, the energy released by their continuing radioactive decay is enough to account approximately for the observed rate of heat flow to the surface. The very long half-lives of these isotopes guarantee, moreover, that this source of energy for geological change will have been diminished only slightly a billion years hence.

The processes of melting and resolidification, sinking and uplifting, the motion of tectonic plates of continental scale, the gouging and pushing of massive glaciers, and the different rates of weathering and erosion associated with different climates and different combinations of exposed rocks have combined to produce a tremendous variety of geological features. [8] The importance of these features to human beings is severalfold. The landforms--plains, mountains, valleys, and so on--are one major determinant of the extent to which different parts of the planet's surface are habitable. The soils that have resulted from geological and biological processes over

[7] It is possible that there is some additional contribution by frictional heat generation resulting from tidal forces on the molten and plastic parts of Earth's interior.

[8] The reader interested in pursuing this complex but fascinating subject should consult one of the several good geology books listed at the end of this chapter.

the millennia are another (and more limiting) Acterminant of how many people can be supported and where. The zones of earthquakes and volcanism present serious environmental hazards to humans. And the distribution of fossil fuels and metals in scattered deposits far richer than the average crustal abundance is a geological phenomenon of enormous practical importance.

Although the processes that produced these features often act imperceptibly slowly in human terms, the temptation to consider the geological forces to be beyond human influence--or to take for granted their contributions to human well-being--must be resisted. Soil that has taken a thousand years to accumulate can be washed or blown away in a day through human carelessness; and there is evidence that the activities of human societies worldwide--cultivation, overgrazing, deforestation, construction--have doubled the prehistoric rate of sediment transport

to the sea (Chapter 6 and Chapter 11). Earthquakes are widely feared and are called natural disasters, but the lack of foresight in planning and construction that has characterized the development of human settlements in active earthquake zones suggests that the consequences are due as much to human ignorance and irresponsibility as to nature's harshness. There are circumstances, moreover, in which human activities actually *cause* earthquakes (injection of liquid wastes into rock formations, for example), and conceivably there may someday be technological means by which the frequency of strong earthquakes can be diminished. Without concentrated deposits of mineral ores, industrial civilization as we know it could not have arisen; they represent a coincidental natural subsidy for society, provided by the work of natural energy flows over eons. The notion that technological civilization is now clever enough to do without this subsidy, once it is used up, by extracting needed materials from common rock is a dubious one. (We will examine this idea more closely in Chapter 9.)

THE HYDROSPHERE

Most forms of life on Earth require the simultaneous availability of mineral nutrients, certain gases, and water in liquid form. The boundaries of the biosphere--which are fuzzy, rather than sharp--can be defined as the places where the concentration of one or more of these essentials drops too low to sustain life. The principal reservoirs of available mineral nutrients are soil and sediment, the main reservoir of the needed gases is the atmosphere, and the primary supply of water is, of course, in the oceans. Where they meet, these reservoirs intermingle to produce the most fertile parts of the biosphere: the upper layers of soil, where gases and moisture readily penetrate, and the shallower parts of the oceans, where nutrients from the land and the bottom mingle with dissolved gases and light that penetrates downward from the surface.

The oceans include not only some of the planet's most hospitable environments for life (and, almost surely, the environment where life began) but also make up by far the largest single habitat on Earth's surface. They cover almost 71 percent of the planet and their volume is an almost incomprehensible 1.37 billion cubic kilometers (330 million mi^3). The term *hydrosphere* refers not only to the oceans themselves, however, but also to the "extensions" of the oceans in other realms--the water vapor and water droplets in the atmosphere, the lakes and the rivers; the water in soil and in pockets deep in layers of rock; the water locked up in ice caps and glaciers. The sections that follow here examine, first, some of the important characteristics of the oceans, then the behavior of ice on Earth's surface, and, finally, the hydrologic cycle, which makes water so widely available even far from the seas.

The Oceans

More than 97 percent of the water on or near the surface of Earth is in the oceans (Table 2-6). This enormous reservoir is a brine (salts dissolved in water) of almost uniform composition. The concentration of the dissolved salts ranges from 3.45 percent (by weight) to about 3.65 percent, varying with depth and latitude. The density of seawater varies between 1.026 and 1.030 grams per cubic centimeter, depending on depth and salinity, compared to 1.000 grams per cubic centimeter for fresh water at the reference temperature of 4° C (39° F). An average cubic meter [9] of seawater weighs 1027 kilograms

[9]One cubic meter (m^3) = 35.3 cubic feet = 264 gallons.

TABLE 2-6 Water Storage in the Hydrosphere

Storage	*Volume (1000 km^3)*[*]
Average in stream channels	1
Vapor and clouds in atmosphere	13
Soil water (above water table)	67

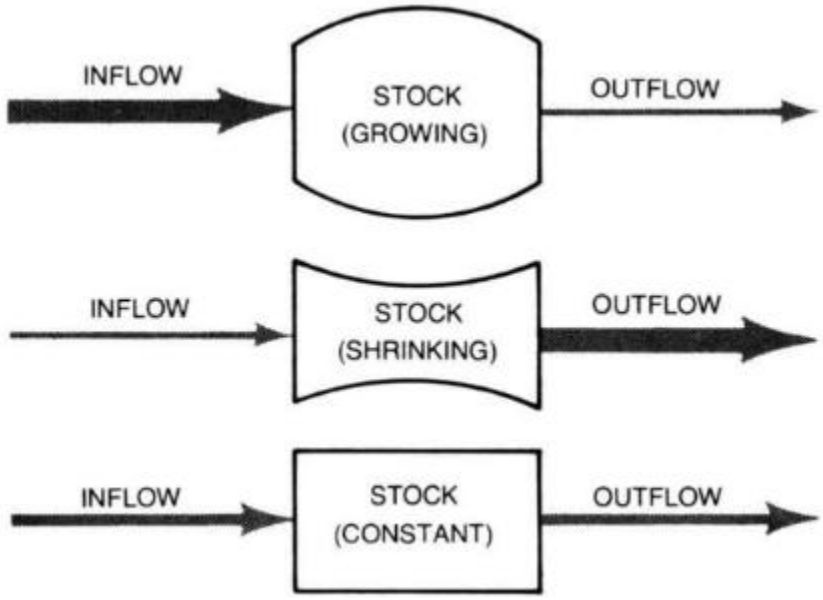
(1.027 MT, or 1.13 short tons), of which about 36 kilograms is dissolved salts. Although most of this material is the familiar sodium chloride, more than half of all the known elements are present in seawater at trace concentrations or more.

The concentrations of several elements in seawater are given in Table 2-7. It is thought that this composition has remained essentially unchanged during most of geologic time. This would mean that the inflow of minerals reaching the oceans from rivers, from the atmosphere, and from undersea volcanoes has been roughly balanced by the outflow--namely, the incorporation of inorganic precipitates and dead organic matter into sediments on the ocean floor. [10] In a situation of *equilibrium* of this kind (with inflow balancing outflow it is easy to calculate the average time an atom of a given element spends in the ocean between entering it and leaving it. This is called the *residence time*; it is an important concept in the study of nutrient cycles and of pollution. The concepts of equilibrium and residence time, along with some related ideas that find widespread application in environmental sciences, are reviewed in Box 2-2. The residence times of

[10] A superb and detailed treatment of the processes maintaining the composition of the oceans appears in Ferren MacIntyre, "Why the sea is salt". This and other *Scientific American* articles on the oceans referred to in this section are collected in J. Robert Moore, ed., *Oceanography*.



BOX 2-2 Flows, Stocks, and Equilibrium

The terms *mass balance, energy balance, input/output analysis*, and *balancing the books* all refer to fundamentally the same kind of calculation--one that finds extensive application in physics, chemistry, biology, and economics and in the many disciplines where these sciences are put to use. The basic idea is very simple: everything has to go somewhere, and it is possible and useful to keep track of where and how fast it goes.

The concepts and terminology are illustrated in the diagram here. A stock is a supply of something in a particular place--money in a savings account, water in a lake, a particular element in the ocean. The stocks can be measured in terms of value (dollars), volume (liters), mass (grams), energy (joules), number of molecules, or other units, but not time. Time appears, instead, in the complementary concept of *flows*, the inflow (or input) being the amount of commodity added to the stock per unit of time and the outflow (or output) being the amount of commodity removed from the stock per unit of time. Thus, flows are measured in units like dollars per year, liters per minute, grams per day, or joules per second (watts). In the diagram, the sizes of the flows are indicated by the widths of the arrows. In a savings account, the inflow is deposits plus interest, the outflow is withdrawals, and the stock is the balance at any given time.

Clearly, if the inflow is greater than the outflow, the stock becomes larger as time passes; if outflow exceeds inflow, the stock shrinks. The change in the size of the stock in a given period is the difference between inflow and outflow, multiplied by the length of the period. (If the inflow and outflow vary during the period, one must use their averages.) In the event that the inflow and the outflow have exactly the same magnitude, the size of the stock remains constant. This last situation, where inflow and outflow balance is called equilibrium, or, more specifically, *dynamic equilibrium* (something is flowing, but nothing is changing). The more restrictive case where nothing at all is happening--that is, no inflow, no outflow--is called *static equilibrium*.

In a state of equilibrium, there is not necessarily any relation between the size of the flows (*throughput*) and the size of the stock. [*] For example, a small lake in equilibrium may be fed by a large river and drained by an equally large one (small stock, large throughput), or a large

lake in equilibrium may be fed by a small river and drained by an equally small one (large stock, small throughput). If one divides the size of a stock in equilibrium by the size of the throughput, one obtains a very useful quantity--the *average residence time* (τ). In the example of the lakes, this is the average length of time a water molecule spends in the lake between entering and leaving. For a lake of 100 million cubic meters, fed and drained by two rivers with flows of 100 cubic meters per second each, the average residence time would be given by:

$$\tau = \frac{100{,}000{,}000\ \mathrm{m}^3}{100\ \mathrm{m}^3/\mathrm{sec}} = 1{,}000{,}000\ \mathrm{sec}$$

,
which is about twelve days. A smaller volume
and/or a larger throughput would produce a shorter residence time.

The concept of residence time is useful not only for describing geophysical processes but also for analyzing economic and biological ones. Economic "residence times" include replacement periods for capital and labor. And, to cite an example from biology, if the stock is the world's human population, then the inflow is the rate at which people are born, the outflow is the rate at which people die, and the average residence time is the life expectancy. Clearly, a given population size could be maintained at equilibrium by conditions of high throughput (high birth rate, high death rate, short life expectancy) or by conditions of low throughput (low birth rate, low death rate, long life expectancy). This subject is taken up in more detail in later chapters.

---

*Throughput means just what you would think--"what flows through"--and in general has the magnitude of the smaller of the inflow and outflow in a given situation. In equilibrium, inflow and outflow and throughput are all the same number.

TABLE 2-8 Residence Times of Some Constituents of Seawater

Element	Residence time (million years)

some important constituents of seawater are listed in Table 2-8.

The absolute quantities of materials dissolved in a cubic kilometer of seawater are quite large--175 metric tons of lithium, 3 metric tons of copper, 200 kilograms of silver, and 4 kilograms of gold, to mention some elements commonly regarded as scarce. Multiplying such numbers by the total volume of the oceans gives very large numbers, indeed, and these staggering quantities, combined with the ready accessibility of the oceans, have stimulated much discussion of mining seawater for its riches. In mining, it is the *concentration* of the material that counts, however (a subject to which we return in Chapter 9). To get the three tons of copper in a cubic kilometer of seawater, for instance, this desired material must somehow be separated from the billion metric tons of other elements mixed up with it, and this is not easy.

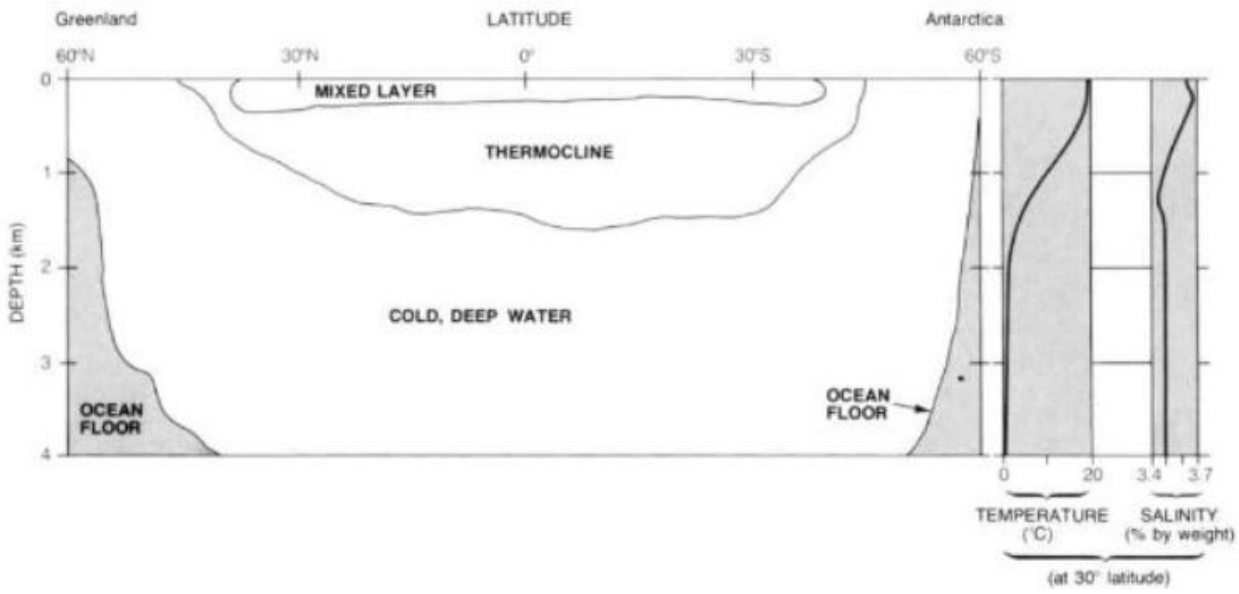
Probably a more important reason for looking into the details of the composition of the oceans is to evaluate the seriousness of various kinds of ocean pollution. If pollutants such as lead and mercury, for example, are added to the oceans in sufficient quantities to alter substantially the natural concentrations of those elements over large areas, one might suspect that significant biochemical consequences could result. If, on the other hand, the discharge of an element into the ocean produces concentration changes small compared to natural variations in space and time of the concentration of this substance, little or no harm would be expected.

One cannot assume, of course, that substances added to the oceans are quickly diluted by this vast volume of water. How far? How deep? How fast? are the questions, and the answers are found in the rather complicated patterns of horizontal circulation and vertical mixing in the oceans, as well as in the functioning of biological systems that may concentrate them (Chapter 4). Vertical mixing is rapid only near the surface. The turbulence (violent mixing motions) produced by wave action at the surface penetrates only to a depth of from 100 to 200 meters, and this defines the thickness of the layer within which most of the absorbed solar energy is distributed.

Below this warm, well-stirred surface layer is a transitional region called the *thermocline*, where the temperature drops rapidly. In this region there is usually less vertical motion than in the surface layer. Here heat penetrates partly by conduction (molecules passing on energy by jostling their neighbors) but mostly by convection (transport of energy by bulk motion of a warm medium) in large, slow eddies. There are two reasons for the relative lack of vertical motion in the thermocline: (1) motions originating at the surface have been damped out by friction before penetrating so deep and (2) the colder water near the bottom of the thermocline tends to be denser than the warmer water near the top of this layer, stifling thermal circulation. [11] In some circumstances, however, variations in salinity can influence density enough to produce a vertical circulation, despite the countervailing influence of the temperature profile. The bottom of the thermocline lies between 1000 and 1500 meters below the surface; from this level down, the temperature is nearly uniform and lies in the range from 0° to 5° C. (Seawater freezes at -2° C, or about 28.4° F.) Like the thermocline, this deepest ocean layer is thermally stratified, with the coldest water lying at the bottom. In the deep layer, moreover, salinity increases with depth; the saltier water is, the denser it is, so the salinity profile and the temperature profile both place the densest water at the bottom, inhibiting vertical mixing.

This simplified view of the vertical layering of the oceans is illustrated schematically in Figure 2-5. Note that the stratification breaks down near the poles, where

[11] Thermal circulation, or thermal convection, occurs when warm fluid (liquid or gas), finding itself below colder, denser fluids, rises, while the colder material sinks. This is what happens when a fluid, such as water in a pan, is heated from below. The ocean is heated mainly at the top.



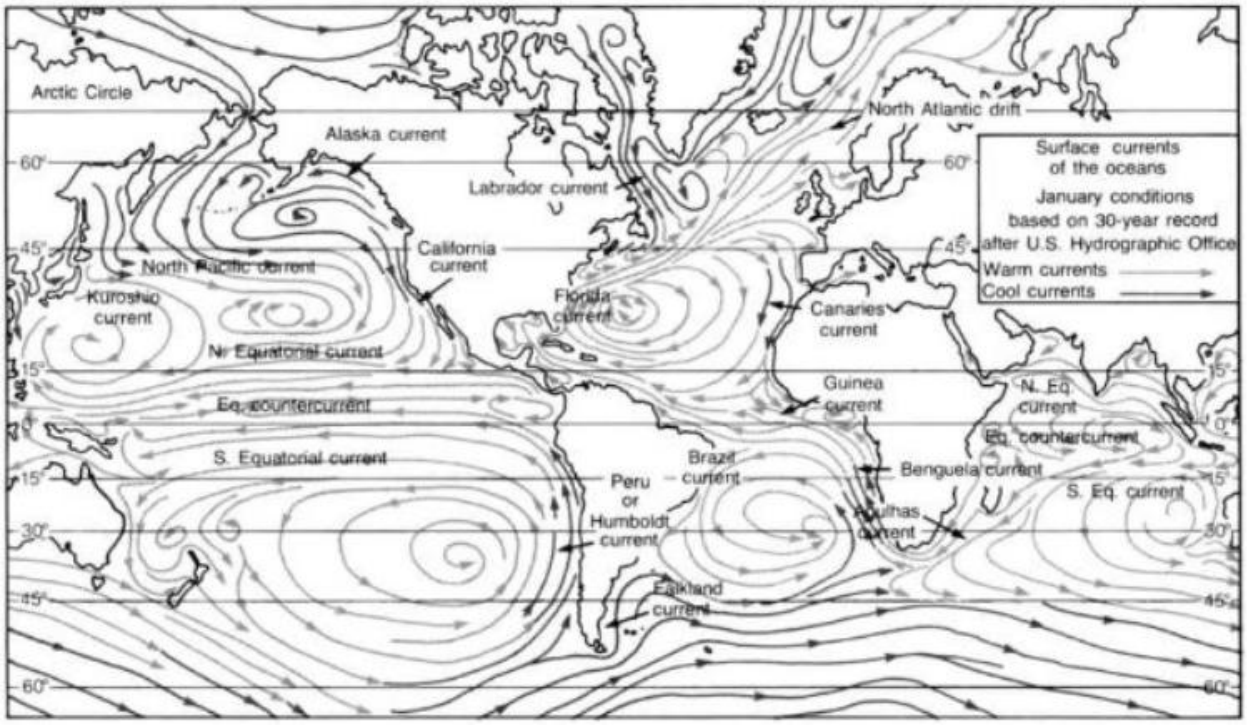


FIGURE 2-5 Schematic diagram of the vertical structure of oceans.

the cold layer extends all the way to the surface. That the surface waters in the Arctic and Antarctic oceans should be considered outcroppings of the deep layer that extends throughout the world ocean is suggested not only by patterns of temperature and salinity but also by the distribution of certain creatures. The huge Greenland shark, for example, once thought to inhabit only Arctic waters, has been photographed three or four kilometers deep in waters off Baja California and in the Indian ocean. [12]

The stable stratification of the oceans also breaks down at scattered places and times far from the poles, as in upwellings in which winds push the surface water away from a steep continental slope and cold water rises from below to replace it (off the coast of Peru, for example) or when rapid cooling of surface water under unusual circumstances causes it to sink. The mean residence times for water in the various ocean layers illustrate the relative rarity in space and time of large vertical movements: a typical water molecule in the mixed layer may spend 10 years there, whereas one in the thermocline spends 500 years before reaching the deep layer, and a water molecule in the deep layer typically spends 2000 or 3000 years before reaching one of the upper layers. Clearly, it must be assumed that most substances added to the oceans near the surface and dissolved there will remain near the surface for years, being diluted only by the small fraction of the ocean water that makes up the well mixed top layer (between 3 and 5 percent).

Horizontal circulation in the oceans is considerably faster than vertical mixing. Water in the main currents, which generally involve only the mixed layers, typically moves at speeds of 1 kilometer per hour (km/hr), and occasionally up to 5 kilometers per hour. Thus, an object or a substance being carried in the current might easily move 1000 kilometers in a month and cross an ocean in, six months to a year. (The main oceanic surface currents appear on the map in Figure 2-6.) The principal features are the circular movements, called *gyres*, centered in the subtropical latitudes (25° to 30° north and south of the equator), an equatorial countercurrent (most prominent in the Pacific) that provides a return pathway for water that would otherwise be piling up against Asia and Australia, and the Antarctic circumpolar current, flowing uninterrupted from west to east around the far southern part of the globe. These currents are produced

[12] John D. Isaacs, *The nature of oceanic life*.

Mercator's projection FIGURE 2-6 Main oceanic surface currents.

by a complex interaction of the effects of the winds, Earth's rotation, and the placement of continents and islands. [13] By moving enormous quantities of water-sometimes warm, sometimes cold--from one region to another, the ocean currents exert a major influence on climate, a subject taken up in more detail later. The two mightiest currents on Earth, the Antarctic circumpolar current and the main branch of the Gulf Stream, each carries some fifty times the combined flow of all the world's rivers. [14]

The horizontal circulation in the deep layer of the ocean is much less thoroughly mapped than that of the surface layer and has been widely supposed to be much less vigorous. Typical speeds in these deep currents have been thought to be on the order of 0.1 kilometer per hour or less. An increasing number of direct measurements of deep ocean currents now suggest a much more vigorous deep-ocean circulation, however, involving powerful eddies 100 kilometers or more in horizontal extent, containing currents of 0.5 to 1 kilometer per hour. [15] One would expect the general flow to be from the poles toward the equator, inasmuch as some cold water enters the deep layer from above at the poles and some rises in upwellings closer to the equator. But the actual situation is made quite complicated by Earth's rotation, by the irregular distribution of landmasses, and by the complex topography of the ocean floor.

It has been true historically and is still true today that the usefulness of the oceans to civilization and, in turn, civilization's impact on the oceans have been greatest in the shallower waters at the edges of the continents. This

[13] See, for example, R. W. Stewart, *The atmosphere and the ocean*.
[14] P. H. Kuenen, *Realms of water*, p. 47.

[15]F. Bretherton, *Recent developments in dynamical oceanography*.

is so partly for simple reasons of accessibility, and partly because of the particular fertility of the near-shore waters and the richness of the underlying sediment in minerals of economic interest. The term *continental shelf* refers to that part of the near-shore underwater topography that is actually an extension of flatlands on a continent itself. Although the outer edge of a continental shelf is often defined as the line along which the depth of the water reaches 200 meters, a less arbitrary boundary is the point where there is a marked increase in the downward slope of the bottom. The steeply sloping region just beyond this boundary is called the *continental slope*. The "foothills" leading from the ocean floor to the seaward edge of the continental slope are called the *continental rise*.

Using the definition of continental shelf just given, it has been estimated that continental shelves underlie 7.5 percent of the area of the oceans (an area equal, however, to 18 percent of Earth's land area). [16] These shelves vary in width from essentially nothing to 1500 kilometers, and their seaward edges vary in depth from 20 to 550 meters (the average depth at the edge is 133 meters). The circulation patterns in shallow, continental-shelf waters are complex, and the residence times of dissolved substances over the shelf can be surprisingly long -- as much as several years to migrate from the coastline to the outer edge of a wide shelf like that off the east coast of the United States.

Glaciers and Sea Ice

Fifteen thousand years ago, much of what is now continental shelf was dry land. Sea level was 130 meters lower than it is today. Where was the 45 million cubic kilometers of water (about 12 billion billion gallons!) this difference in sea level represents? It was locked up in the great glaciers of the ice age. In the warmer period in which we find ourselves today, the water that remains frozen as ice still far exceeds all other reservoirs of fresh water on Earth (Table 2-6). Were this ice to melt, sea level would rise another 80 meters.

It is important in this connection to distinguish between *glaciers* and *sea ice*. A glacier is a sheet of ice formed *on land* when accumulated snow is compressed and hardened into ice by the weight of overlying layers. Sea ice is ice formed from seawater; it floats on the ocean's surface, although it may be attached to land at its edges.

The glaciers that usually come to mind when one hears this term are the scattered "mountain and valley glaciers" that occur throughout the world's high mountain ranges -- the Himalayas, Andes, Rockies, and Alps, for example. The larger glaciers of this variety are some tens of kilometers long, a kilometer or more across, and a few hundred meters thick. These glaciers are constantly in motion, being fed by snowfall at their surfaces in the higher elevations and moving downhill as the deep layers, under great pressure, flow as a plastic solid. (Perhaps the easiest way to visualize what is going on in such flow, which as we noted earlier also occurs in rock in Earth's mantle, is to consider the plastic solid to be an extremely viscous fluid.) The speed of advance varies along the length of the glacier, but is typically 100 meters per year or more in the main

body of the larger mountain glaciers. The advance of such glaciers is terminated by melting of the tongue of the glacier at the lower end.

By far the greatest part of the world's inventory of ice -- more than 99 percent -- is tied up in a second kind of glacier, the land ice or ice sheets, that cover the bulk of the Greenland and Antarctic landmasses. The formation of such a sheet requires an arctic climate, sufficient precipitation, and fairly flat land. The ice layer that results covers essentially the entire landscape in a gently sloping dome, interrupted only by a few projecting mountain peaks. The Greenland ice sheet covers an area of 1.74 million square kilometers (about 80 percent of the total area of Greenland) and has an average thickness of about 1600 meters (5250 ft). The Antarctic ice sheet covers 13 million square kilometers with ice up to 4000 meters thick (13,000 ft) and averaging perhaps 2300 meters. [17] About 91 percent of the world's ice thus is in the Antarctic sheet and about 9 percent in the Greenland sheet. These ice sheets, like mountain and valley glaciers,

[16]K. O. Emery, *The continental shelves*.
[17]Press and Siever, *Earth*, p. 371; Strahler and Strahler, *Environmental geoscience*, pp. 434-436.

are in motion, carrying to the sea the ice formed from precipitation in the central regions. Typical speeds are some tens of meters per year on the ice sheet proper, but they can be much higher -- hundreds, and even thousands, of meters per year -- where certain glacial tongues meet the sea.

Where the ice sheets meet the sea in broad expanses, they may extend into the ocean as more-or-less floating ice shelves, from tens to hundreds of meters thick. In the Antarctic, these shelves reach widths of hundreds of kilometers. The largest, the Ross Ice Shelf, covers more than 500,000 square kilometers. Icebergs originate when great masses of ice break off from the tips of glacial tongues or the edges of ice shelves and are carried away (often into shipping lanes) by currents (see Figure 2-7).

Sea ice, as distinguished from floating extensions or pieces of glaciers, is formed by the freezing of seawater on the ocean surface. The North Pole ice pack, with a mean extent of about 10 million square kilometers, is a collection of slabs of sea ice floating on the Arctic Ocean. In winter, these slabs are frozen together and attached to land at various points around the ocean's periphery. In summer, some of the slabs break apart and are separated by narrow strips of open water, and the southern limit of the ice retreats northward. The sea ice, which begins to form at -- 2° C, is porous, and the enclosed cavities often contain water saltier than seawater. Glacial ice, by contrast, consists of fresh water, being simply compacted and recrystallized snow.

The maximum thickness of sea ice is only between 3 and 5 meters. Once it reaches this thickness, the layer of ice insulates the underlying water so well that no more can freeze -- heat is supplied from the deeper water faster than the surface layer can lose it through the ice. (Ice is a poor conductor of heat and snow an even poorer one, which is why snow igloos stay so warm inside.) If the average thickness of the North Pole ice pack is 2 meters, it contains less than one-hundredth as much ice as the Greenland ice sheet. [18] Of course, melting of the sea ice would have

no direct effect on sea level, even if the volume of this ice were much greater; the ice is floating, thus displacing an amount of water equal to its weight, so

FIGURE 2-7 A glacier feeding ice into the sea in Paradise Bay, Antarctica. No large icebergs are visible in this picture. (Photo by P. R. Ehrlich.)

[18]Ten million km^2 of area multiplied by 0.002 km average thickness is 20,000 km^3 of ice in the polar pack, compared to 1.7 million km^2 multiplied by 2.2 km average thickness, or 2,700,000 km^3 of ice, in the Greenland sheet.

it is already contributing exactly as much to the level of the oceans as it would if it melted. Aside from the sea-level issue, however, which relates solely to glacial ice sheets, the sea ice has great importance for climate.

The Hydrologic Cycle

Although oceans and ice caps contain some 99.3 percent of all the water on Earth (Table 2-6), the fraction of 1 percent residing at any given time in the atmosphere, in lakes and streams, and in soil and subsurface layers plays unique and important roles. The flow of water on the surface is a major determinant of the configuration of the physical environment. Soil moisture is essential to most terrestrial plant life. The stocks and flows of ground and surface water are

major links in the transport and cycling of chemical nutrients and important determinants of what kinds and intensities of human activity can be supported in what locations. And water in the atmosphere has several functions that are central to shaping climates.

The set of processes that maintain the flow of water through the terrestrial and atmospheric branches of the hydrosphere is called the *hydrologic cycle*. The cycle includes all three physical states of water -- liquid, solid (ice and snow), and gas (water vapor). It also includes all of the possible transformations among these states -- *vaporization,* or evaporation (liquid to gas); *condensation* (gas to liquid), *freezing* (liquid to solid); melting, or *fusion* (solid to liquid); and *sublimation* (gas to solid, or the reverse).

The principal flows in the hydrologic cycle are: (1) *evaporation* of water from the surface of the oceans and other bodies of water, and from the soil; (2) *transpiration* of water by plants, the result of which is the same as that of evaporation -- namely, the addition of water vapor to the atmosphere; (3) horizontal *transport* of atmospheric water from one place to another, either as vapor or as the liquid water droplets and ice crystals in clouds; (4) *precipitation,* in which atmospheric water vapor condenses (and perhaps freezes) or sublimates and falls on the oceans and the continents as rain, sleet, hail, or snow; and (5) *runoff,* in which water that has fallen on the continents as precipitation finds its way, flowing on and under the surface, back to the oceans. Because it is difficult and not particularly useful to distinguish between the contributions of evaporation and transpiration on the continents, these two terms are often lumped together as *evapotranspiration*.

The magnitudes of these flows, averaged over all the continents and oceans and expressed in thousands of cubic kilometers of water per year, are shown in Figure 2-8. [19] These magnitudes are based on the assumption that the various components of the hydrosphere are in equilibrium, which is at least a good first approximation. That is, on a year-round average, inflows and outflows for the atmosphere, the oceans, and the continents all balance. (For example, in thousands of cubic kilometers, the atmosphere receives 62 + 456 = 518 as evaporation from the surface and gives up 108 + 410 = 518 as precipitation.)

The magnitude of the flows in the hydrologic cycle is more readily grasped if one thinks of the flows in terms of the equivalent depth of water, averaged over the surface area involved. In these terms, the world's oceans annually lose to evaporation a layer of water 1.26 meters deep (about 4 feet) over their entire surfaces, gaining back 1.14 meters from precipitation and 0.12 meters from the discharge of rivers and groundwater. The continents receive precipitation each year equivalent to a layer of water 0.73 meters (29 in) deep over their entire surface areas, of which 0.42 meters is lost to evaporation and 0.31 meters makes up the runoff.

Combining the foregoing information on equilibrium flows with the information on stocks in the hydrosphere summarized in Table 2-6 permits us to estimate the average residence time of water in the different parts of the cycle (see Box 2-2). These residence times, which are of great importance in analyzing the transport of pollutants, as well as nutrients, by the hydrologic cycle, are listed in Table 2-9. There is an enormous range, from the average nine days a water molecule spends in the atmosphere between being evaporated from the surface and falling again as precipitation, to the 10,000 years a

[19]The values presented here are at the high end of a range of published estimates, in which the differences of professional opinion amount to as much as 25 percent.

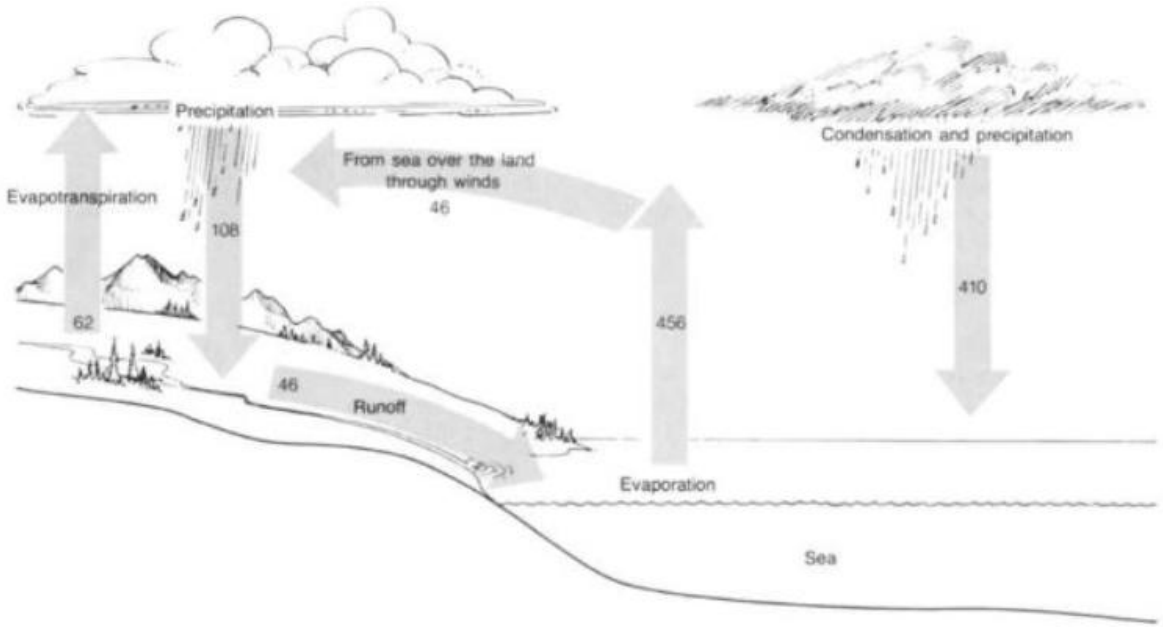

FIGURE 2-8 The hydrologic cycle (1000 km3/yr). (Data from M. I. Budyko, 1974.)

TABLE 2-9 Residence Times of Water Molecules in the Hydrologic Cycle

Location	Residence time
Atmosphere	9 days
Rivers (typical speed, 1 m/sec)	2 weeks
Soil moisture	2 weeks to 1 year
Largest lakes	10 years
Shallow groundwater (speed, 1-10 m/day)	10s to 100s of years
Mixed layer of oceans (1st 150 m)	120 years
World ocean	3000 years
Deep groundwater	up to 10,000 years
Antarctic ice cap	10,000 years

Sources: Computed from Table 2-6 and Figure 2-8 or adapted from SMIC, *Inadvertent climate modification*, and Strahler and Strahler, *Environmental geoscience*.

molecule of water typically spends as ice between falling in a snowflake on the Antarctic ice sheet and rejoining the ocean with the melting of an iceberg. It is also important to remember that there are large deviations from the average in any given category -- a water molecule may fall in a raindrop not nine days but an hour after being evaporated from Earth's surface; another may wander not two weeks but two years in the delta of the Amazon River before reaching the

sea. Nevertheless, the average residence times can provide useful insights into a variety of important problems, and the approach can be refined whenever information more pertinent than global averages is available.

The balance between precipitation and evapotranspiration varies widely from continent to continent, as shown in Table 2-10. The size of the runoff (the difference between precipitation and evapotranspiration) is a measure of how much water is potentially available for domestic and industrial uses by society (including dilution and removal of wastes) and for the other functions that flowing water performs. Note in Table

TABLE 2-10 Average Water Balance of the Continents

	Precipitation (cm/yr)	*Evaporation (cm/yr)*	*Runoff*

2-10 the remarkable fact that South America has a runoff per unit of surface area almost three times that of North America, the continent with the next greatest runoff. It is perhaps not so surprising, then, that the discharge of the Amazon River, which drains the wettest third of South America, amounts to about a seventh of the runoff of the entire world.

Much of the runoff on the continents takes place not on the surface but beneath it. Although the quantities can only be estimated, it is clear that most rivers receive at least as much of their flow from see page through the ground as from flow over the ground; and a certain amount of water reaches the oceans via flowing aquifers and see page at the edges of the continents without ever joining a surface river at all. [20] Water beneath the land's surface is called *soil moisture,* or soil water, when it is distributed in the first meter or so of soil (a zone defined by the depth of penetration of the roots of most plants.) Below the zone of soil moisture is an intermediate zone where the water percolates downward through open pores in the soil and rock; and below this is the *water table,* marking the surface of the body of *groundwater* that saturates the soil or rock in which it finds itself, filling all pores and spaces in the soil or rock completely. The groundwater extends downward until it is limited by an impermeable layer of rock. In some circumstances, there are successive layers of groundwater (*aquifers*) separated by impermeable layers of rock. The absolute lowest limit of groundwater is probably about 16 kilometers from the surface, where the pressure is so great that all pores are closed and any rock becomes impermeable.

Most groundwater is flowing, albeit very slowly [10 meters per day (m/d) in coarse gravel near the surface, more commonly 1 m/d, and much more slowly at greater depths.] At 1 meter per day, of course, it takes almost three years to move 1 kilometer. Figure 2-9 is a schematic diagram of the zones and flows of subsurface water, showing the intersection of the water table and a surface river.

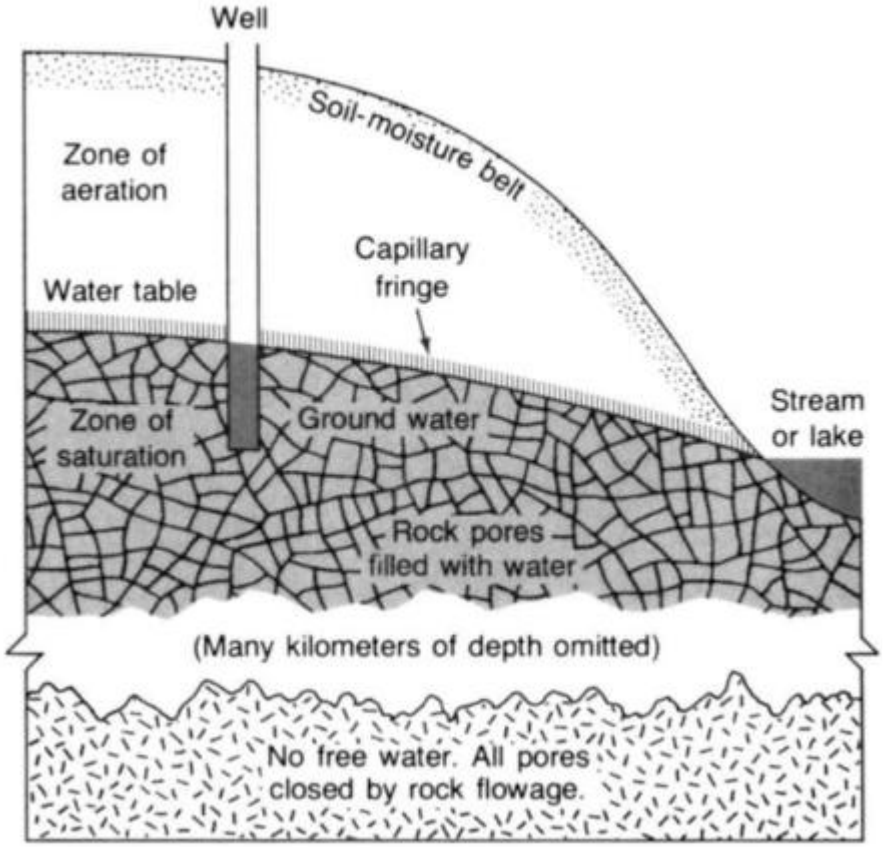

FIGURE 2-9 Zones of subsurface water. (After Ackerman, Colman, and Ogrosky, in A. N. Strahler and A. H. Strahler, *Environmental geoscience*.)

[20]See, for example, Strahler and Strahler, *Environmental geoscience*, Chapter 12, and Kuenen, *Realms of Water*, Chapter 5.

The energy that drives the hydrologic cycle is energy from the sun -- indeed, this function is the largest single user of the solar energy reaching Earth's surface. The reason so much energy is required is that it takes a great deal of energy to evaporate water -- 2250 joules per gram at the boiling point of 100° C and 2440 joules per gram at Earth's average surface temperature of 15° C. (This is the highest heat of vaporization of any known substance.) It takes fifty times as much energy to evaporate a gram of water as it does to lift it to an altitude of 5 kilometers. The energy used to evaporate the water is stored as latent heat of vaporization (see Box 2-1), which is released to the environment as heat whenever and wherever the water vapor condenses into liquid. Thus, energy delivered by the sun at one point on Earth's surface may be released high in

the atmosphere over a point 1000 kilometers away. This mechanism of redistributing energy by the transport and condensation of water vapor is a major determinant of Earth's climate.

As noted above, the energy the sun supplies at the time of evaporation reappears as heat at the time of condensation. Similarly, the smaller amount of solar energy that does the work of lifting the water vapor against the force of gravity appears as frictional heat when falling droplets of condensed vapor collide with molecules of air and when rushing mountain streams rub against their rocky beds. That all the energy the sun supplies to terrestrial processes comes back again in one form or another is not coincidence or quirk, but an illustration of the first law of thermodynamics -- the law of conservation of energy. Further excursions into the machinery of the physical world -- and of human technology -- will require some familiarity with this law and with its companion, the second law of thermodynamics, so an introduction to both is provided in Box 2-3.

ATMOSPHERE AND CLIMATE

The blanket of gases that makes up Earth's atmosphere has many functions. Of the four elements required in greatest quantity by living organisms [carbon (C), oxygen (O), hydrogen (H), nitrogen (N)] the atmosphere provides the main reservoir of one (N), the most accessible reservoir of two others (C, O), and an essential link in the continuous recycling of the fourth (H, in the form of H2O). The atmosphere is substantial enough to protect the organisms on Earth's surface from a variety of harmful particles and radiations that reach the planet from the sun and from space, but it is transparent enough to permit an adequate amount of life-giving sunlight to penetrate to that surface. Acting as a thermal insulator, the atmosphere keeps Earth's surface much warmer, on the average, than it would be if there were no atmosphere. And the stirrings of the atmosphere, transporting energy and moisture from one place to another, are a major part of the patterns of climate so important to the character and distribution of life.

For simplicity, we begin our investigation of the atmosphere by ignoring its internal vertical and horizontal motions and considering its properties as a static body of gas.

Air

The term *air* refers to the particular mixture of gaseous compounds making up the atmosphere. The average composition of this mixture, not including water, is shown in Table 2-11. An important property of gases is that a given number of molecules at a given temperature and pressure will occupy almost exactly the same volume, regardless of the mass or size of the molecules. This property has led to the use of the somewhat confusing terms *percent by volume or fraction by volume* to describe the relative abundance of the various constituents of gaseous mixtures. That is, if three-quarters of the molecules in a container of fixed volume are gas A and one-quarter are gas B, one can think of gas A as "occupying" three-fourths of the volume and gas B as "occupying" one-fourth. (What is happening in reality, of course, is that both gases, mixed together, occupy the whole volume, with gas A accounting for three-fourths of the pressure in the volume and gas B accounting for one-fourth of the pressure.) We will use the term *molecular fraction* (number of molecules of a constituent divided by the total number of molecules in the

mixture), because it is unambiguous and works for solids and liquids as well as gases. The reader should simply be aware that this term is interchangeable with the term

TABLE 2-11 Average Composition of Clean Dry Air

Constituent	Symbol	Molecular weight	Molecular fraction of air	Mass fraction of air
Nitrogen	N_2	28	0.7809	0.755
Oxygen	O_2	32	0.2095	0.232
Argon	Ar	40	0.0093	0.013
Carbon Dioxide	CO_2	44	320 ppm	486 ppm
Neon	Ne	20	18 ppm	12 ppm
Helium	He	4	5.2 ppm	0.7 ppm
Methane	CH_4	16	2.9 ppm	1.6 ppm
Krypton	Kr	84	1.1 ppm	3.2 ppm

BOX 2-3 Availability, Entropy, and the Laws of Thermodynamics

Many processes in nature and in technology involve the transformation of energy from one form into others. For example, light from the sun is transformed, upon striking a meadow, into thermal energy in the warmed soil, rocks, and plants; into latent heat of vaporization as water evaporates from the soil and through the surface of the plants; and into chemical energy captured in the plants by photosynthesis. Some of the thermal energy, in turn, is transformed into infrared electromagnetic radiation heading skyward. The imposing science of thermodynamics is just the set of principles governing the bookkeeping by which one keeps track of energy as it moves through such transformations. A grasp of these principles of bookkeeping is essential to an understanding of many problems in environmental sciences and energy technology.

The essence of the accounting is embodied in two concepts known as the first and second laws of thermodynamics. No exception to either one has ever been observed. The first law, also known as the law of conservation of energy, says that energy can neither be created nor destroyed. If energy in one form or one place disappears, the same amount must show up in another form or another place. In other words, although transformations can alter the *distribution* of amounts of energy among its different forms, the *total* amount of energy, when all forms are taken into account, remains the same. The term *energy consumption,* therefore, is a misnomer; energy is used, but it is not really consumed. One can speak of fuel consumption, because fuel, as such, does get used up. But when we burn gasoline, the amounts of energy that appear as mechanical energy, thermal energy, electromagnetic radiation, and other forms are exactly equal all together to the amount of chemical potential energy that disappears. The accounts must always balance; apparent exceptions have invariably turned out to stem from measurement errors or from

overlooking categories. The immediate relevance of the first law for human affairs is often stated succinctly as, "You can't get something for nothing."

Yet, if energy is stored work, it might seem that the first law is also saying, "You can't lose!" (by saying that the total amount of stored work in all forms never changes). If the amount of stored work never diminishes, how can we become worse off? One obvious answer is that we can become worse off if energy flows to places where we can no longer get at it -- for example, infrared radiation escaping from Earth into space. Then the stored work is no longer accessible to us, although it still exists. A far more fundamental point, however, is that *different kinds of stored work are not equally convertible into useful, applied work.* We can therefore become worse off if energy is transformed from a more convertible form to a less convertible one, even though no energy is destroyed and even if the energy has not moved to an inaccessible place. The degree of convertibility of energy -- stored work -- into applied work is often called *availability*.

Energy in forms having high availability (that is, in which a relatively large fraction of the
(*Continued*)

BOX 2-3 (*Continued*)
stored work can be converted into applied work) is often called high-grade energy. Correspondingly, energy of which only a small fraction can be converted to applied work is called low-grade energy, and energy that moves from the former category to the latter is said to have been degraded. Electricity and the chemical energy stored in gasoline are examples of high-grade energy; the infrared radiation from a light bulb and the thermal energy in an automobile exhaust are corresponding examples of lower-grade energy. The quantitative measure of the availability of thermal energy is temperature. More specifically, the larger the *temperature difference* between a substance and its environment, the more convertible into applied work is the thermal energy the substance contains; in other words, the greater the temperature difference, the greater the availability. A small pan of water boiling at 100° C in surroundings that are at 20° C represents considerable available energy because of the temperature difference; the water in a swimming pool at the same 20° C temperature as the surroundings contains far more total thermal energy than the water in the pan, but the availability of the thermal energy in the swimming pool is zero, because there is no temperature difference between it and its surroundings.With this background, one can state succinctly the subtle and overwhelmingly important message of the second law of thermodynamics: *all physical processes, natural and technological, proceed in such a way that the availability of the energy involved decreases.* (Idealized processes can be constructed theoretically in which the availability of the energy involved stays constant, rather than decreasing, but in all real processes there is *some* decrease. The second law says that an *increase* is not possible, even in an ideal process.) As with the first law, apparent violations of the second law often stem from leaving something out of the accounting. In many processes, for example, the availability of energy in some *part* of the affected system increases, but the decrease of availability elsewhere in the system is always large enough to result in a net decrease in availability of energy overall. What is consumed when we use energy, then, is not energy itself but its availability for doing useful work.The statement of the second law given above is deceptively simple; whole books have been written about

equivalent formulations of the law and about its implications. Among the most important of these formulations and implications are the following:

In any transformation of energy, some of the energy is degraded.
No process is possible whose sole result is the conversion of a given quantity of heat (thermal energy) into an equal amount of useful work.
No process is possible whose sole result is the flow of heat from a colder body to a hotter one.
The availability of a given quantity of energy can only be used once; that is, the property of convertibility into useful work cannot be "recycled."
In spontaneous processes, concentrations (of anything) tend to disperse, structure tends to disappear, order becomes disorder.

That Statements 1 through 4 are equivalent to or follow from our original formulation is readily verified. To see that statement 5 is related to the other statements, however, requires establishing a formal connection between order and availability of energy. This connection has been established in thermodynamics through the concept of *entropy,* a well defined measure of disorder that can be shown to be a measure of unavailability of energy, as well. A statement of the second law that contains or is equivalent to all the others is: *all physical processes proceed in such a way that the entropy of the universe increases.* (Not only can't we win -- we can't break even, and we can't get out of the game!)

Consider some everyday examples of various aspects of the second law. If a partitioned container is filled with hot water on one side and cold water on the other and is left to itself, the hot water cools and the cold water warms -- heat flows from hotter to colder. Note that the opposite process (the hot water getting hotter and the cold getting colder) does not violate the first law, conservation of energy. That it does not occur illustrates the second law. Indeed, many processes can be imagined that satisfy the first law but violate the second and therefore are not expected to occur. As another example, consider adding a drop of dye to a glass of water. Intuition and the second law dictate that the dye will spread, eventually coloring all the water -- concentrations disperse, order (the dye/no dye ar-

BOX 2-3 (*Continued*)
rangement) disappears. The opposite process, the spontaneous concentration of dispersed dye, is consistent with conservation of energy but not with the second law.

A more complicated situation is that of the refrigerator, a device that certainly causes heat to flow from cold objects (the contents of the refrigerator -- say, beer -- which are made colder) to a hot one (the room, which the refrigerator makes warmer). But this heat flow is not the *sole* result of the operation of the refrigerator: energy must be supplied to the refrigeration cycle from an external source, and this energy is converted to heat and discharged to the room, along with the heat removed from the interior of the refrigerator. Overall, availability of energy has decreased, and entropy has increased.

One illustration of the power of the laws of thermodynamics is that in many situations they can be used to predict the maximum efficiency that could be achieved by a perfect machine, without specifying any details of the machine! (Efficiency may be defined, in this situation, as the ratio of useful work to total energy flow.) Thus, one can specify, for example, what *minimum* amount of energy is necessary to separate salt from seawater, to separate metals from their ores, and to separate pollutants from auto exhaust without knowing any details about future inventions that might be devised for these purposes. Similarly, if one is told the temperature of a source of thermal energy -- say, the hot rock deep in Earth's crust -- one can calculate rather easily the maximum efficiency with which this thermal energy can be converted to applied work, regardless of the cleverness of future inventors. In other words, *there are some fixed limits to technological innovation, placed there by fundamental laws of nature*. (The question of how far from the maximum attainable efficiencies industrial societies operate today is taken up in Chapter 8.)

More generally, the laws of thermodynamics explain why we need a continual input of energy to maintain ourselves, why we must eat much more than a pound of food in order to gain a pound of weight, and why the total energy flow through plants will always be much greater than that through plant-eaters, which in turn will always be much greater than that through flesheaters. They also make it clear that *all* the energy used on the face of the Earth, whether of solar or nuclear origin, will ultimately be degraded to heat. Here the laws catch us both coming and going, for they put limits on the efficiency with which we can manipulate this heat. Hence, they pose the danger (discussed further in Chapter 11) that human society may make this planet uncomfortably warm with degraded energy long before it runs out of high-grade energy to consume.

Occasionally it is suggested erroneously that the process of biological evolution represents a violation of the second law of thermodynamics. After all, the development of complicated living organisms from primordial chemical precursors, and the growing structure and complexity of the biosphere over the eons, do appear to be the sort of spontaneous increases in order excluded by the second law. The catch is that Earth is not an isolated system; the process of evolution has been powered by the sun, and the decrease in entropy on Earth represented by the growing structure of the biosphere is more than counterbalanced by the increase in the entropy of the sun. (The process of evolution is discussed in more detail in Chapter 4.)

It is often asked whether a revolutionary development in physics, such as Einstein's theory of relativity, might not open the way to circumvention of the laws of thermodynamics. Perhaps it would be imprudent to declare that in no distant corner of the universe or hithertounexplored compartment of subatomic matter will any exception ever turn up, even though our intrepid astrophysicists and particle physicists have not yet found a single one. But to wait for the laws of thermodynamics to be overturned as descriptions of everyday experiences on this planet is, literally, to wait for the day when beer refrigerates itself in hot weather and squashed cats on the freeway spontaneously reassemble themselves and trot away.

fraction by volume, often used elsewhere for gases. In many applications it is also useful to work with the *mass fraction* (grams of constituent/gram of mixture). This is a more precise statement of what is meant by the common term *fraction by weight or percent by weight*. [21]

A *mole* of any substance is 6.02×10^{23} molecules, and the mass of a mole is equal to the molecular weight of the substance in grams. For example, the mass of a mole of nitrogen gas (N_2) is 28 grams. It is often convenient to speak of air as if it were a single substance; the term a *mole of air* means 6.02×10^{23} molecules, of which 78.09 percent are nitrogen molecules, 20.95 percent are oxygen molecules, and so on. Such a collection of molecules has a mass of about 29 grams, which is called the *molecular weight of air*. (These definitions will be of importance later in interpreting what is meant by pollution standards expressed in different ways.)

Although nitrogen and oxygen comprise 99 percent of dry air, the trace constituents carbon dioxide (CO_2) and ozone (O_3) play exceedingly important roles because of the special properties of these molecules, as described below. Methane, nitrous oxide, and hydrogen also have roles in atmospheric chemistry and physics, albeit smaller ones. Argon, helium, krypton, and neon, by contrast, are chemically inert, monatomic gases, whose presence in the atmosphere is of interest only as resources for certain applications in technology. [22]

Water Vapor

The water content of the atmosphere varies greatly from place to place and time to time. Three commonly used measures of water content are *absolute humidity, specific humidity,* and *relative humidity*. Absolute humidity is the mass of water vapor per unit volume of air, and it varies from almost zero over the driest deserts to around 25 grams per cubic meter over jungles and tropical seas. Specific humidity is the mass of water vapor per unit mass of air. (A closely related term, the *mixing ratio,* is the mass of water vapor mixed with each unit mass of *dry* air.) Relative humidity, usually expressed as a percentage, is the ratio of the actual molecular fraction of water vapor in air to the molecular fraction corresponding to saturation at the prevailing temperature. (*Saturation* refers to the condition that ensues if air is left for a long time in a sealed container partly filled with pure water; the number of molecules of water vapor per unit volume of air under these circumstances depends only on the temperature.) [23] Relative humidity usually is between 0 and 100 percent, but under special circumstances (supersaturation) it can significantly exceed 100 percent.

Under ordinary circumstances, water vapor in the atmosphere begins to condense into droplets of liquid, forming clouds, as soon as the relative humidity exceeds 100 percent by even a small amount. The process of condensation is greatly facilitated by the virtually universal presence in the atmosphere of small particles that provide surfaces where the condensation can commence. Called *condensation nuclei* when they perform this function, these particles include salt crystals formed by the evaporation of sea spray, dust raised by the wind, ash from volcanoes and forest fires, decomposed organic matter, and, of course, particles produced by various technological activities. Even in "unpolluted" air, particles that might serve as condensation nuclei are seemingly abundant in absolute terms (more than 100 particles per cubic centimeter), but the extent of condensation and precipitation apparently are related to specific physical characteristics of the condensation nuclei as well as to their number.

The molecular fraction of water vapor corresponding to saturation increases as temperature increases -- warm air can "hold" more water vapor than cool air. Accordingly, there are two ways in which relative humidity can be raised from less than 100 percent to more, initiating

[21]Weight means the force exerted upon a mass by gravity. Weight and mass are more or less interchangeable (using the relation, weight equals mass multiplied by acceleration of gravity) only if one stays on Earth's surface, where gravity is nearly constant. An astronaut has the same mass on the surface of the moon as on Earth, but a very different weight, because the acceleration of gravity on the moon is much less than on Earth.

[22]For discussions of how the atmosphere came to have the composition it does, the reader should consult Preston Cloud and Aharon Gibor, *The oxygen cycle*; and Preston Cloud, ed., *Adventures in earth history*.

[23]The often encountered definition of saturation as "the maximum amount of water vapor air can hold at a given temperature" is not quite correct. A good discussion of this and the following points is given by Morris Neiburger, James G. Edinger, William D. Bonner, *Understanding our atmospheric environment*, Chapter 8.

condensation and perhaps precipitation: (1) more water vapor can be added to the air by evaporation from an exposed water surface; (2) the air can be cooled so that the vapor content corresponding to saturation falls. At a given vapor content (a fixed specific humidity), the temperature at which the relative humidity reaches 100 percent is called the *dew point*. Addition of water vapor to the air by evaporation is a slow process, but cooling of the air can be very rapid. Rapid cooling to below the dew point is the mechanism immediately responsible for most condensation phenomena -- the appearance of dew and fog at night as air is cooled by radiation of heat to the night sky; formation of clouds and rain in updrafts as the air is cooled by expansion; and formation of beads of water on the outside of a pitcher of ice water on a hot day, as air adjacent to the pitcher is cooled by contact with the cold surface.

Pressure, Temperature, and Vertical Structure

The pressure exerted by the atmosphere on objects at Earth's surface is essentially equal to the weight of the overlying air, which at sea level amounts on the average to 10.3 metric tons per square meter (14.7 lb/in^2). This amount of pressure, defined as I atmosphere, is the same as would be exerted at sea level by a column of water about 10 meters high (33 ft) or a column of mercury 760 millimeters (mm) high (29.92 in). This means that the mass of the atmosphere is only equivalent to that of a 10-meter layer of water covering Earth (you can check this in Table 2-2) and that pressure under water increases by the equivalent of I atmosphere for every 10 meters of depth. The usual metric unit for the measurement of atmospheric pressure is the millibar; 1 millibar is 100 newtons (N) per square meter (see Box 2-1 for the definition of the newton and I atmosphere is 1013.25 millibars.

Atmospheric pressure is not ordinarily perceived as a force because it acts equally in all directions (up, down, sideways); organisms are not crushed by it because the gases and liquids in tissue are also at atmospheric pressure, so the inward and outward forces balance. Pressure

becomes perceptible as a (painful) pressure *difference* if the pressure outside an organism changes more rapidly than the interior pressure can accommodate (an example would be the pain in one's ears associated with a rapid change in altitude).

Unlike water, whose density at the bottom of the deepest ocean trenches at pressures of hundreds of atmospheres is only a few percentage points higher than its density at the surface, the air in the atmosphere is highly compressible -- that is, density increases markedly as pressure increases. Indeed, air behaves very much like a "perfect gas," for which pressure (p), density (ρ), and temperature (T) are related by the equation $p = \rho RT$ For this equation to be valid, the temperature T must be measured with respect to *absolute zero*, the temperature at which there is no molecular motion. Temperature measured from this zero point, which is the same for all substances, is called *absolute temperature*, and the corresponding unit of measurement in the metric system is the degree kelvin. [24] The R in the equation is the gas constant, which for dry air equals 287 joules per kilogram per degree kelvin. According to the perfect gas equation, the density of dry air varies in direct proportion to pressure, if temperature is held constant.

Because the atmosphere is compressible, its mass is concentrated in the lower layers. Forty percent of the air in the atmosphere lies below the altitude of the summit of Mount Whitney in California's Sierra Nevada range (4.4 km) and two-thirds lies below the altitude of the summit of Mount Everest (8.9 km). The density of air at an altitude of 12 kilometers, where most subsonic jet airliners fly, is about one-fifth the density at sea level. The average variation of pressure and temperature with altitude above sea level is shown in Figure 2-10.

The atmosphere is subdivided into horizontal layers according to the pattern of temperature variation. The lowest layer, called the troposphere, is characterized by a rather uniform average rate of temperature decline with altitude of 6.4° C per kilometer. Almost all the atmo-

[24] Absolute zero, or 0 degrees kelvin (K) equals -273.15° C. An attempt was made recently to standardize the unit of absolute temperature as simply the kelvin, rather than the degree kelvin, but the change has not been generally adopted.

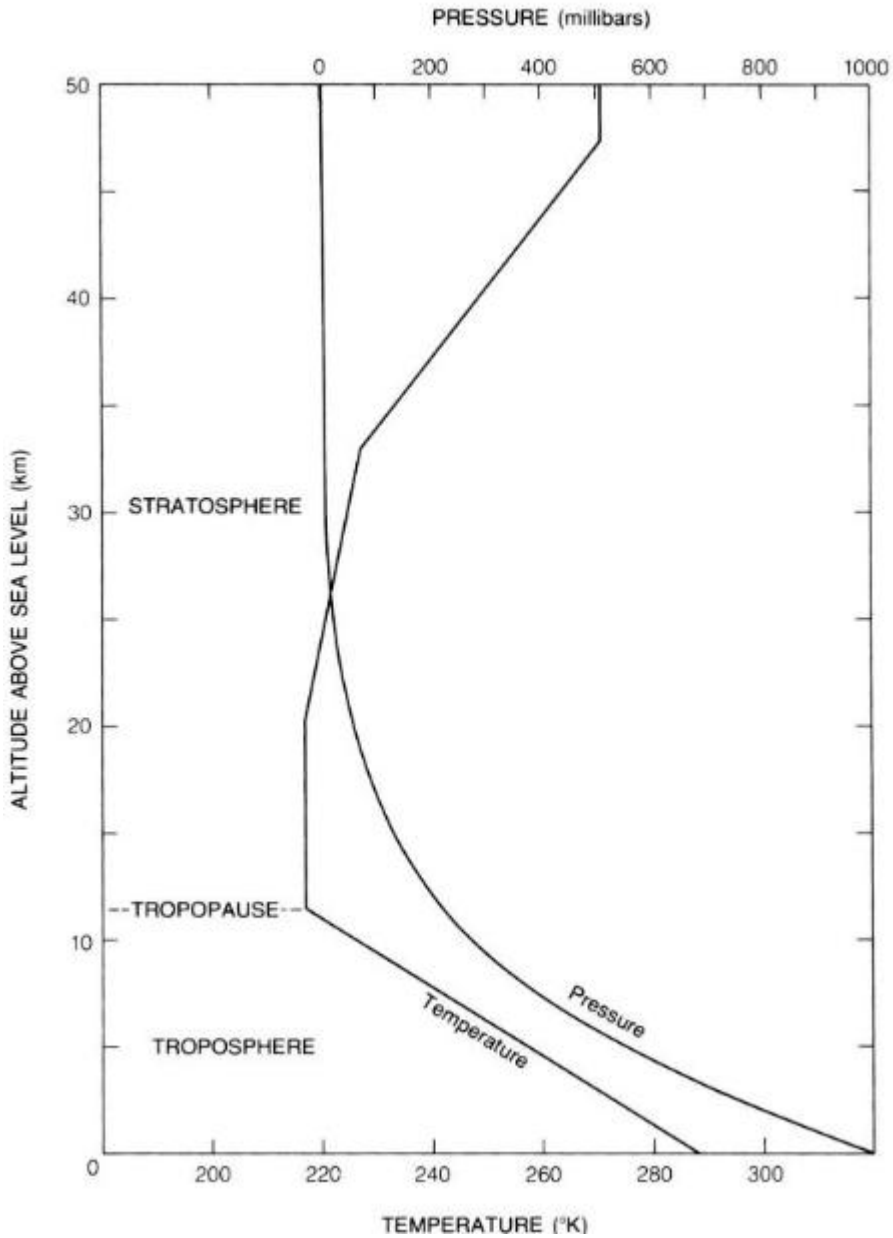

FIGURE 2-10 Variation of atmospheric temperature and pressure with altitude (idealized).

spheric phenomena that govern climate take place in the troposphere. The top of the troposphere is called the *tropopause*, where the temperature decline stops and a layer of uniform temperature at about -55° C commences. The tropopause is typically found at an altitude of from 10 to 12 kilometers, but it ranges from a low of 5 or 6 kilometers at the poles to around 18 kilometers at the equator.

The *stratosphere* extends from the tropopause up to the stratopause (about 50 km) and is characterized over much of this interval by temperatures increasing with altitude (reaching almost 0° C at the stratopause). The gaseous composition of the stratosphere is essentially the same as that at sea level, with two significant exceptions. First, there is very little water vapor in the stratosphere; the mixing ratio is typically two or three parts per million (ppm), or 1000 to

10,000 times less than is common near sea level. Second, there is a great deal more ozone in the stratosphere than in the troposphere; the maximum molecular fraction of ozone is 10 ppm near 25 km

altitude, or 1000 times more than the average for the whole atmosphere. [25] The air pressure and density at the top of the stratopause are on the order of a thousandth of the values at sea level.

Above the stratosphere lies the *mesosphere* (to about 90 km), wherein the temperature again decreases with altitude. The composition of the mesosphere remain much like that of the lower layers, except for certain trace constituents such as water vapor and ozone. The troposphere, stratosphere, and mesosphere together are called the *homosphere*, referring to their relatively uniform composition. Above the mesosphere is the *thermosphere* (temperature again rising with altitude), which contains the *heterosphere* (so named because the molecular constituents are there separated into distinct layers of differing composition) and the *ionosphere* (referring to the presence of free electrons and the positively charged ions from which the electrons have been stripped). The thermosphere has no well defined upper limit; its density at 100 kilometers is around one-millionth of atmospheric density at sea level, and by 10,000 kilometers it has faded off to the density prevailing in interplanetary space.

Radiant Energy Flow in the Atmosphere

What accounts for the complicated way in which temperature changes with altitude in the atmosphere? The answer involves the way in which different atmospheric constituents interact with radiant energy arriving from the sun and with radiant energy trying to escape Earth into space. The same processes, of course, determine how much and what kinds of energy reach Earth's surface, so they are crucial in determining the conditions that govern life. To understand these processes requires at least a modest acquaintance with the character of radiant energy (or electromagnetic radiation), and this is supplied in Box 2-4.

The energy in the electromagnetic radiation reaching the top of Earth's atmosphere from the sun is distributed over a range of wavelengths, as shown in Figure 2-11. One can determine from such a graph that about 9

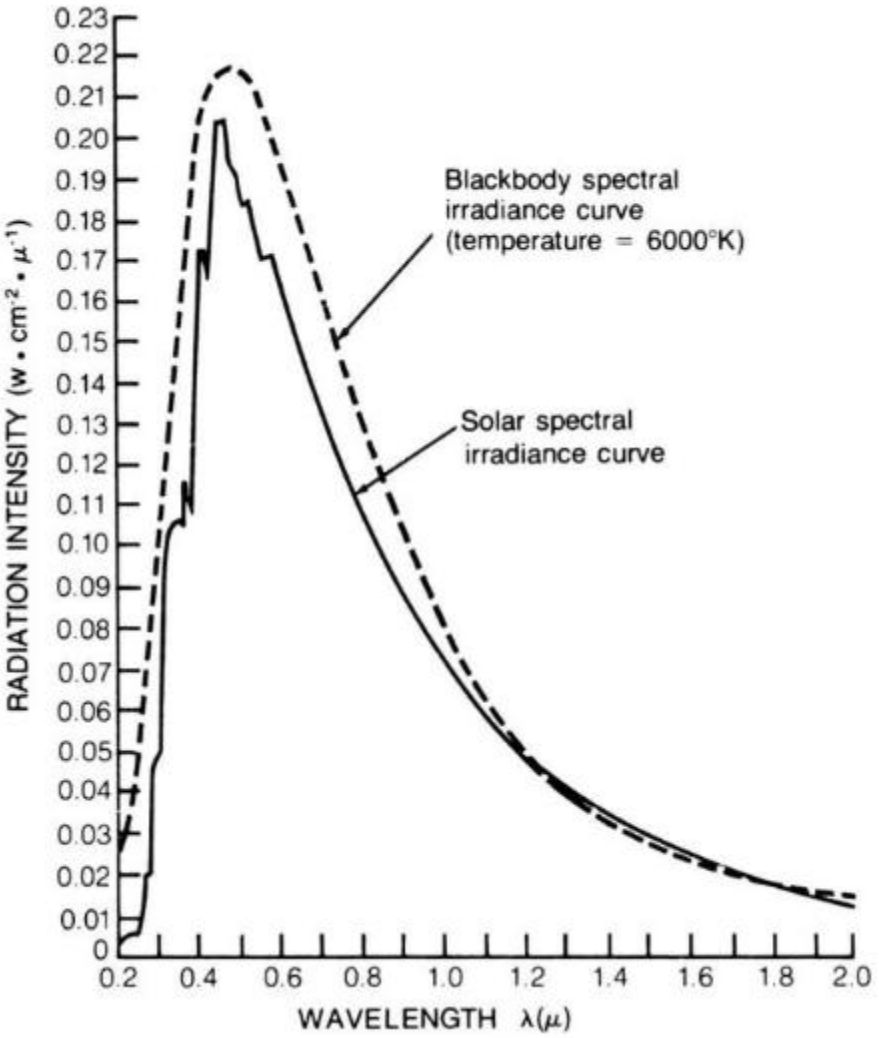

FIGURE 2-11 Solar irradiance spectrum and 6000°K blackbody radiation reduced to mean solar distance. (From Neiburger, Edinger, and Bonner, 1973.)

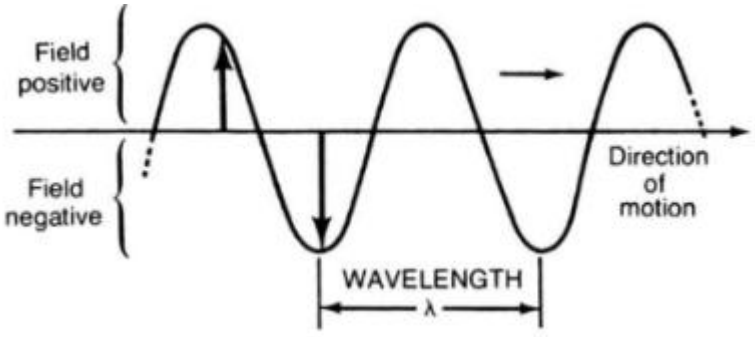
percent of the total incoming energy is in the ultraviolet part of the electromagnetic spectrum, 41 percent is in the visible part of the spectrum, and 50 percent is in the infrared part. A significant part of this energy is prevented from reaching Earth's surface by gaseous constituents of the atmosphere that are opaque to certain wavelengths. This opacity is due not to reflection but to absorption (the energy in the radiation is absorbed by the gas molecules, warming the atmospheric layers where these processes take place).

The depletion of incoming radiation by absorption in atmospheric gases is summarized in Table 2-12. The main results are that ultraviolet solar radiation with wavelengths less than 0.3 microns (μ) is almost completely absorbed high in the atmosphere, and infrared solar radiation is substantially depleted through absorp-



[25]Study of Critical Environmental Problems (SCEP), *Man's impact on the global environment*, p. 41.

Box 2-4 Electromagnetic Radiation

Light, X-rays, radio waves, infrared radiation, and radar waves are all variations of the same thing -- phenomena with the interchangeable names *electromagnetic radiation, electromagnetic waves*, and *radiant energy*.

Energy in this form travels at the speed of light (*c*, or 299,792 km/sec in vacuum), and -- as the words *in vacuum* imply -- requires no material medium to support the energy flow. This property contrasts with the other, much slower forms of energy transport (conduction and convection) which do require a medium. Convection involves the bulk motion of matter; conduction involves molecular motion. What moves in the case of electromagnetic radiation is a combination of electric and magnetic fields of force.

For many purposes, it is useful to visualize this pattern as a traveling wave, as shown in the diagram here. There the curve denotes the spatial pattern of the strength of the electric or magnetic field, and the pattern is moving to the right with speed *c*. (Actually, there should be separate curves for the electric and magnetic fields, but this detail need not trouble us here.) The *wavelength (λ)* is the distance between successive crests or troughs. * At any fixed point along the path of the wave, the field is seen to oscillate with *frequency (υ)* related to wavelength and the speed of light by the relation $\upsilon = c/\lambda$.

The different forms of electromagnetic energy are distinguished by their different wavelengths (or, equivalently, their frequencies, since one can be computed from the other using the relation $\lambda\upsilon 8, = c$). Visible electromagnetic radiation has wavelengths between 0.40 microns (violet light) and 0.71 microns (red light). A micron (μ) is one-millionth of a meter. The entire range of wavelengths that have been observed, from tiny fractions of a micron to tens of kilometers, is called the *electromagnetic spectrum*. Some types of electromagnetic radiation occupying different parts of the spectrum are indicated in the table below.

Type of radiation	Wavelength range
radio	1-10 m
radar (microwaves)	1-30 cm
infrared	0.71-100 μ

Type of radiation	Wavelength range
visible	0.40-0.71 μ
ultraviolet	0.10-0.40 μ
X-rays	10^{-5}-10^{-2} μ

The way electromagnetic radiation interacts with matter depends in a complicated manner on

---

*Unfortunately, there are more concepts in science than there are Greek letters. Thus, for example, lambda (λ) represents wavelength in physics and finite rate of increase in population biology (Chapter 4).

the wavelength of the radiation, on its intensity (energy flow per unit of area, measured -- say -- in watts per square meter and on the properties of the matter. Radiant energy that encounters matter may be transmitted, reflected, or absorbed. To the extent that radiation of a given wavelength is transmitted, the material is said to be transparent to that wavelength; to the extent that the radiation is reflected or absorbed, the material is said to be opaque to that wavelength. Most materials are transparent to some wavelengths and opaque to others. Many gases, for example, are rather opaque to most ultraviolet wavelengths but transparent to radio waves, visible light, and X-rays. Human flesh is opaque to visible light but transparent to X-rays.

Often, transmission, reflection, and absorption all take place at once. Consider a glass window in the morning sunlight: the glint off the window indicates that reflection is taking place; the room behind the window is illuminated and warmed, so there is certainly transmission; and the window itself gets warm, so absorption is happening, too.

Both transmission and reflection can be *direct* or *diffuse*. Direct means that a beam of electromagnetic radiation arriving from a single specific direction is sent on or sent back in a single specific direction. Diffuse means that the incoming beam is split up and sent on or sent back in many different directions. The phenomenon that produces diffuse transmission and reflection is called *scattering*. All light reaching the ground on a completely overcast day is diffuse light that has been scattered by the water droplets in the cloud layer.

All matter that is warmer than absolute zero can *emit* radiation. (The "machinery" by which emission occurs has to do with the behavior of the electrons in matter. We will not dwell on this machinery here, summarizing instead only the main results of its operation.) Some substances emit only radiation of certain wavelengths, and all substances can absorb only the wavelengths they can emit. A body that absorbs all the radiation that hits it in all wavelengths is called a *blackbody*, a useful idealization that is approached in the real world but never quite reached. A blackbody is not only a perfect absorber, but also a perfect emitter; the amount of electromagnetic energy emitted at any given wavelength by a blackbody of a specified temperature is the theoretical maximum that any real body of that temperature can emit at that wavelength. The total amount of radiation emitted by a blackbody is proportional to the fourth power of the body's absolute temperature. The wavelength at which a blackbody emits most

intensely decreases in inverse proportion to the absolute temperature -- that is, the higher the temperature, the shorter the wavelength.

The characteristics of the sun as a source of electromagnetic radiation are very closely approximated by those of a blackbody with a temperature of 5800° K. The wavelength at which its emission is most intense is 0.5 microns, corresponding to blue-green light (see Figure 2-11).

TABLE 2-12
Absorption of Solar Radiation by Atmospheric Gases

Wavelength range (μ)	*Fate of radiation*
UNTRAVIOLET	
Less than 0.12	All absorbed by O_2 and N_2 above 100 km
0.12-0.18	All absorbed by O_2 above 50 km
0.18-0.30	All absorbed by O_3 between 25 and 50 km
0.30-0.34	Part absorbed by O_3
0.34-0.40	Transmitted to Earth almost undiminished
VISIBLE	
0.40-0.71	Transmitted to Earth almost undiminished
INFRARED	
0.71-3	Absorbed by CO_2 and H_2O, mostly below 10 km

tion by carbon dioxide and (especially) by water vapor at lower altitudes. The atmosphere's gases are almost completely transparent to the visible wavelengths, where the intensity of solar radiation reaches its peak (Figure 2-11), and to the "near-ultraviolet" radiation, with wavelengths just shorter than the visible. (This nearultraviolet radiation is an important contributor to sunburn.) Significantly, the only atmospheric gas that is opaque to ultraviolet radiation between 0.18 and 0.30 microns in wavelength is ozone. Without the trace of ozone that exists in the stratosphere, this radiation would reach Earth's surface -- where it could be extremely disruptive to the life forms that evolved in the absence of these wavelengths (Chapter 11). The absorption of ultraviolet radiation by ozone in the stratosphere has a second important effect -- it produces the stratospheric heating that causes temperature to increase with altitude in this layer of the atmosphere, with consequences discussed in the next section.

Some of the incoming radiation that is not absorbed by atmospheric gases is scattered by them (Box 2-4). Some of the scattered radiation returns to space (diffuse reflection), and some reaches the ground as diffuse solar radiation. The physics of scattering by the molecules in air is such that blue light is scattered much more than is red light. The sky appears blue because what reaches the eye is mostly scattered light and hence -- owing to the preferential scattering of blue wavelengths by air molecules -- mostly blue. That the sun appears red at sunset is precisely the

same phenomenon at work; then one is looking at direct-beam radiation -- the unscattered part - from which the blue has been removed (by scattering) and in which mainly the red remains.

Absorption and scattering of solar radiation are done by *aerosols* as well as by gases. An aerosol is a suspension of solid or liquid particles in a gas. Fog, clouds, smoke, dust, volcanic ash, and suspended sea salts are all aerosols. Whether a given aerosol acts mainly as an absorber or mainly as a scatterer depends on the size and composition of the particles, on their altitude, and on the relative humidity of the air they are in. Certainly, the aerosols that interact most strongly with solar radiation are clouds, which at any given time cover about half Earth's surface with a highly reflective layer.

The reflectivity of a surface or a substance is called its *albedo* (formally, albedo equals reflected energy divided by incoming energy). This property depends not only on the characteristics of the surface, but also on the angle at which the incoming radiation strikes the surface (the angle of incidence). The albedo is much higher at shallow angles of incidence than at steep (nearly perpendicular) angles. The albedo of clouds ranges from 0.25 (thin clouds, perpendicular incidence) to more than 0.90.

Averaged around the year and around the globe, the amount of energy that penetrates to Earth's surface is about half of what strikes the top of the atmosphere. Of that which penetrates, somewhat more than half is diffuse and somewhat less than half is direct. Upon

TABLE 2-13 Albedo of Various Surfaces

Surface	Albedo
Snow	0.50-0.90
Water	0.03-0.80
Sand	0.20-0.30
Grass	0.20-0.25
Soil	0.15-0.25
Forest	0.05-0.25

reaching the surface, this energy meets several fates. Some is reflected, with the albedo varying from land to water and from one type of vegetation to another -- and, of course, depending on the angle of incidence (Table 2-13). Some is absorbed by the melting or sublimation of ice or snow, or the vaporization of water. Some is absorbed to warm the surface and objects on or under it. And a tiny fraction is captured and transformed into chemical energy by the process of photosynthesis in plants.

The fate of solar energy striking the top of Earth's atmosphere is summarized in Figure 2-12. Note that the average albedo of the Earth-atmosphere system is about 0.28, of which two-thirds is accounted for by clouds.

Now from the first law of thermodynamics (Box 2-3), which says energy can neither be created nor destroyed, and from elementary considerations of stocks and flows (Box 2-2), one can draw some important conclusions about energy flow in the Earth-atmosphere system. First, the rate at which Earth's atmosphere and surface are absorbing solar energy must be matched by the rate at which the system loses energy, or else the amount of energy stored on the surface and in the atmosphere would be steadily changing. In other words, if the system is to be in equilibrium, outflow must equal inflow. Lack of equilibrium, if it occurred, would mean a changing stock of energy in the Earth-atmosphere system. This could manifest itself as an upward or downward trend in mean temperature (a changing stock of thermal energy), or in mean absolute humidity or mean volume of ice and snow

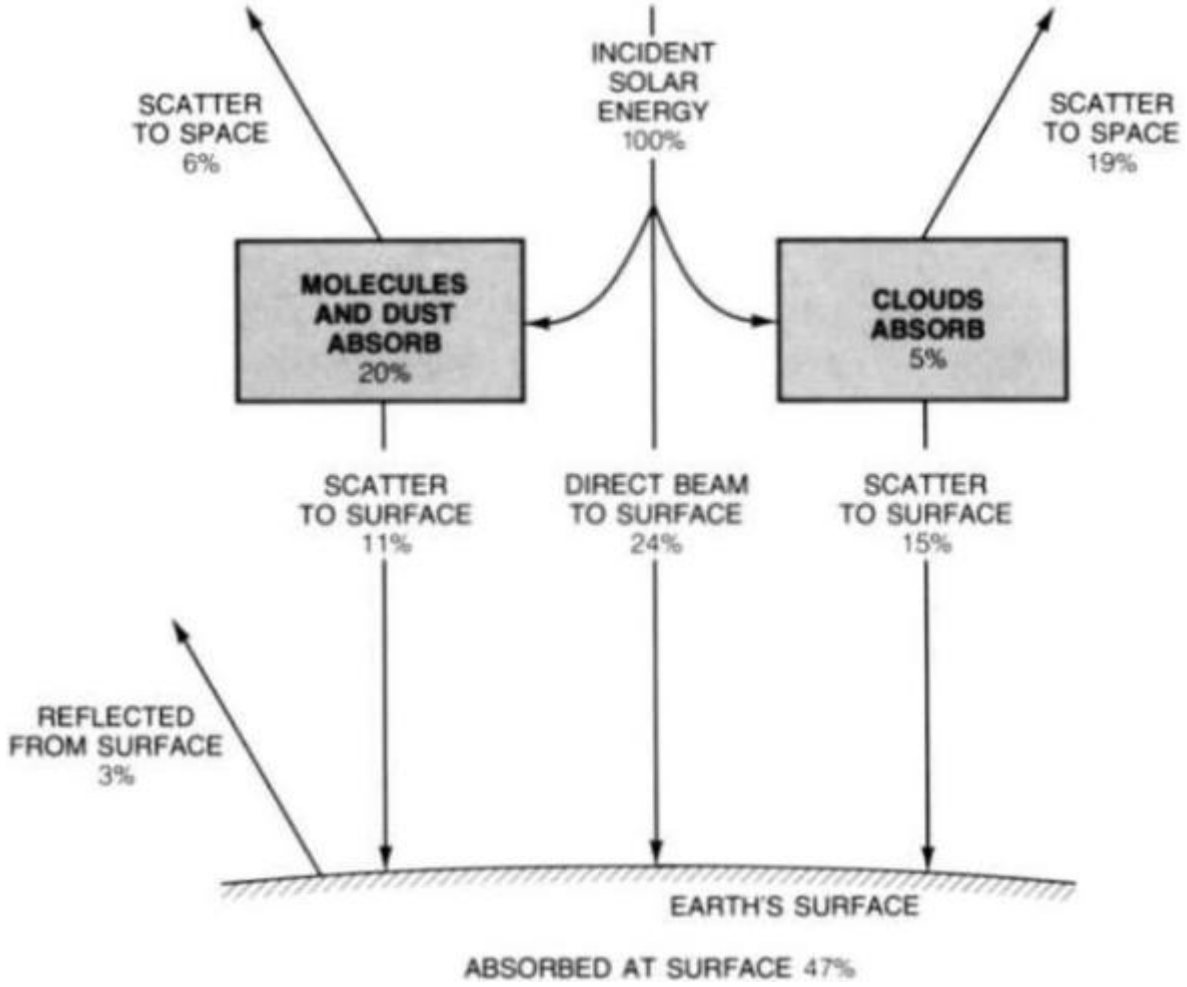

FIGURE 2-12 The fate of incoming solar radiation. Figures represent global annual averages.

(a changing stock of latent energy of vaporization and fusion), or in mean quantity of organic matter (a changing stock of chemical energy). Of course, different parts of Earth's surface and atmosphere at different times of year are out of equilibrium -- temperature, humidity, snow cover, and quantity of vegetation generally change dramatically with seasons. Inflow and outflow of energy at a given time and place in general do not balance. But they *must* balance on a year-round average for the whole globe or else there will be year-to-year changes in the *mean* values of these indices of stored energy. Such changes have occurred in the past as cooling periods leading into ice ages and warming periods leading out of them. These changes and the potential for further ones, with or without human influence, are discussed below. As a first approximation, however, it is reasonable to assume that inflows and outflows of energy are in balance on the global, annual average.

The second conclusion is that the same considerations of inflow, outflow, and equilibrium that apply to the Earth-atmosphere system as a whole must apply separately to its components. If the atmosphere is to be in equilibrium in a global, time-averaged sense, it must be losing energy at the same rate it is receiving it. The same must hold for Earth's surface.

Clearly, then, the energy flow shown in Figure 2-12 is not the complete picture. The figure shows a net accumulation of energy in the atmosphere (gas molecules, clouds, dust) equal to 22 percent of the solar energy that strikes the top of the atmosphere and a net accumulation of energy at the surface equal to 47 percent of total incoming solar energy.

What is the fate of this absorbed energy, amounting in all to 69 percent of the solar input? The answer is this: after running the machinery of winds, waves, ocean currents, the hydrologic cycle, and photosynthesis, the energy is sent back to space as *terrestrial radiation*.

Terrestrial radiation refers to the electromagnetic radiation emitted by Earth's surface and atmosphere in accordance with the principles summarized in Box 2-4: the amount of energy radiated per unit of area is proportional to the fourth power of the absolute temperature of the radiating substance, and the wavelength of most intense radiation is inversely proportional to the absolute temperature. If the Earth-atmosphere system were a blackbody at temperature, T, the exact relation for the rate of emission of radiation, S, would be:
$S = \sigma T^4$.

If S is measured in watts per square meter and T is measured in degrees kelvin, then the proportionality constant a (the Stefan-Boltzmann constant) has the numerical value 5.67 X 10-^{8}. On the assumption that the energy returned to space as terrestrial radiation should exactly balance the 69 percent of incoming solar energy that is absorbed, one can compute the effective blackbody temperature of the Earth-atmosphere system to be about 255° K (- 18° C or about 0° F). This is the temperature a perfect radiator would have to have in order to radiate away into space the same amount of energy per unit of area as the Earth-atmosphere system actually does radiate away, on the average.

Actually, the Earth-atmosphere system closely resembles a blackbody radiator, so the above temperature is not unrealistic. Why, then, is that temperature so much lower than the observed mean surface temperature of 288° K (15° C, or 59° F)? The reason is that most of the terrestrial

radiation actually escaping from the Earthatmosphere system is emitted by the atmosphere, not the surface. (You can see from Figure 2-10 that the temperature 255° K corresponds to an altitude of about 5 kilometers, or halfway between sea level and the tropopause.) Most of the terrestrial radiation emitted by the warmer surface does not escape directly to space because the atmosphere is largely opaque to radiation of these wavelengths. The wavelength of radiated energy, you should recall, increases as the temperature of the radiator decreases: Earth, being much cooler than the sun, emits its radiation at longer wavelengths. The peak intensity of terrestrial radiation occurs at a wavelength of around 10 microns, which is in the infrared part of the spectrum, in contrast to solar radiation's peak intensity at a wavelength of about 0.5 microns in the visible part of the spectrum. [26]

[26] There is almost no overlap in the wavelength ranges of solar and terrestrial radiation; at 3 microns, the intensity of solar radiation has fallen to 5 percent of its value at the 0.5-micron peak, while that of terrestrial radiation has only attained about 10 percent of its value at the 10-micron peak. Meteorologists often refer to solar radiation as short-wave radiation and terrestrial radiation as long-wave radiation.

The opaqueness of the atmosphere to outgoing infrared radiation from the surface is due mainly to three atmospheric constituents: carbon dioxide, water vapor, and clouds. (A more modest contribution is made by ozone.) Carbon dioxide absorbs infrared radiation in a narrow band of wavelengths around 3 microns, in another narrow band near 4 microns, and in the wavelengths between 12 and 18 microns. Water vapor absorbs infrared radiation in narrow bands around 1, 1.5, and 2 microns, and in broader ones from 2.5 to 3.5 microns, from 5 to 8 microns, and from 15 microns through the remainder of the infrared. Clouds are very much like blackbodies in the entire infrared part of the electromagnetic spectrum -- they absorb most of the infrared radiation that reaches them. The infrared radiation absorbed by carbon dioxide, water vapor, and clouds is subsequently *reradiated* by these substances -- much of it being sent back in the direction of Earth's surface and some escaping into space. The atmosphere, therefore, through the properties of clouds, water vapor, and carbon dioxide, acts as a thermal blanket that keeps Earth's surface about 33° C warmer than it would be without these constituents.

Because of this effect of clouds, all else being equal, clear nights are colder than cloudy nights; in the absence of clouds, more infrared radiation leaving the surface escapes directly to space without being intercepted. The additional thermal-blanket effect of water vapor and carbon dioxide is sometimes called the *greenhouse effect*. This is because glass, like carbon dioxide and water vapor, is relatively transparent to visible radiation but more opaque to infrared radiation. Light enters a greenhouse more readily than heat can escape, a situation resembling that in the atmosphere. The *main* reason a greenhouse is warmer inside than outside, however, is that the glass prevents convection from carrying away sensible heat and latent heat of vaporization. [27] Thus, the term *greenhouse effect* is not entirely appropriate for the role of carbon dioxide and water vapor in the atmosphere.

The flows of terrestrial radiation are summarized in Figure 2-13, expressed as a percentage of solar energy striking the top of the atmosphere and computed as a global annual average. Note

that the rate at which infrared radiation is emitted from Earth's surface actually exceeds the rate of solar input at the top of the atmosphere and is far larger than the rate at which solar energy is directly received at the surface. This large radiation output and the high temperature responsible

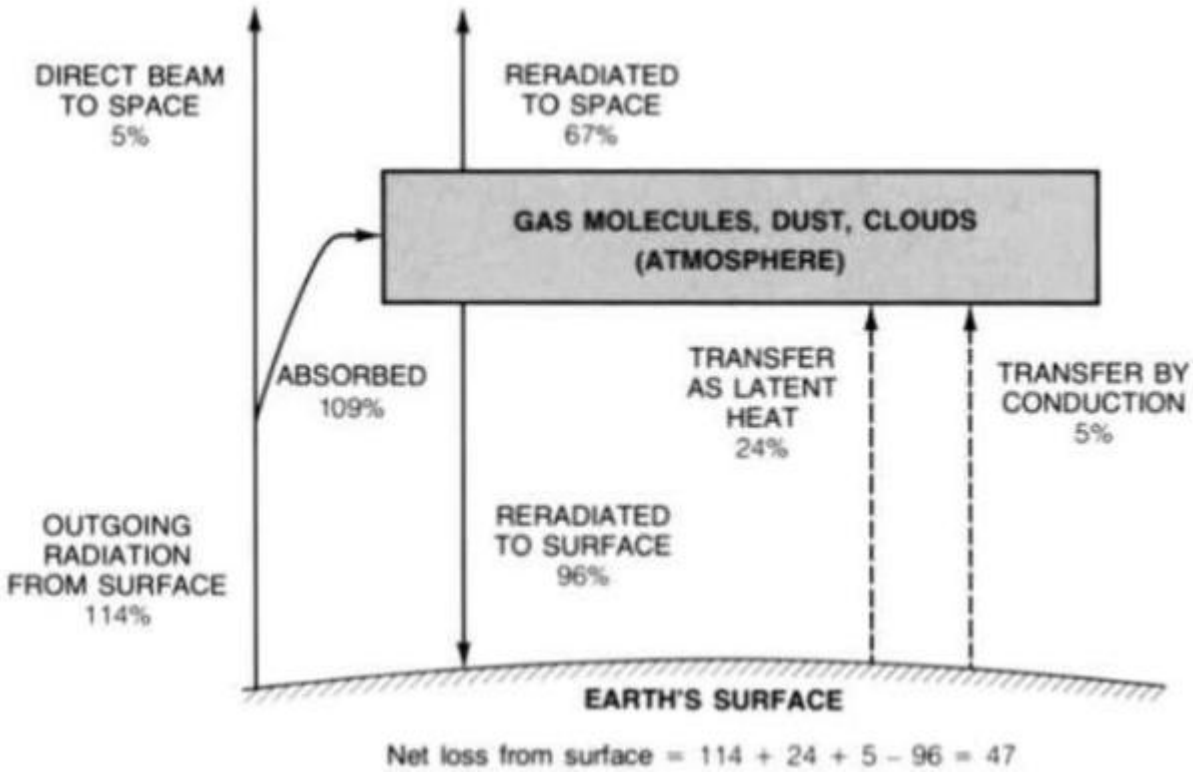

FIGURE 2-13 Flows of terrestrial radiation. Percentage of solar energy incident at the top of the atmosphere (global annual averages).

[27]This fact has been demonstrated by building a greenhouse of rock salt (which is as transparent to infrared radiation as to visible radiation) next to a greenhouse of glass. The rock-salt greenhouse, simply by preventing convection, stayed almost as warm inside. (See, for example, Neiburger et al., *Understanding*.)

for it are made possible by the large flow of infrared radiation reradiated to the surface by the atmosphere, as discussed earlier. Any alteration of the composition of the atmosphere by pollution can have an important influence on this downward reradiated energy flow (see Chapter 11).

Two important energy flows other than radiation are represented in Figure 2-13 by broken lines. The larger of these flows is the transfer of energy from the surface to the atmosphere as latent heat of vaporization. That is, energy that has been used to evaporate water at the surface moves into the atmosphere in the form of the latent heat of vaporization that is associated with the water vapor (see Box 2-1). This energy is eventually surrendered to the atmosphere as sensible heat when the water vapor condenses. The magnitude of this surfaceto-atmosphere energy flow is equal to almost a quarter of the solar energy flow reaching the top of the atmosphere. The second

major nonradiative flow (perhaps a fifth as large as that of latent heat) is the transfer of sensible heat from the surface to the atmosphere by conduction -- that is, the warming of the air by contact with the surface. Sensible heat transported across the interface of surface and air in this way then moves upward in the atmosphere by convection. (Of course, in some places and at some times the atmosphere is warmer than the surface, with the result that sensible heat flows from the atmosphere to the surface rather than the reverse. Remember, we have been discussing the global, annual-average situation here.)

Atmospheric Energy Balance and Vertical Motions

With the information in the preceding section, one can construct average energy balances for Earth's surface, for the atmosphere, and for the Earth-atmosphere system as a whole. Such a set of balances is given in Table 2-14, both in terms of the percentage of solar energy flow at the top of the atmosphere and in watts per square meter of Earth's surface area. Energy flow per unit of area is called flux. The solar flux through a surface perpendicular to the sun's rays at the top of the atmosphere is called the solar constant and is equal to about 1360 watts per square meter [1.95 calories (cal)/cm^2/minute (min), or 1.95 langleys/min, in units often used by meteorologists]. [28] As a sphere (to a very good approximation), Earth's total surface area is 4 times the area of the cross section it presents to the sun's rays. Hence, the average amount of solar energy reaching the top of the atmosphere per square meter of Earth's surface is just one-fourth of the solar constant, or 340 watts per square meter, as indicated in Table 2-14. The average solar flux reaching Earth's surface is 173 watts per square meter of horizontal surface. Solar flux measured this way at the surface is often termed *insolation*.

The difference between the amount of energy incident on Earth's surface as radiation (solar and terrestrial) and the amount leaving as radiation is called by meteorologists the *net radiation balance*, or sometimes just net radiation. This amount of energy flow, which as shown in Table 2-14 averages 105 watts per square meter flowing into the surface for the whole globe, is of special meteorological significance because it is the amount of energy available for the climatically crucial processes of evaporation of water and surface-to-air transfer of sensible heat. Many discussions of human impact on climate use the net radiation balance, rather than the incident solar energy, as the yardstick against which civilization's disturbances are measured (Chapter 11).

The pattern of Earth-atmosphere energy flows that has been described here provides the explanation for the observed temperature distribution in the lower atmosphere. Basically, the atmosphere is heated from the bottom -- by direct contact with warm land or water surfaces, by the release of latent heat of vaporization when water vapor condenses (virtually entirely in the troposphere and mostly in its lowest third), and by the absorption of terrestrial infrared radiation in water vapor, clouds, and carbon dioxide. Water vapor and clouds are most abundant in the lower troposphere, so that is where a large part of the absorption takes place. These effects, differentially heating the atmosphere near the bottom, produce the general trend of decreasing temperature with altitude in the troposphere. Only above

[28] It is actually not known exactly how constant the solar constant really is (see, for example, S.

Schneider and C. Mass, *Volcanic dust, sunspots, and temperature trends*).

TABLE 2-14 Energy Balances for Earth's Surface, Atmosphere, and Surface-Atmosphere System (global annual averages, accurate to perhaps ± 10%)

	Percentage of solar energy flow at top of atmosphere	***Average energy flow (w/m^2)***
SURFACE-ATMOSPHERE SYSTEM		
Solar radiation reaching top of atmosphere	100	340
Total inflow	100	340
Solar radiation scattered from atmosphere	25	85
Solar radiation scattered from surface	3	10
Terrestrial direct radiation, surface to space	5	17
Terrestrial radiation, atmosphere to space	67	228
Total outflow	100	340
SURFACE		
Solar direct radiation	24	82
Solar diffuse radiation, via clouds	15	51
Solar diffuse radiation, via air, dust	11	37
Terrestrial reradiation from clouds, vapor, CO_2	96	326
Total inflow	146*	496
Reflected solar radiation	3	10
Outgoing terrestrial radiation	114	387
Latent heat to atmosphere	24	82
Sensible heat to atmosphere	5	17
Total outflow	146*	496
ATMOSPHERE		
Solar radiation interacting with clouds, air, dust	76	258
Terrestrial radiation from surface, absorbed	109	371
Latent heat from surface	24	82
Sensible heat from surface	5	17
Total inflow	214*	728
Solar radiation scattered to space	25	85

	Percentage of solar energy flow at top of atmosphere	*Average energy flow (w/m^2)*
Solar radiation scattered to surface	26	88
Absorbed radiation reradiated to space	67	228
Absorbed radiation reradiated to surface	96	327
	---	---
Total outflow	214*	728

*These flows exceed 100 percent of incoming solar radiation because, in addition to the solar throughput, an internal stock
of energy is being shifted back and forth between surface and atmosphere.

the tropopause does atmospheric heating by absorption of ultraviolet solar radiation (particularly by ozone) reverse the trend and produce temperatures that increase with altitude (refer to Figure 2-10). Ozone also absorbs outgoing terrestrial infrared radiation in a narrow wavelength band at 9.6 microns, to which other atmospheric gases are largely transparent.

The structure of the troposphere, with the warmest air n the bottom, promotes vertical instability (hot air rises, and cold air sinks). Sensible heat and latent heat of vaporization are thus transported upward by convection, and the troposphere tends to be vertically well mixed. The mixing time in the lower half of the troposphere -that is, the time it takes for a molecule at 5 kilometers

NO INVERSION, WELL-MIXED

INVERSION LAYER (0.5 1.5 km), WELL-MIXED ABOVE AND BELOW FIGURE 2-14

Inversions in the troposphere. Temperature versus altitude in different circumstances.

altitude to change places with one at the surface -- is usually on the order of a few days. (In convective storms it can be hours.) The stratosphere, by contrast, is vertically stratified; like the ocean, its warmest layer is on top, with progressively colder layers below, which tends to suppress vertical motion. The vertical mixing time in the stratosphere is on the order of a year or two.Under some circumstances, the usual temperature profile of the troposphere near the ground is altered so that temperature increases with altitude. In this situation (called an *inversion*), vertical mixing is suppressed over the altitude range where the temperature is increasing. (Vertical mixing is also suppressed in circumstances where temperature decreases with altitude but not rapidly enough to overcome the stratifying effect of the density variation.) Some of the main possibilities are indicated in Figure 2-14. Inversions are of special importance in environmental science because they inhibit the dilution of pollutants, as is discussed further in Chapter 10.

Variation of Incoming Solar Flux with Place and Season

If the vertical energy flows discussed in the preceding sections were all there were to climate, it would not be so difficult to analyze. So far, however, we have only been working with energy flows averaged over the whole globe and the whole year; the real complexity lies in the tangled patterns of energy flow that arise from differences between day and night, summer and winter, land surfaces and water surfaces, and so on.Let us first consider the geometrical factors that produce variations from season to season and from latitude to latitude in the amount of solar radiation that strikes the top of the atmosphere. They are:

Earth is essentially spherical.

Earth travels around the sun in an orbit that is not quite circular.

Earth spins on an axis that is tilted 23.5' from perpendicular to the plane of its orbit.

Because Earth is a sphere, the maximum solar flux at any moment is received at the subsolar point (that is, the point that is directly "under" the sun, or equivalently, the point at which the sun appears to be directly overhead) and declining values of flux are received as one moves away from this point on the surface of the sphere. This is so because a flat surface of given area intercepts a maximum of the solar beam when the surface is perpendicular to the beam, and progressively less at angles away from the perpendicular. This situation is illustrated in Figure 2-15.

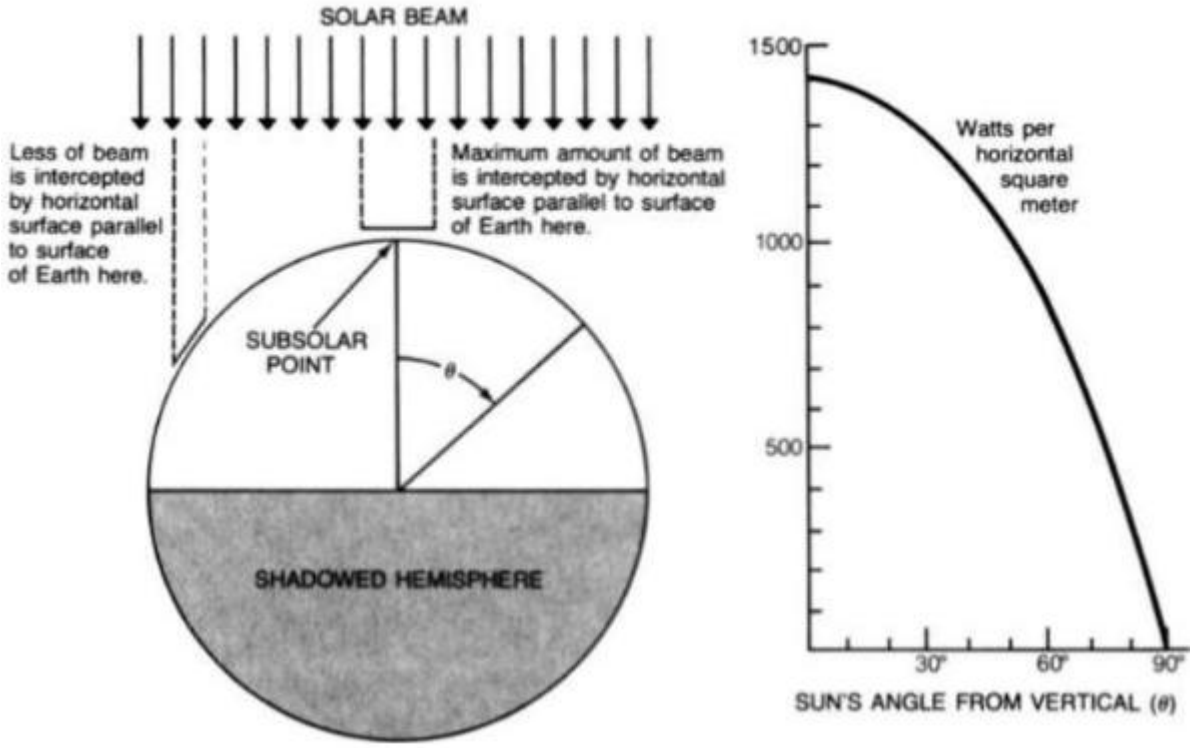

FIGURE 2-15 Insolation at the top of the atmosphere.

Earth's elliptical orbit around the sun deviates from a circle just enough to make the distance between Earth and sun vary by ± 1.7 percent from the mean value of 149.6 million kilometers. This variation in distance produces a difference of ± 3.4 percent in solar flux (that is, the solar energy flow incident on a surface perpendicular to the sun's rays above the atmosphere varies from a maximum of 1406 w/m^2 to a minimum of 1314 w/m^2, the average of 1360 w/m^2 being the "solar constant" given earlier). The minimum distance occurs in the first few days of January, when the Northern Hemisphere is having its winter and the Southern Hemisphere its summer, and the maximum occurs in the first few days of July.

Clearly, the seasons are not produced by the slight ellipticity in Earth's orbit, but rather by the tilt of Earth's axis of rotation. The orientation of this tilt remains fixed as Earth circles the sun, as shown schematically in Figure 2-16. This means that the Northern Hemisphere is tilted directly

toward the sun at the June 21 solstice, corresponding to the first day of summer in the Northern Hemisphere and the first day of winter in the Southern Hemisphere, and the Southern Hemisphere is tilted directly toward the sun at the December 21 solstice. On June 21 the subsolar point is on the Tropic of Cancer (23.5° north latitude) [29] and the entire area north of the Arctic Circle (66.5° north latitude) is illuminated by the sun during all twenty-four hours of the day. On December 21 the subsolar point is on the Tropic of Capricorn (23.5° south latitude), and the entire area within the Antarctic Circle is illuminated for all twenty-four hours of the day. At the equinoxes (March 21 and September 23) the subsolar point is on the equator, and day and night are each twelve hours long everywhere on Earth (except in the vicinity of the poles, which experience continuous twilight).

The net effect of these geometrical aspects of the Earth-sun relationship is to produce strong north-south differences, or *gradients*, in the incoming solar flux perpendicular to Earth's surface at the top of the atmosphere. The size and shape of the gradients vary

[29]The subsolar point becomes a subsolar line as Earth performs its twenty-four hour rotation.

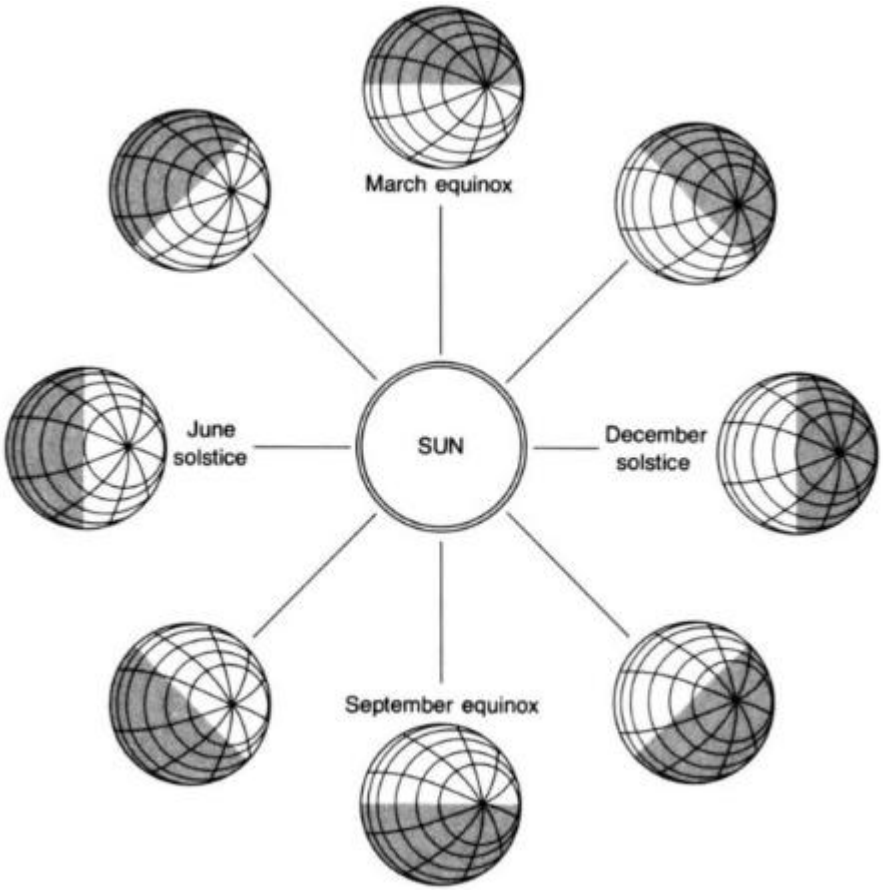

FIGURE 2-16 Earth's orbit around the sun.

with the seasons. Figure 2-17 shows the solar flux at the top of the atmosphere, in calories per square centimeter per day, as it varies throughout the year at three different latitudes in the Northern Hemisphere. Note the strong equator-to-pole contrast in the winter, which is reduced as summer approaches and actually reverses in midsummer. (The summer pole receives more energy per unit of surface area in midsummer than does the equator, because the sun is shining twenty-four hours a day at the summer pole.)

The amount of solar radiation reflected back into space also varies with latitude (more is reflected at the extreme northerly and southerly latitudes, where the radiation strikes the surface at angles far from perpendicular) and with season (ice and snow reflect more than do vegetation and water). Finally, the amount of terrestrial radiation leaving the top of the atmosphere varies with latitude and season, because the emission of such radiation depends on temperature and other characteristics of the atmosphere and the surface below. An accounting of the

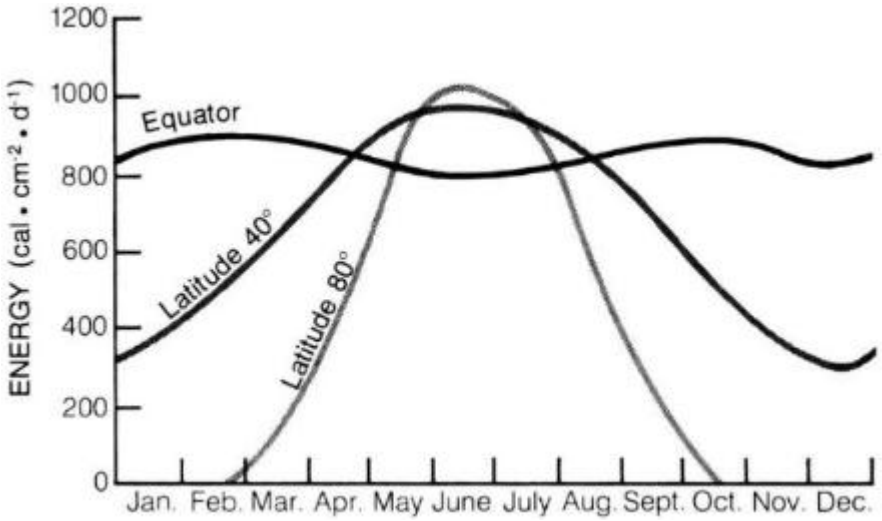

FIGURE 2-17 Seasonal variation of solar flux on a horizontal surface outside the atmosphere. (From Gates, 1971.)

radiation flows across an imaginary surface at the top of the atmosphere, then, must include incoming sunlight, outgoing reflected sunlight, and outgoing terrestrial radiation. Where the inflow exceeds the outflows across such a surface, it is said that the underlying column of atmosphere has a *heating excess*. Where the outflows exceed the inflow, there is said to be a *heating deficit*.

The Machinery of Horizontal Energy Flows

If there were no mechanisms to transfer energy horizontally over Earth's surface from regions of heating excess to regions of heating deficit, the result would be much greater extremes in conditions than actually exist. Energy would accumulate in the areas of heating excess until the additional outgoing infrared radiation produced by higher temperatures restored a balance; similarly, energy would be lost to space from areas of heating deficit until the drop in outgoing radiation associated with lower temperatures restored the incoming-outgoing balance in those

areas. To say that the extremes of temperature on Earth's surface would be greater under these circumstances is an understatement. It is plain from Figure 2-17, for example, that the region north of 80° north latitude receives no incoming radiation at all from mid-October to late February (although, of course, the emission of outgoing terrestrial radiation continues). In the absence of energy inflows from warmer latitudes, then, the radiative energy loss in winter at the latitudes having darkness twenty-four hours a day would cool the surface rapidly and continuously toward absolute zero.

But there *are* horizontal energy flows -- principally, the transport of sensible heat and latent heat of vaporization by the motions of the atmosphere and the transport of sensible heat by ocean currents. (These *convective* energy transfers are much bigger and faster than conduction. See Box 2-4, to review the difference.) These flows are driven largely by the north-south temperature differences arising from the radiation imbalances just described, and they are largely responsible for the general features of global climate. The overall pattern of the north-south energy flows on an annual average basis is indicated in Table 2-15.

The atmospheric motions that carry energy toward the poles as sensible heat and latent heat must, of course, be balanced by return flows of air toward the equator. Otherwise, air would be piling up at the poles! Two kinds

TABLE 2-15 Average Annual North-South Energy Flows (w/m2)

Latitude zone	Net radiation at top of atmosphere (incoming minus outgoing)	Net latent heat (precipitation minus evaporation)	Net sensible heat transport by atmosphere	Net sensible heat transport by ocean
60-70°N	-65	11	43	11
50-60°N	-40	20	5	15
40-50°N	-16	12	-5	9
30-40°N	5	-17	0	12
20-30°N	19	-41	21	1
10-20°N	31	-15	-3	-13
0-10°N	39	44	-51	-32
0-10°S	41	19	-32	-28

of circulation that move heat poleward but keep the air distributed are particularly important. The first of these is the thermal circulation illustrated in Figure 2-18A ; the poleward flow is high in the troposphere; the equatorward flow, near the surface. The second is the cyclonic circulation shown in Figure 2-18B, which can be thought of as taking place in a horizontal plane. Actually, Earth's major atmospheric circulations are generally combinations of vertical and horizontal components. The term

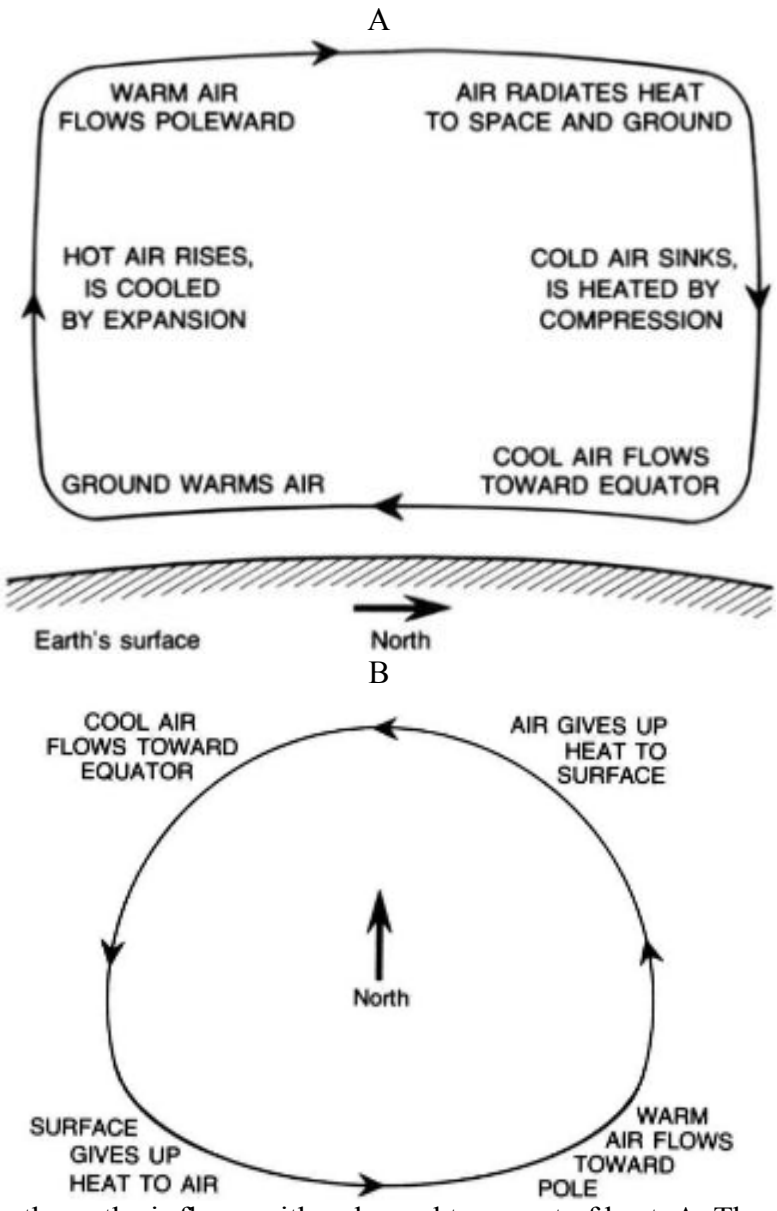

FIGURE 2-18 North-south air flows with poleward transport of heat. A. Thermal circulation, cross-section looking west, parallel to Earth's surface in the Northern Hemisphere. B. Cyclonic circulation, looking down on Earth's surface in the Northern Hemisphere.

wind is usually reserved for the horizontal motion, and the terms *updraft* and *downdraft* describe the vertical. The horizontal motion is almost always much faster than the vertical: typical wind speeds range from 1 to 20 meters per second; typical vertical speeds in large-scale atmospheric

circulations are 100 times less, although local updrafts associated with clouds and mountain ranges may be 10 meters per second or more. Typically, then, a "parcel" of air (an arbitrarily defined collection of molecules whose behavior one chooses to trace) might move 100 kilometers horizontally while rising one kilometer.

Like solids, gases such as air move in response to the forces exerted upon them in ways described by Newton's laws of motion. One important kind of force in the atmosphere is associated with *pressure gradients*. The pressure-gradient force is a push from regions of high pressure, associated with high temperature and/or density, toward regions of low pressure. Another important force in the atmosphere is gravity, which exerts a downward pull on every molecule of air. (Vertical motions in the atmosphere generally are slow because the vertical pressure-gradient force usually balances the force of gravity almost exactly.) The distribution of regions of high pressure and low pressure in the atmosphere is complex, owing not only to the variations in insolation, reflection, and absorption with latitude and altitude, but also to local differences associated with topography and the distribution of vegetation, land, and water. But the atmospheric circulation patterns are not what would be expected from consideration only of the pressure gradients associated with these features, together with the force of gravity, because two other important factors come into play. These are the *Coriolis deflection* (usually inappropriately called the Coriolis force) and *friction*.

The Coriolis deflection is a complication that arises from the rotation of the planet. Specifically, Earth tends to rotate out from under objects that are in motion over its surface (for example, fired artillery shells and moving parcels of atmosphere). That is, such objects do not go quite where they seem to be heading, because the place they were heading is rotating at a different velocity than the point of origin (rotational speed is highest at the equator, where a point must move some 40,000 km/day, and lowest near the poles). Thus, in the Norther

Hemisphere a parcel of air moving north will appear to a terrestrial observer to be deflected to the right (east), the direction of the Earth's rotation, because it will carry the higher velocity of its place of origin. The Coriolis "force" is the *apparent* extra force (besides pressure gradients, gravity, and any other "real" forces that may be acting) needed to explain to an observer on Earth's rotating surface the observed paths of moving objects. We say "apparent" because no work is done to produce the deflection -- it is a function of the position of the observer. A person in space observing the trajectory of an artillery shell relative to the solar system (assume, for example, that the shell were visible but the rest of Earth were invisible) would not see any Coriolis deflection. The magnitude of the Coriolis deflection is greatest at the poles and zero on the equator; the magnitude also varies in direct proportion to the speed of an object -- a stationary object is not subject to Coriolis deflection. [30] The *direction* of the Coriolis deflection is always perpendicular to the direction of an object's motion. It changes the direction of motion but not the speed. Motions in the Northern Hemisphere are deflected to the right; motions in the Southern Hemisphere, to the left.

Consider the effect of the Coriolis deflection in the Northern Hemisphere on the flow of air into a region of low atmospheric pressure from surrounding regions of higher pressure. The pressure-

gradient force tries to drive the flow straight in, but the Coriolis deflection bends it to the right (Figure 2-19). The resulting spiral patterns are actually visible in most satellite photographs of Earth, because the winds carry clouds along with them (Figure 2-20). The spirals associated with low-pressure centers (clockwise in the Southern Hemisphere, counterclockwise in the northern) are called *cyclones*, and the outward spirals associated with high-pressure centers (clockwise in the Northern Hemisphere, counterclockwise in the southern) are called *anticyclones*.

The force of friction adds two features to the wind patterns described thus far. It slows down the wind near Earth's surface -- most dramatically in the first few tens of

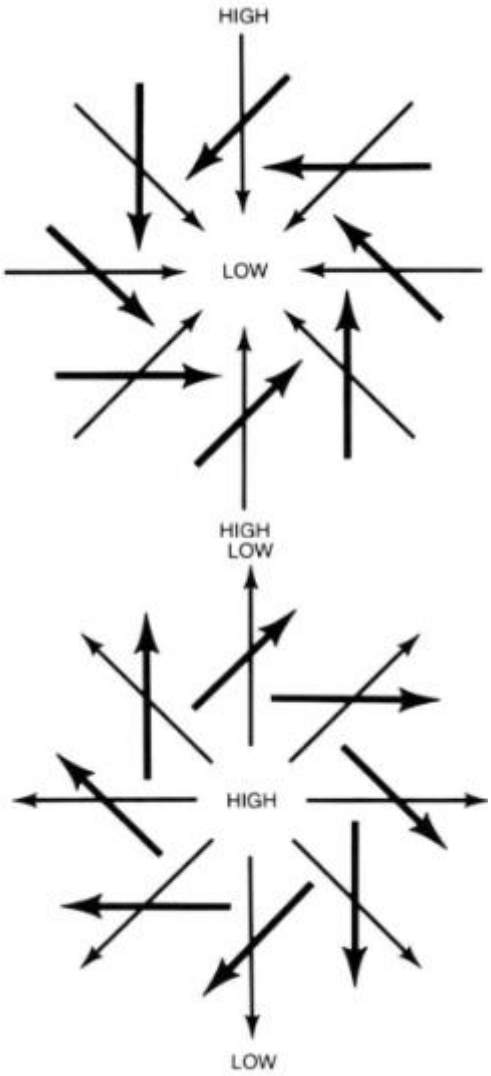

FIGURE 2-19 Coriolis deflection of the wind. Light arrows denote the direction of pressure-gradient force, which would also be wind direction on a nonrotating Earth. Heavy arrows show the Coriolis deflection of the wind directly to the right (Northern Hemisphere).

[30]The magnitude of the Coriolis deflection associated with horizontal motion at velocity *v* m/sec at latitude ϕ is $2\Omega v \sin\phi$/kg mass, where $\Omega = 7.29 \times 10\text{-}5$ radians/sec is the angular velocity of

Earth's rotation. (There are 2π radians, or 360 degrees, in one revolution.) See, for example, Neiburger et al., *Understanding*, pp. 99-104.

FIGURE 2-20 Atmospheric circulation patterns as revealed by cloud distributions. (NASA).

meters, but still significantly at altitudes up to a few hundred meters. And, because of the way the friction force interacts with the pressure-gradient force and the Coriolis deflection, it causes the *direction* of the wind to change with altitude for the first several hundred meters. The horizontal pressure gradients themselves may be quite different at one altitude than at another, which also gives rise to significant changes in the wind patterns as one moves away from Earth's surface. [31]

The General Circulation

The overall pattern of atmospheric motions resulting from the phenomena just described is called the *general circulation*. Its main features are illustrated in Figure 2-21. The associated variation of average sea level pressure is indicated in Figure 2-22.

The surface circulation in the tropical regions north and south of the equator is dominated by the trade winds, blowing, respectively, from the northeast and the southeast. These very steady winds are associated with the pressure drop between the subtropical highs and the

[31] More detailed explanations of the operation of the friction force and the variation of pressure gradients with altitude are given in Neiburger et al., *Understanding*, pp. 109-114.

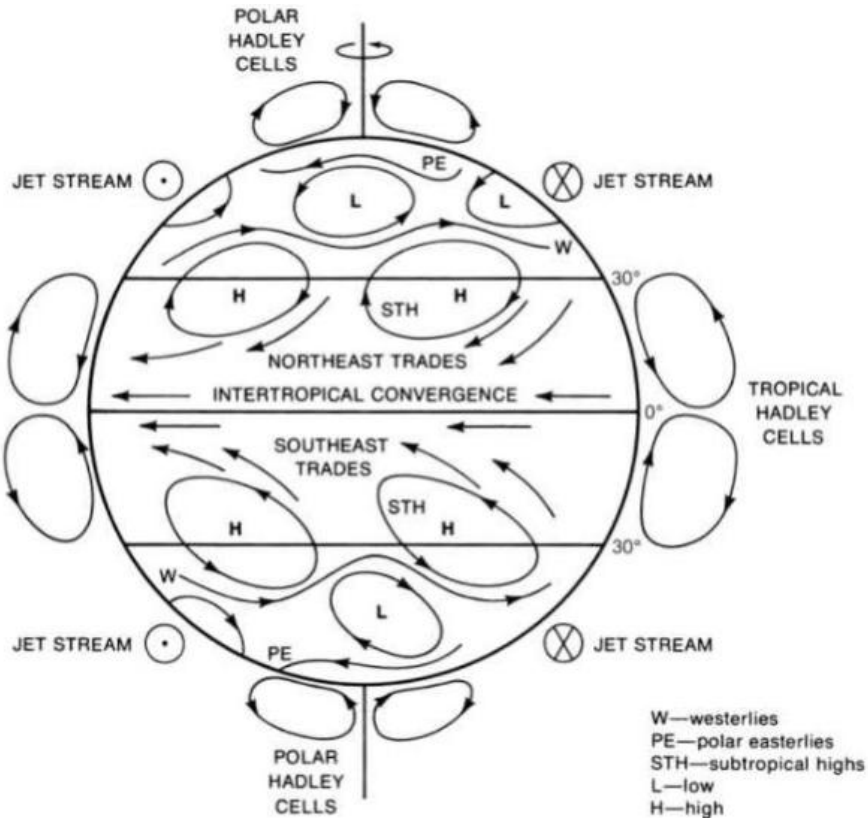

FIGURE 2-21 Main features of the general global circulation. Flows near the surface and cross-sections of the main circulations in the upper troposphere.

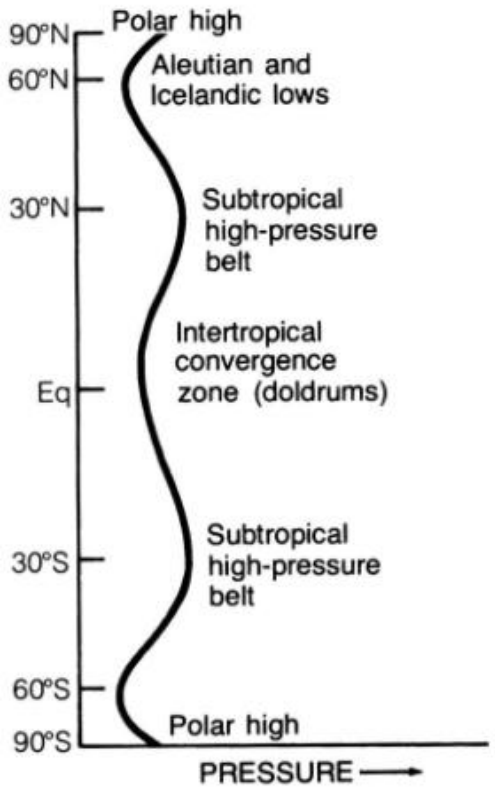

FIGURE 2-22 Variation of average see-level pressure with latitude. (From Neiburger, Edinger, and Bonner, 1973).

low-pressure *doldrums* on the equator. The trade winds are deflected from the direction of the pressure drop by the Coriolis force -- to the right in the Northern Hemisphere, to the left in the southern -- as explained above. The region where the trade winds meet to form a belt of easterly winds encircling the globe near the equator is called the *intertropical convergence zone*.

The vertical part of the circulation in the tropics consists of thermal circulations of the form shown in Figure 2-18A, one immediately north of the equator and one immediately south. These are called *Hadley cells*, after the British meteorologist who first postulated their existence. In the Hadley cells, the air rising over the equator is moist as well as warm. As it rises, the air cools, whereupon some of the contained moisture condenses into droplets and falls as rain. The latent heat of

vaporization released in this process helps drive the air farther upward, producing more condensation, more release of latent heat, and more rain. Thus, the air rising near the equator in the Hadley cells is largely "wrung out," producing in the process the very rainy climates for which the tropics are known. Having lost its moisture and some of its sensible heat in ascending, the air flowing poleward in the upper part of the Hadley cells continues to lose heat by radiating energy to space more rapidly than it absorbs radiant energy from the warmer atmospheric layers and the surface below. At around 30° north and south latitude, the relatively cold, dry air

commences to sink. In sinking into higher pressure it is warmed by compression. This descending flow of warm, dry air in the 30* latitude belts is a major reason these belts are characterized by deserts all around the world. (The Sahara of northern Africa, the Kalahari of southern Africa, the Atacama of Chile, and the Sonoran desert of Mexico and the United States are examples.) Finally, as the dry air moves equatorward on the surface to complete its circuit, it picks up both heat and moisture from the increasingly warm surfaces of the land and water of the tropics.

Thermal circulation patterns similar to the Hadley cells of the tropics are also found in the vicinity of the poles, but they are smaller and weaker than those on either side of the equator. The temperature and pressure differences driving the polar flow are less than those nearer the equator, and the transfers of moisture and latent heat are also much smaller.

Although it was postulated at one time that there must be an indirect cell linking the equatorial and polar cells in each hemisphere -- that is, a cell in which air sinks on the side toward the equator, flows poleward on the surface, and rises on the polar side -- measurements indicate that this pattern is either extremely weak or entirely missing. Rather than being borne by such circulations, the poleward energy flow in the middle latitudes is accomplished instead by the great, swirling, horizontal flows associated with the subtropical highs (see Figure 2-18B, as well as Figure 2-21) and with the wavy boundary between those highs and the subpolar lows. Along that boundary in both hemispheres, the winds are predominantly westerly (that is, flowing from west to east) both at the surface and high in the troposphere.

Embedded in the westerlies at the upper edge of the troposphere and on the boundary between the subpolar lows and the subtropical highs are the *circumpolar jet streams*, encircling the globe in a meandering path covering latitudes from 40° to 60°. The core of a jet stream is typically 100 kilometers wide and 1 kilometer deep, and is characterized by wind speeds of 50 to 80 meters per second [110 to 180 miles per hour (mph)]. These high speeds are the result of a large pressure change over a relatively short horizontal distance on the boundary between low-pressure and high-pressure circulation systems. In addition to the circumpolar jet streams, there are westerly subtropical jet streams at about 30* north and south latitudes, associated with the poleward edges of the Hadley cells, and some seasonal jet streams of lesser importance. [32]

On the boundary between the subpolar lows and the polar highs, there are weak easterly winds at the surface, giving way to westerlies at higher altitudes. The highaltitude flow, then, is entirely westerly. The part of this flow lying poleward of the subtropical highs is cold air -- essentially a great west-to-east spinning cap of it, draped over each pole -- and is called the *circumpolar vortex*. The circumpolar vortex in the winter hemisphere is larger and wavier at the edge than the one in the summer hemisphere, because the equator-to-pole temperature difference that is the basic driving force behind these features is much greater in winter. The waviness at the edge of the circumpolar vortex is caused by cold, low-pressure circulation systems being pushed equatorward into the temperate zones, producing the cold fronts and accompanying storms common in winter.

In the summer hemisphere, the characteristics of the general circulation associated with the equator-to-pole temperature difference are much less strongly developed. The intertropical

convergence crosses the equator into the summer hemisphere, the summer-hemisphere Hadley cell weakens and nearly vanishes, and the circumpolar vortex subsides. This weakening and relative disorganization of the general circulation in the summer hemisphere permits the pattern to be dominated by asymmetries connected with the distribution of land and bodies of water. Among the most important of these are

[32]Strahler and Strahler, *Environmental geoscience*, pp. 96-98.

the summer monsoons of Asia and sub-Saharan Africa, in which moist, cool air sweeps inland over warm landmasses, rises, and drops the moisture as rain. This climatic feature is essential to the food supply of a substantial part of the world's population.

Weather, Climate, and Climate Change

Weather and climate are not the same thing, and the difference between the two terms involves the time span in which one is interested. *Weather* refers to the conditions of temperature, cloudiness, windiness, humidity, and precipitation that prevail at a given moment, or the average of such conditions over time periods ranging from hours to a few days. The weather can change from hour to hour, from day to day, and from week to week.

Climate, on the other hand, means the *average pattern* in which weather varies in time, and the average is determined over longer periods (from a month to decades). Thus, one might speak of the climate of a given region as being characterized by hot, dry summers and severe winters. Within this region, one would still expect some periods (days or weeks) of cool weather in summer and mild weather in winter. If the weather for an entire summer were cooler than usual, one would still speak of an exceptional summer's weather or a short-term climatic fluctuation but not of climate change. But if the weather averaged over ten or twenty consecutive summers were significantly cooler than the average for the previous thirty, then one could begin to call the phenomenon a change in climate.

Local weather and climate are determined by the complicated interaction of regional and global circulation patterns with local topography, vegetation, configuration of lakes, rivers, and bays, and so on. [33] Successful weather prediction requires combining knowledge of these general patterns and known local features with the most detailed available information about the weather conditions of the moment and the past few days -- not just at the location whose weather is being predicted, but at other locations, as well. That is, to predict tomorrow's weather, one must know as much as possible about today's. What happens in Los Angeles on Saturday may be largely foreseeable from what was happening in San Francisco on Friday, which could have been a storm that was in Portland on Wednesday, which originated as a disturbance in the Gulf of Alaska on Monday.

As everyone knows, forecasting the weather even one day ahead is not an exact science. This inexactitude is not because there are undiscovered physical processes at work; all the basic physical laws involved are actually known. The imperfections in prediction have two origins:

first, the actual system involved -- atmosphere, ocean, other water bodies, land -- is far too complicated for the known physical laws to be applied exactly, even with the largest computers; second, the initial conditions -- the state of the system at the time the analysis begins -- can be specified only approximately, owing to fundamental monitoring limitations. The farther in advance one wishes to make a local weather forecast, the more difficult the task becomes, because the larger is the area of the globe whose present conditions can influence subsequent conditions at the place one is interested in. Also, temperature and pressure anomalies small enough to slip through the global network of weather stations today may have grown large enough in a week's time to determine the weather over large regions. Weather satellites have made the meteorologist's task somewhat easier, especially because they provide information about meteorological conditions over the oceans, where surface monitoring stations are relatively scarce; but reliable weather forecasting a week in advance is still not a reality. Because the meteorological system is so complex, reliable forecasting two weeks ahead may never be attainable.

Understanding and predicting the changes in climate that have occurred and will continue to occur over time spans of decades, centuries, and millennia is in some respects even more difficult than forecasting the weather from day to day. The weather forecaster has the disadvantage of having to deal with tremendous detail in terms of variations over short times and short distances, but the advantage of access to a tremendous body of observa-

---

[33] In this chapter we have emphasized the large-scale processes that govern the patterns of weather and climate over large regions, continents, and hemispheres. Investigating in detail the *microclimates* that influence intimately the human and biological communities in specific small regions would take us deeper into the demanding and technical subject of meteorology than space and the nature of this book permit. The interested reader should consult Neiburger et al., *Understanding our atmospheric environment*, or another basic meteorology text for an introduction to the micrometeorology missing here.

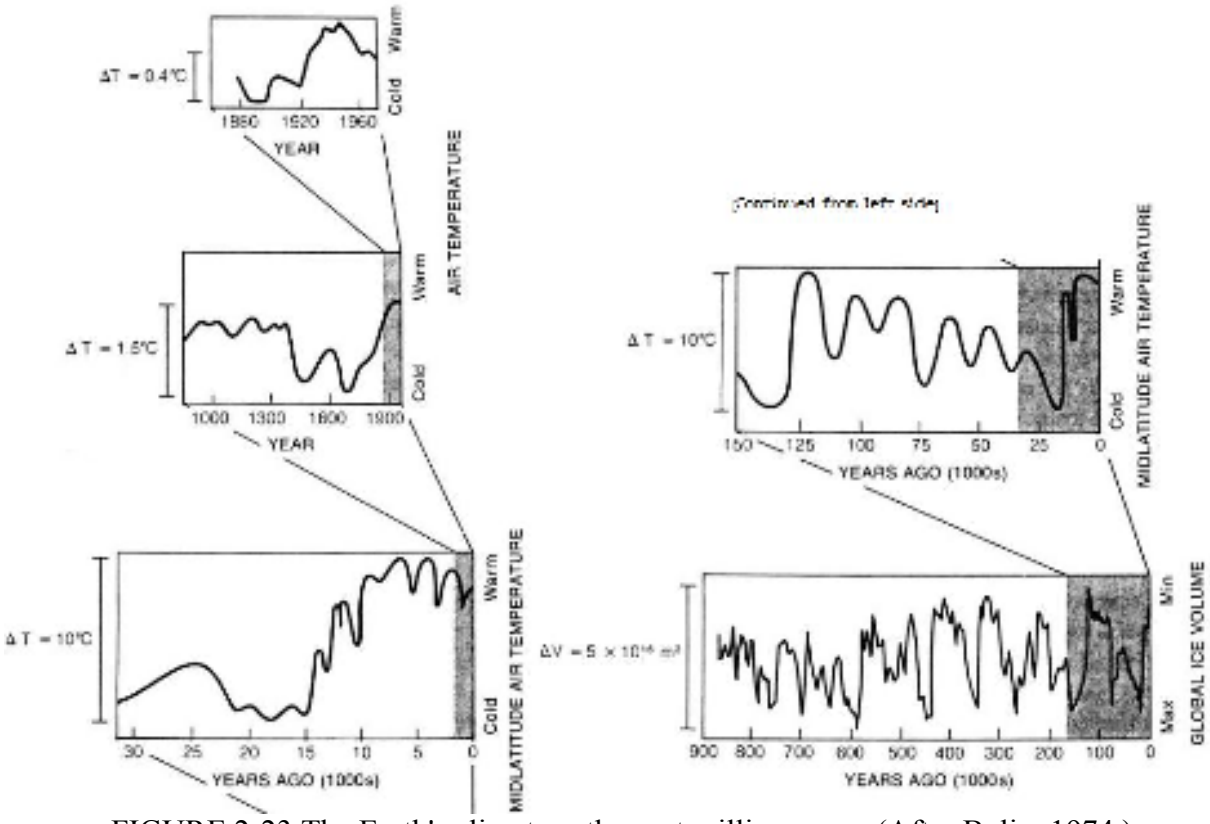

FIGURE 2-23 The Earth's climate -- the past million years. (After Bolin, 1974.)

tional data -- the weather happens every day, and many skilled observers with good instruments are watching and recording. The climatologist has reasonably good, direct, observational data only for the past few decades, spotty records for the past century or so, and only indirect evidence before that (scattered historical writings dating back several centuries, some archeological evidence going back a few thousand years, and only the fossil record and geological evidence before that). The plight of the climatologist is something like trying to learn all about weather on the basis of good data for the past two days, spotty data for the past two weeks, and only some fuzzy clues as to what might have happened before then.On the basis of the limited evidence available to them, climatologists have done a remarkable job of reconstructing in a plausible way Earth's climatic history for about the past million years and, more roughly, for the past 60 million years. [34] Some of the main features of the more recent history are illustrated in Figure 2-23. It shows a series of fluctuations in average midlatitude air temperature, with different amplitudes associated with different time scales. (The amplitude of a fluctuation is the difference between the maximum and minimum values associated with it.) The amplitude of the indicated variation in the past hundred years is about 0.5° C (roughly, 1° F); the amplitude of the fluctuations with a time scale of a few hundred to a thousand or so years is from about 1.5° to 2.5° C; and the amplitude of the fluctuations with a time scale of tens of thousands of years is in the range of between 5° and 10° C.Several points with respect to this climatic history deserve emphasis:

Variability has been the hallmark of climate over the millennia. The one statement about future climate that can be made with complete assurance is that it will be variable -- a conclusion not without significance for food production (see Chapter 7).

Rather small changes in average midlatitude temperatures are likely to be associated with

larger changes in the seasonal *extremes* of temperature at those latitudes,

---

[34]Study of Man's Impact on Climate (SMIC), *Inadvertent climate modification*, pp. 28-45; Bert Bolin, *Modelling the climate and its variations*.

> and with even larger changes in the extremes nearer the poles. These extremes in temperature are likely to have a more crucial influence on flora and fauna than are the averages.
>
> Modest changes in average temperature and the accompanying larger changes in temperature extremes are often associated with significant changes in the circulation patterns, humidities, amounts of rainfall, and other features that make up regional climates. These changes, too, can drastically influence the character of the plant and animal communities that exist in different regions.
>
> The drop in average midlatitude temperature associated with major ice ages is as little as 4° or 5° C. It is possible that an even smaller drop could *trigger* such an ice age. [35]
>
> The onset of significant climatic change in the past has sometimes been quite rapid. There is evidence to suggest, for example, that the advance of the continental ice sheets in a cooling period that commenced about 10,800 years ago destroyed living forests wholesale within the space of a single century or less. [36]
>
> The world finds itself in the last part of the twentieth century A.D. in one of the warmest periods in recent climatic history. What people alive today assume is normal -- namely, the climate of the past thirty to sixty years -- is in reality near one of the extremes of the persistent historical fluctuations. Even without the possibility of inadvertent human influence on climate, it could not be predicted on the basis of present knowledge how much longer this present extreme climate might last. Past evidence suggests, however, that when it ends, it will end (barring human intervention) with a cooling trend.

Several questions present themselves. What has caused the climatic fluctuations of the past? If climate change is a historical fact of life, is there any reason to worry about future changes? Is civilization capable of inadvertently influencing climate -- for example, by accelerating natural change or initiating a different trend? Is there any prospect of deliberate intervention to stop a threatening trend in climate? We consider the first two questions in the next few paragraphs; the last two will be touched on only briefly here and then taken up in detail in Chapter 11.

The causes of past changes in climate are not well understood. One possibility is variation in the rate at which the sun emitted energy, but there is no convincing evidence to show that this has occurred, and no convincing theory that predicts it has been proposed. [37] A second set of possibilities involves changes in atmospheric composition, influencing the transmission of incoming solar radiation and/or outgoing terrestrial radiation. For example, periods of intense volcanic activity might have added enough ash to the atmosphere to affect climate significantly, or biological and geophysical processes might have caused the atmospheric stock of carbon dioxide to deviate appreciably from its present value. Evidence to connect these possibilities with the actual onset of ice ages is lacking, however. Still another possibility is variations in Earth's orbit, which would have affected the amount and timing of incident solar energy. Such variations

are known to have occurred and to be occurring, but they appear to have been too small *by themselves* to have produced the onset or retreat of ice ages.

A likely contributing factor is that the circulation patterns and other phenomena that produce the gross features of climate are not very stable. If they were stable, the systems governing climate would tend to return after any disturbance to the conditions that prevailed before the disturbance. Many examples are known in physical science of systems that are stable if the disturbances imposed on them are not too large, but unstable -- that is, they fall into altogether different patterns of behavior than the initial ones -- if a disturbance exceeds some threshold. The idea of stability and the related concept of *feedback mechanisms* are explored by means of some simple examples in Box 2-5.

The number of feedback mechanisms influencing the stability of the global climate, both positively and negatively, is very large. [38] Some of the more important ones are indicated in Figure 2-24. It is not unlikely, under these circumstances, that the ocean-atmosphere

---

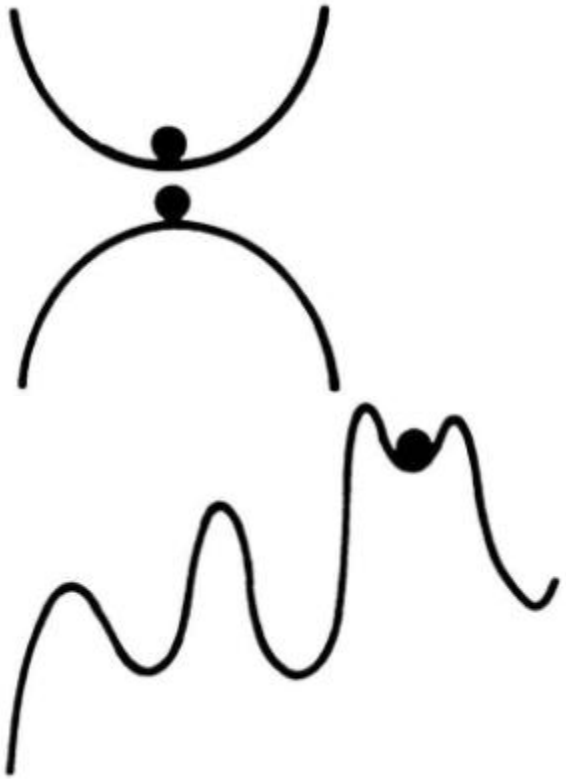
BOX 2-5 Stability and Feedback



In general, a system is said to be *stable* if it tends to return to its initial state after any perturbation, and *unstable* if a perturbation would cause the system to depart permanently from its initial state. Often the character of the perturbation determines whether a system is stable or unstable.

As a simple example, consider a system consisting of a marble in a round bowl, as shown in cross-section in the diagram here. The "state" of this system is the position of the marble, and in the initial state the marble is at rest at the bottom of the bowl (A). The system is stable against small sideways displacements of the marble -that is, if one pushes it to the side, the marble will roll back toward the center and eventually come to rest again in the initial state. The system is *not* stable against displacements so large that the marble is pushed out of the bowl (or against entirely different kinds of perturbations, such as turning the bowl over!). A similar system (B), in which the bowl is inverted and the marble rests on top, is unstable even against small perturbations. Any displacement causes the marble to roll away.

It seems likely that the stability properties of Earth's meteorological system are analogous to those of the third arrangement (C). In this case, there are several states of equilibrium -- that is, states in which the system can remain unchanged for an extended period. Each equilibrium state

is stable against small perturbations, but a large perturbation can cause the system to shift to a different equilibrium, which in turn is stable until a large enough perturbation happens along to cause another shift. Such systems are often called *metastable*.

When the forces or flows that affect the system are in balance, at least temporarily, then the system will be in equilibrium. A perturbation generally alters the forces or flows, and the *way* it alters them determines whether the system is stable or unstable. In a stable system, a perturbation sets in motion changes in forces or flows that tend to restore the initial state. Processes that work this way are called *negative feedback* (a change in the state of a system induces an effect that reduces the change). *Positive feedback* occurs when a change induces an effect that enlarges the change.

A. STABLE B. UNSTABLE C. METASTABLE

Consider the marble inside the bowl again. A displacement leads to a force that pulls the marble back toward its initial position, reducing the displacement; this is negative feedback. If the marble is on top of an inverted bowl, the force that results from any displacement acts to increase the displacement; this is positive feedback. Cause and effect relations of this kind -- cause producing effect that reacts back on cause -- are sometimes called *feedback mechanisms* or *feedback loops*, terms that originated in the narrower context of control systems for machinery, aircraft, and so on.

We have already considered some simple feedback mechanisms in this chapter without calling them that. An important one for climate is the negative feedback mechanism connecting surface temperature and outgoing terrestrial radiation. If a perturbation should increase the surface

temperature, this would cause the rate of energy outflow in terrestrial radiation to increase; all else being equal, this would cause the surface temperature to fall, reducing the initial perturbation. If a perturbation should reduce the surface temperature, the rate of energy loss via terrestrial radiation would fall, which would tend to raise the temperature again.

Often, one must trace feedback mechanisms through two or more physical processes. Consider, for example, another mechanism involving Earth's surface temperature: an increase in surface temperature causes an increase in evaporation rate, causing increased concentration of water vapor in the atmosphere, causing an enhanced greenhouse effect, causing a further increase in surface temperature. In complicated systems such as those influencing climate, many different feedback mechanisms -- some positive, some negative -- are operating at the same time, and predicting the net effect of a given perturbation can therefore be very difficult.

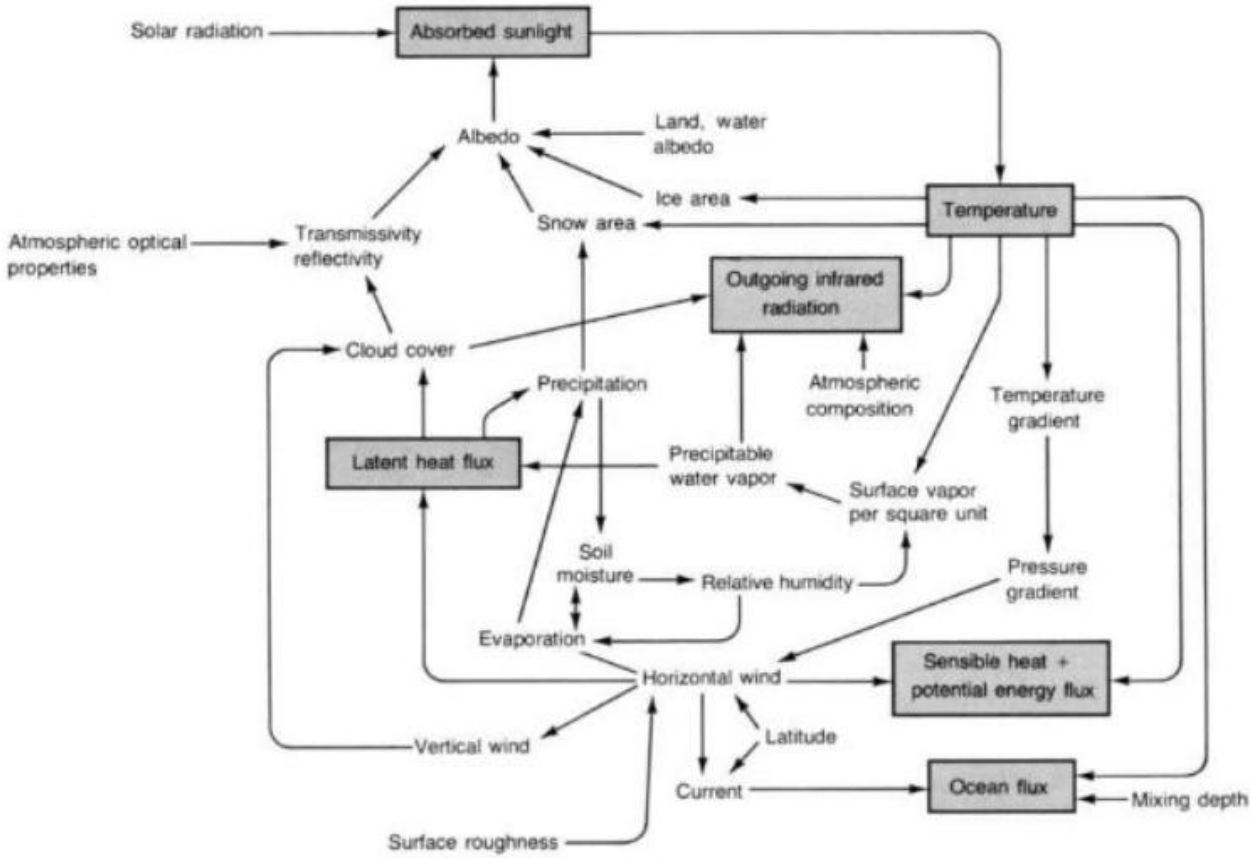


FIGURE 2-24 Some feedback loops governing global climate. (After Kellogg and Schneider, 1974.)

system governing climate belongs to the class of physical systems that are stable against small disturbances but change quite drastically and semipermanently if a larger disturbance happens along. In the case of Earth's climate, a disturbance (such as a change in solar output or in the amount of solar energy reaching Earth) need not involve an energy flow larger than the flows in the main climatic processes in order to start an instability. It would be enough that the energy

associated with the disturbance be sufficient to tip the balance between two competing feedbacks, each of which might involve a much larger energy flow than that of the disturbance. Such phenomena -- sometimes called *trigger effects* -- are encountered frequently in environmental sciences.

There is increasing evidence suggesting that certain large variations in regional weather patterns are caused by a feedback effect in which anomalies in ocean surface temperatures play a major role. [39] The heat capacity of the oceans (that is, the amount of energy stored for each degree the temperature rises) is far greater than those of the atmosphere or the land. As a result, small changes in the temperature of large masses of ocean water absorb or release enormous quantities of heat, and this permits the oceans to serve as thermal buffers, moderating what would otherwise be more extreme changes in seasonal temperatures in the overlying atmosphere and on the adjacent landmasses. That weather and climate are largely the result of the behavior of the *ocean-atmosphere system*, and not the behavior of the atmosphere alone, has been known for a long time. More specifically, however,

[39] Jerome Namias, Experiments in objectively predicting some atmospheric and oceanic variables for the winter of 1971-72. S. A. Farmer, A note on the long-term effects on the atmosphere of sea surface temperature anomalies in the north Pacific Ocean.

recent studies indicate that weather cycles of hot and cold or wet and dry, which are observed on a time scale of ten to fifteen years in many regions, are connected with changes in ocean surface temperatures that persist over large areas for similar periods. Apparently, such changes can produce a longitudinal (east-west) shift in the wavy pattern of alternating high- and low-pressure zones at the edge of the circumpolar vortex. What causes the changes in ocean temperatures themselves is not completely understood.

A hypothesis believed by many climatologists to explain longer-term climatic change is that the historical changes in Earth's orbit have been large enough to trigger a positive feedback involving the albedo in polar regions: reduced solar input leads to more areas being covered with ice and snow, leading to increased albedo (more reflectivity), leading to less solar energy absorbed at the surface, leading to further expansion of the ice and snow. [40] Eventually, other (negative) feedbacks would come into play to limit the expansion of the ice and snow cover, but the new distribution of surface cover and associated circulation patterns -- an ice age -- might persist for thousands of years.

Although the causes of ice ages (also called *glaciations*) are not well understood, there is good evidence concerning the actual conditions that prevailed in the Wisconsin glaciation, which was the most recent of several Pleistocene glaciations and ended only about 10,000 years ago. Compared to today's values, mean global temperatures were lowered 5° or 6° C (9° to 11° F), and mean temperatures were lowered by 12° C or more in the vicinity of the ice sheets themselves. [41] Sea level dropped at its lowest to 125 meters below today's level, the water being tied up in the continental ice sheets that covered what is now Canada, the north central United States, Scandinavia, and much of northern Europe (see Figure 2-25). [42] The drop in sea level

exposed much of what is now continental shelf, which became a richly vegetated landscape. The snow line in most mountain areas dropped 1000 to 1400 meters, and 700 to 900 meters in

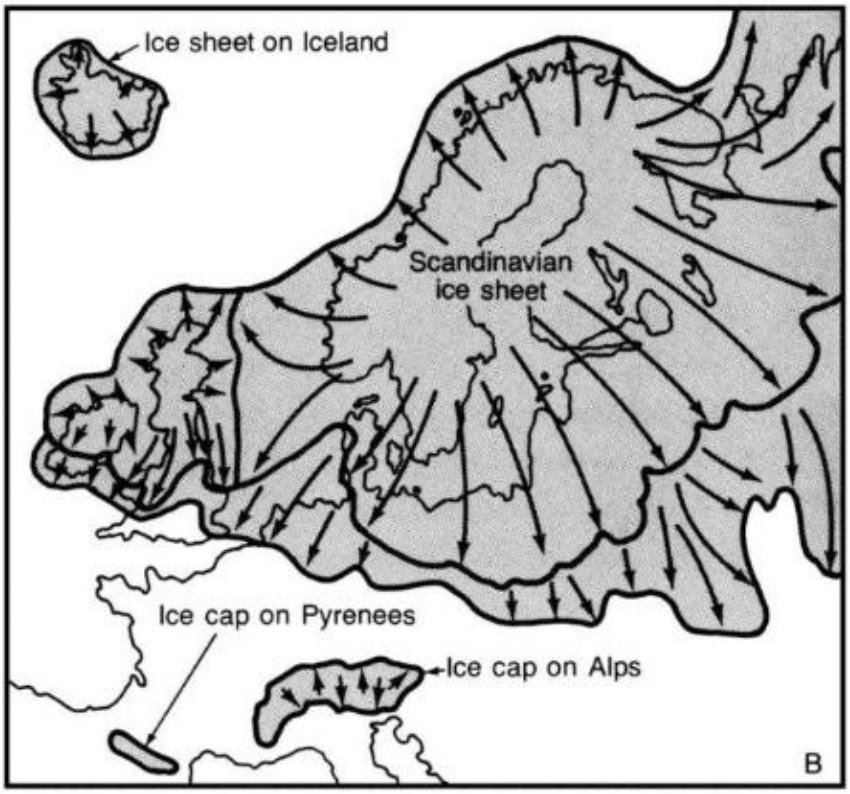

FIGURE 2-25 Maximum extent of Pleistocene glaciation in the Northern Hemisphere. A. North America. B. Europe.

[42]Strahler and Strahler, *Environmental geoscience*, p. 454.

the tropics, compressing the life zones that exist between the snow line and sea level (see Chapter 4).

It is worth mentioning again that the changes producing these conditions generally may have been -- and in some regions certainly were -- quite rapid. Although one tends to think of glaciation as a slow process involving the plastic flow of glacial ice (as described earlier), there is a much faster mechanism available for the advance of glaciers during the onset of ice ages: snow falls over a large region, fails to melt, and is compressed under the weight of new snow the following winter. Thus, the area under a semipermanent cover of ice and snow can increase enormously in a single season. This process of rapid glaciation has aptly been termed the *snow blitz*. [43]

The evidence suggests that the departure of the Wisconsin glaciers was even more sudden than the onset. At the peak of the warming period that followed this most recent retreat of the ice sheets, average global temperatures rose to 2° or 3° C warmer than today's, sea level rose to today's level but apparently not above it, and the prevailing circulation patterns produced considerably more rainfall in the Sahara and the eastern Mediterranean lands than occurs today.

[44] These conditions, called the postglacial optimum by climatologists, occurred between 5000 and 6000 years ago.

The fact that Earth has a long history of climate change offers small consolation, unfortunately, to today's human population, faced as it is with the prospect of further change in the future. Significant climate change in any direction -- hotter, colder, drier, wetter -- in the world's major food-producing regions would be likely to disrupt food production for years, and even decades, because the animals and crops now relied upon are relatively well adapted to existing climate conditions. The recent historical record and the nearness of present conditions to a temperature maximum, moreover, suggest that the most *likely* major trend to occur next is cooling. This almost certainly would disrupt food production for as long as the lowered temperatures persisted, by reducing the area and growing season available for some of the most important food crops. The dependence of agriculture on climate is explored further in Chapter 7 and Chapter 11. Other ecological effects of climate change could also have serious human consequences, which are treated in Chapter 11.

How and when human activities could themselves cause, accelerate, or prevent climate change is a complicated and imperfectly understood subject, which is also postponed until Chapter 11. What is most relevant to that discussion from the foregoing treatment of the machinery of climate and natural climate change are the complexity and probable instability of the patterns of energy flow in the ocean-atmosphere system, and the speed with which changes, once triggered, may spread and intensify.

CHAPTER 3
Nutrient Cycles

All things from eternity are of like form and come round in a circle.

-- Marcus Aurelius

The main flow of energy that helps shape conditions on Earth's surface comes from space; and when the energy's work here is done, to space it returns. With respect to energy, then, Earth is an open system. With respect to its chemical endowment, however, Earth is a closed system. That is, the amounts of carbon, hydrogen, oxygen, iron, gold, and other elements in the planet-atmosphere system do not change with time; the chemical arrangement and physical distribution of these elements can and do vary, but essentially nothing enters and nothing leaves the system. [1]

The elements in this closed system that are essential to life are called *nutrients*. They can be divided into three categories: the 4 main chemical building blocks of living matter (carbon, oxygen, hydrogen, nitrogen); 7 *macronutrients*, of which smaller but still significant quantities

are required for life; and 13 *micronutrients*, or trace elements, of which tiny quantities perform essential functions (see Table 3-1). [2] The suitability of any terrestrial or aquatic environment for the support of life depends on the availability of nutrients in appropriate forms and quantities. The processes that govern this availability (or lack of it) are known collectively as *nutrient cycles*, because of the way the individual basic stocks of physical material move cyclically through the living and nonliving parts of the physical world.

These cycles function in support of life not merely by making nutrients continuously available -- in other

[1]The main exceptions are some hydrogen escaping into space from the top of the atmosphere, some hydrogen arriving in the "solar wind" from the sun, and some iron and other elements arriving in the form of meteorites. The quantities involved in these flows are negligible for the purposes of this discussion.

[2]Frieden, *The chemical elements of life*.

words, by maintaining the fertility of the environment -but also by limiting the accumulation of material in quantities, forms, and places in which it would damage organisms. It is important to recognize in this connection that the same elements and compounds that serve as nutrients for some organisms in some concentrations are often toxic for other organisms, or even for the same organisms at higher concentrations. For example, molecular oxygen (O_2) is toxic to anaerobic organisms and, at high enough concentrations, even to mammals. Ammonia (NH_3) is an important source of nutrient nitrogen for many plants but is toxic to people. Hydrogen sulfide (H_2S) is a nutrient for certain types of bacteria but is extremely toxic to mammals.

TABLE 3-1 The Chemical Elements of Life

Symbol	Name	Atomic number	Atomic weight
BASIC BUILDING BLOCKS			
H	Hydrogen	1	1
C	Carbon	6	12
N	Nitrogen	7	14
O	Oxygen	8	16
MACRONUTRIENTS

DYNAMICS OF NUTRIENT CYCLING

The steps that make up all nutrient cycles involve two basic processes: physical transport and chemical transformation.

The principal agents of physical transport are discussed in Chapter 2. They are: (1) the hydrologic cycle, including evaporation and precipitation as well as the flow of streams, groundwater, and ice; (2) winds; (3) ocean currents; and (4) geologic movement, especially the upward and downward motions at the boundaries of tectonic plates and geologic uplifting on continents. A fifth agent of physical transport that is important in a few circumstances is the movement of organisms. For example, fish-eating birds that deposit their excrement on land provide a significant pathway by which nitrogen and phosphorus are transferred from the sea to the land. Fish such as salmon, that feed mostly in the ocean but migrate up freshwater rivers to spawn and die, perform a similar function, as do the ocean-caught fish consumed by continent-dwelling human beings.

How the various mechanisms of transport link the principal "compartments" of the physical world is represented schematically in Figure 3-1. Obviously, the ease (and, hence, the rate) with which a given substance can move through these pathways depends on its physical state (solid, liquid, gas), on other physical properties (solubility, volatility), and on the possibility of chemical transformations that can change those properties. Such chemical transformations take place in living organisms and in the nonliving environment. They are considered in more detail below. The magnitudes of the flows in some of the principal pathways shown in Figure 3-1 are listed in Table 3-2.

Each of the compartments indicated in Figure 3-1 often is divided into subcompartments for the purpose of tracing nutrient flows. Thus, for example, it is customary to consider three subcompartments of material in both the soil and the oceans: living organic matter, dead organic

matter, and the inorganic medium itself. These subcompartments can be further subdivided -- for example, organic matter, into plants, animals, and microorganisms; and seawater, into the well-mixed surface layer and the stratified deeper layers. Finally, within each subdivision of each subcompartment, the magnitudes of

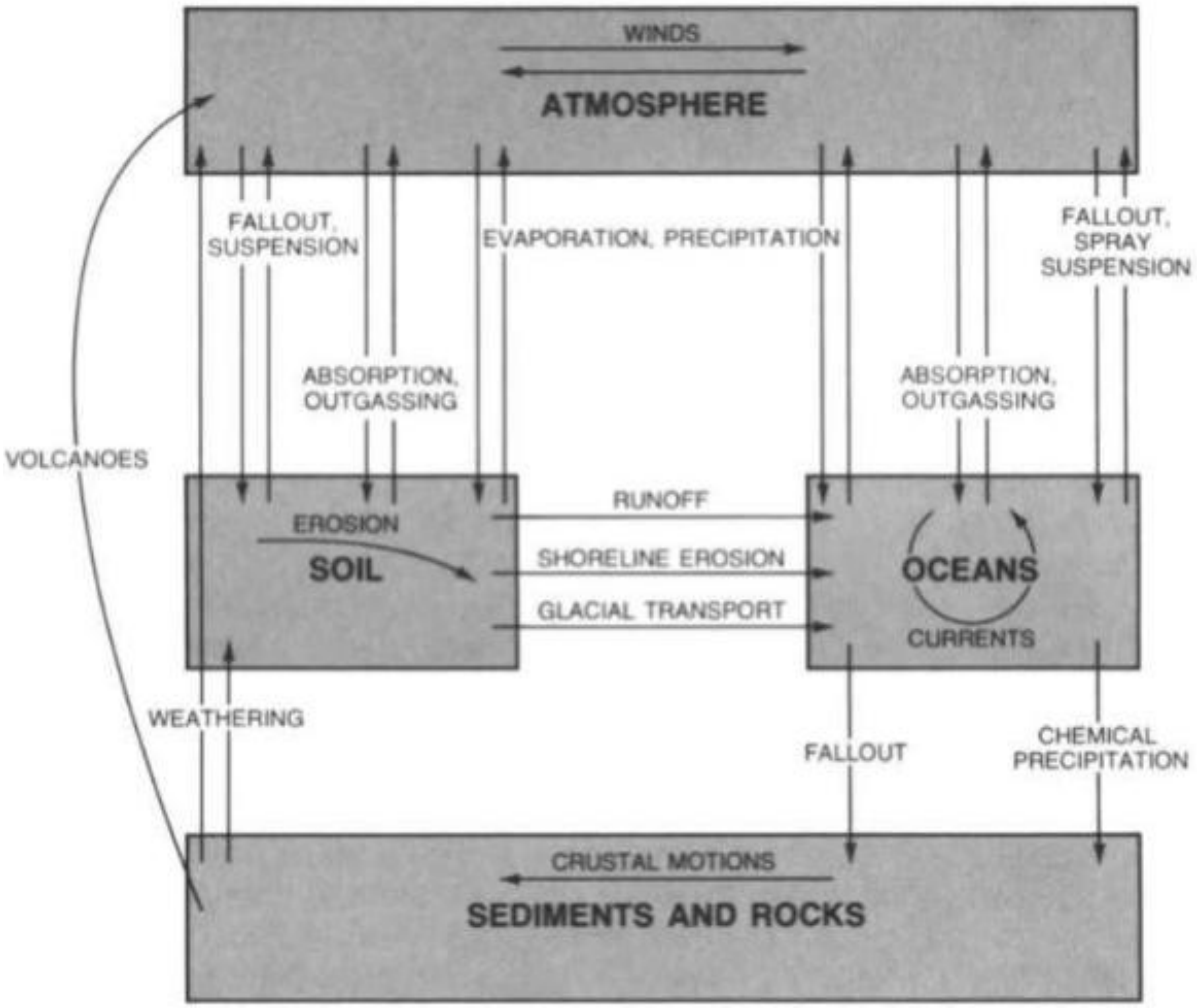

FIGURE 3-1 Transport mechanisms among the "compartments" of the physical world.

the stocks, or pools, of the important elements and compounds are of interest, as are the magnitudes of the flows into and out of the pools (where flows can mean physical movement or chemical transformation or a combination of the two).

For any pool that is in steady state -- that is, for which inflows balance outflows so the size of the pool does not change with time -- an average residence time for a compound can be calculated as the ratio of the size of the pool to the sum of the inflows or outflows (see Box 2-3). For example,

$$\text{residence time (yr)} = \frac{\text{pool (kg)}}{\text{sum of outflows (kg/yr)}}$$

Examination of the residence times for important pools provides quick insight into the dynamics of nutrient cycling, and, indirectly, into the probable vulnerability of specific components of nutrient cycles to disruption by human intervention. For example, a long residence time means the annual flows are small compared to the pool, which means in turn that unless human disruptions cause

TABLE 3-2 Some Global Materials Flows

Pathway	Magnitude of flow (billion MT/yr)
TO OCEANS	
River discharge (H_2O)	32,000
Groundwater flow (H_2O)	4,000
River-borne suspended solids (today)	18
River-borne suspended solids (prehuman)	5(?)
River-borne dissolved solids	4
Ice-sheet transport of solids	2
Shoreline erosion	0.3
TO AND FROM ATMOSPHERE

TABLE 3-3
Residence Times in Some Important Nutrient Pools

Nutrient pool	Residence time (yr)
Nitrogen in atmosphere	64,000,000
Oxygen in atmosphere	7,500
Inorganic nitrogen in soil	100(?)
Carbon in dead terrestrial organic matter	27

Nutrient pool	Residence time (yr)
Carbon in living terrestrial organic matter	17
Carbon dioxide in atmosphere	5
Carbon in living oceanic organic matter	0.10
Sulfur compounds in atmosphere	0.02

Note: Uncertainties are at least ±20 percent.

a very large alteration in inflow or outflow they will affect the size of the pool only very slowly. A short residence time, by contrast, means that significant changes in inflow or outflow can affect the size of the pool very quickly. Approximate residence times for some of the important nutrient pools appear in Table 3-3.

CHEMISTRY OF NUTRIENT CYCLES

Two kinds of chemistry play crucial roles in the principal global nutrient cycles: the chemistry of the sedimentary cycle, associated with the very slow transformation of very large pools of material, and the chemistry of life, associated with the more rapid transformation of much smaller pools. Both kinds of chemistry depend very heavily on the very special roles of water as a source of hydrogen (H+) and hydroxyl (OH-) ions for many chemical reactions, as a medium for holding other chemical compounds in solution where they can react, and as a vehicle for physical transport of compounds from place to place.

Sedimentary Cycle

Nutrients are mobilized in the sedimentary cycle when water comes in contact with rock. Rainwater is slightly acidic, having absorbed some atmospheric carbon dioxide to form weak carbonic acid: [3]

$$H_2O + CO_2 \longrightarrow H_2CO_3$$

$$H_2CO_3 \longrightarrow H^+ + HCO_3^-$$

The pH of rainfall in areas free of industrial pollution is around 5.7. (Recall from basic chemistry that pH is the negative of the log to base 10 of the concentration of hydrogen ions in moles per liter. The pH of distilled water is 7.0, corresponding to 10-7 moles of hydrogen ion per liter.) This slight acidity is enough to facilitate greatly the dissolution of many minerals present in exposed rock -- a process called weathering.

Among the most important weathering reactions is that of the common mineral feldspar (a constituent of granite):

feldspar carbonic acid water

$$2KAlSi_3O_8 + 2(H^+ + HCO_3^-) + H_2O \longrightarrow$$

kaolinite dissolved silica dissolved potassium and bicarbonate ion

$$Al_2Si_2O_5(OH)_4 + 4SiO_2 + 2K^+ + 2HCO_3^-$$

Kaolinite is a clay; it is left behind in this process as a contribution to the formation of soil, whereas the dissolved silica, potassium ion, and bicarbonate ion are carried away in the runoff. The mobilization and removal of positive ions such as (in this case) potassium is called leaching. Note that the reaction consumes some water and that it reduces the acidity of the solution (that is, it removes hydrogen ions) as it proceeds. These properties are characteristic of weathering reactions. Essentially the same reaction also occurs in the weathering of the aluminosilicates of sodium and calcium (NaA1Si3O8, CaA12Si2O8). Other silicate minerals also weather in the same general manner to produce kaolinite or other clays.

The weathering of certain other minerals leads to their complete dissolution; no solid trace is left behind to be incorporated into soil. The most important of these minerals are the limestones, or carbonate rocks, which undergo the following reactions:

$$CaCO_3 + H^+ + HCO_3^- \longrightarrow Ca^{++} + 2HCO_3^-$$

$$CaMg(CO_3)_2 + 2(H^+ + HCO_3^-) \longrightarrow Mg^{++} + Ca^{++} + 4HCO_3^-$$

Still other weathering reactions consume atmospheric oxygen in the oxidation of iron minerals:

$$4FeSiO_3 + O_2 + 2H_2O \longrightarrow 4FeO(OH) + 4SiO_2$$

$$4Fe_3O_4 + O_2 \longrightarrow 6Fe_2O_3$$

$$4FeS_2 + 15O_2 + 8H_2O \longrightarrow 2Fe_2O_3 + 8H_2SO_4$$

[3] A good discussion of this point is given by F. Press and R. Siever in *Earth*, Chapter 6.

Most of the products of the weathering reactions mentioned here eventually reach the sea, either as dissolved ions or as suspended solids. Between the time they are freed from rock and the time they reach the sea, of course, some of these elements have made one or more passages through

the living part of the biosphere as nutrients. In the sea, too, the nutrient substances are captured from the water by living organisms, eventually to be returned to the water or to the sediments on the ocean floor. The reverse of many of the weathering reactions also can occur in seawater in the absence of intervention by living organisms, forming solid precipitates that join the organic debris on the ocean bottom. Apparently these outputs of the major nutrient elements from the oceans roughly balance the inputs, because considerable physical evidence indicates that the salinity of seawater has been approximately constant for at least the past 200 million years. [4]

The sedimentary cycle is finally closed by the geologic processes described in Chapter 2: that is, by the processes of transformation and transportation that turn seafloor sediments into continental rocks, and by volcanic action.

Living Matter

Ecologist Edward S. Deevey, Jr., has pointed out that living matter can be regarded as a chemical compound with the empirical formula [5]
$H_{2960}O_{1480}C_{1480}N_{16}P_{1.8}S$.
This enormous (and completely intentional) oversimplification serves both to call attention to the chemical side of life -- the side with which this chapter is concerned -and, more specifically, to illustrate the relative proportions in which the six most abundant elemental constituents of living material exist.

Actually, there is substantial variation in the ratios of the chemical elements of life in different kinds of organisms, the above formula being a weighted average in which woody plants predominate. The numbers are, in any case, not known with great accuracy. Another source gives the molar ratio H/O/C/N/S/P as 1600/800/800/9/5/1 for land plants (different from Deevey mainly in the abundances of sulfur and phosphorus) and 212/106/106/16/2/1 for living marine plants, soil humus, and organic materials in sedimentary rocks. [6] (Readers who have not studied basic chemistry or who have forgotten it should see Box 3-1 for a review of mole and mass measures.)

The basic reactions that link the water cycle, the carbon dioxide cycle, and the oxygen cycle through living matter are photosynthesis:

$$6\,CO_2 + 12\,H_2O + \text{solar energy} \longrightarrow + 6\,O_2 + C_6H_{12}O_6 + 6\,H_2O$$

and its opposite, respiration, or oxidative metabolism:

$$6\,O_2 + C_6H_{12}O_6 \longrightarrow 6\,CO_2 + 6\,H_2O + \text{heat}$$

The compound ($C_6H_{12}O_6$, or $(CH_2O)_6$, is glucose, the simplest carbohydrate produced by photosynthesis. The photosynthesis reaction is written with what appear to be six extra H_2O

molecules on each side because twelve molecules of H_2O are actually broken up for each molecule of $C_6H_{12}O_6$ synthesized; radioactive-tracer experiments show that all twelve oxygen atoms from the 12 H_2O end up in the $6O_2$, and the oxygen in the six new water molecules comes from the CO_2. [7] The amount of energy transformed from light into stored chemical energy by the photosynthesis reaction is 112 kilocalories (469 kilojoules) per mole of carbon fixed. The net result of the respiration reaction is to transform the same 112 kilocalories per mole of carbon from chemical energy into heat.

Photosynthesis is carried out not only by higher green plants (such as oak trees, grasses, and ferns) but also by various kinds of algae (green, brown, red, blue-green) and by certain bacteria. In the bacteria, substances other than water serve as the sources of hydrogen for the reduction of carbon. [8] For example, the green sulfur

[7]See, for example, A. L. Lehninger, *Biochemistry*, p. 457.
[8]Reduction is the term for gaining electrons in chemical reactions, to be contrasted with oxidation, which means losing electrons. In most cases, gaining a hydrogen atom is equivalent to gaining an electron, because hydrogen effectively gives up its single electron to most elements with which it forms compounds. See, for example, L. Pauling, *General chemistry*, or any other basic chemistry text.

BOX 3-1 Moles, Molecules, and Mass Ratios

Amole of an element is 6.02×10^{23} atoms; a mole of a compound is 6.02×10^{23} molecules. This number -- known as Avogadro's number -- is the number of *atomic mass units* in a gram. (The atomic mass unit is defined as one-twelfth of the mass of the most abundant isotope of carbon, which is carbon-12. One atomic mass unit is approximately the mass of a proton.) It follows from these definitions that a mole of any element or compound -- 6.02×10^{23} atoms or molecules of it -- has a mass in grams equal to the atomic or molecular weight of the substance in atomic mass units. For example, a mole of carbon (atomic weight, 12 atomic mass units) has a mass of 12 g; a mole of carbon dioxide, or CO_2 (atomic weight, 44 atomic mass units), has a mass of 44 g.

The mass ratios of elements in living matter and in other compounds differ from the molar ratios because different elements have different atomic weights. Consider the carbohydrate molecule $(CH_2O)_n$, where n is an integer telling how many times the basic CH_2O building block appears in the molecule. The ratio of moles of hydrogen to moles of carbon to moles of oxygen in this material is 2 to 1 to 1 -- in shorthand, H/C/O = 2/1/1. The ratio of the masses is obtained by multiplying the numbers in the molar ratios by the appropriate atomic weights. The mass ratio H/C/O in $(CH_2O)n$ is (2 x 1)/ (1 x 12)/(1 x 16) = 2/12/16 = 1/6/8.

bacteria use hydrogen sulfide instead of water, according to the equation

$$12\,H_2S + 6\,CO_2 + \text{light} \longrightarrow C_6H_{12}O_6 + 6\,H_2O + 12\,S$$

producing elemental sulfur rather than oxygen. (In fact, these bacteria are obligate anaerobes -- they would be poisoned by oxygen.) The reverse reaction (respiration) consumes sulfur and carbohydrate and liberates heat, carbon dioxide, and hydrogen sulfide. Still other photosynthesis reactions use hydrogen, obtained from H_2O or H_2S or other hydrogen donors, to reduce substances other than carbon dioxide. For example, most higher plants can reduce nitrate, instead of CO_2, in photosynthesis:

$$9\,H_2O + 2\,NO_3^- + \text{light} \longrightarrow 2\,NH_3 + 6\,H_2O + 4\tfrac{1}{2}\,O_2$$

and nitrogen-fixing photosynthetic organisms can reduce atmospheric nitrogen: [9]

$$6\,O_2 + C_6H_{12}O_6 \longrightarrow 6\,CO_2 + 6\,H_2O + \text{heat}$$

These variations notwithstanding, the great bulk of photosynthesis on Earth consists of the reduction of carbon dioxide, with water as the hydrogen source.

The photosynthesis and respiration reactions, as we have written them here, actually represent only the end points of vastly more complicated sequences of chemical events. For example, although burning glucose in air is described essentially completely by the respiration reaction given above,

$6\,O_2 + C_6H_{12}O_6 \rightarrow 6\,CO_2 + 6H_2O + \text{heat},$

to achieve the same result in a living cell (at a temperature far below that of combustion) requires many intermediate steps. The intermediate steps in both respiration and photosynthesis rely heavily on three kinds of organic compounds: the energy carrier ATP (adenosine triphosphate); the electron carrier NADP (nicotinamide adenine dinucleotide phosphate); and various catalysts called enzymes. (Catalysts speed up chemical reactions without themselves being consumed.) [10]

A closer look at these compounds provides some clues to the importance of the elements nitrogen, phosphorus, and sulfur in the chemistry of life. All biochemical reactions of importance (not just photosynthesis and respiration) require enzyme catalysts if they are to proceed at significant rates. All enzymes are *proteins*. Proteins other than enzymes also serve as hormones; as vehicles to transport oxygen; as important structural

[10] For detailed descriptions of the biochemistry of photosynthesis and respiration see R. P.

components of skin, tendons, muscle, cartilage, and bone; and in numerous other roles. All proteins are made up of building blocks called *amino acids*, and all amino acids contain the amino group -- NH_2. A single protein contains from fifty to some tens of thousands of amino acids, and hence at least that many nitrogen atoms. (Some amino acids contain more than one nitrogen.) The shape and stiffness of many proteins -- properties essential to their functions -- are governed and maintained by bonds in which sulfur plays a crucial role, so it, too, is essential to the chemistry of life.

ATP and NADP are examples of *nucleotides*, compounds consisting of a five-carbon sugar to which one or more phosphate groups (-- PO4) and a *nitrogen* base are attached. A nitrogen base is a ring compound containing both nitrogen and carbon in the ring structure. Nucleotides not only perform critical energy-transfer and electron-transfer functions in the chemistry of living cells, but they are also the building blocks of *nucleic acids*. Each nucleic acid molecule contains hundreds to thousands of nucleotides, the arrangement of which is a chemical means of storing information. Nucleic acids control the synthesis of proteins and a variety of other processes in living cells. The nucleic acid DNA (deoxyribonucleic acid) is the *genetic material* -- the bearer of the coded information that is passed from parent cells and organisms to their offspring to "tell" them what to become. The nucleic acid RNA (ribonucleic acid) plays essential roles in carrying out the instructions coded in DNA molecules. [11]

In addition to its role as a constituent of DNA and RNA, phosphorus, in the form of phosphate, is one of the principal anions (ions with a negative charge) that maintains electric neutrality in the fluids of living organisms. Along with calcium, it is also an important component in shells and bony structures. Sulfur, besides playing its role in proteins, in the form of sulfate(-- SO_4) is another principal anion in body fluids and cells. The third principal anion is the chloride ion (-- Cl). The principal cations (positively charged ions) are sodium, potassium, calcium, and magnesium. Magnesium is an essential constituent of many enzymes and of the green pigment chlorophyll. Iron is a key component of many enzymes and of the oxygen-transporting protein hemoglobin. [12]

Oversimplifying considerably, one can say that the quantity of living matter in a given environment is *limited by the stock of that requisite of life that is in shortest supply*. This rather obvious proposition carries the name *Liebig's law of the minimum*. [13] Of course, the limiting factor varies from one type of organism to another and from one environment to another. Generalizations are difficult, but it is fair to say that under many circumstances the quantity of plant material in a given environment is in fact controlled by a *limiting nutrient* (although the density of a given kind of plant is often controlled by a herbivore). [14] In desert regions the limiting nutrient is generally water. Under many conditions where water is not limiting, as in freshwater lakes, the limiting nutrient turns out to be phosphorus; in the open ocean it may be iron. In some richly productive environments, nitrogen and phosphorus are jointly limiting --

producing any more plant material would require supplying more of both nutrients. Obviously, the limiting nutrient in a given biological system represents a leverage point where the effects of natural or human-induced perturbations manifest themselves rapidly.

CYCLES OF THE PRINCIPAL NUTRIENTS

The cycles of many nutrients are tightly linked chemically and biologically. This is so much the case for the cycles of carbon, oxygen, and hydrogen that we consider them together. The cycles of nitrogen, phosphorus, and sulfur, on the other hand, can usefully be examined separately, as they are here.

Carbon-Oxygen-Hydrogen

It is appropriate to begin our closer examination of the carbon-oxygen-hydrogen cycles with their intersection in the green plant, the basis of almost all life on Earth.

Carbon and energy in living plants. Most living plants not only fix (store) energy by means of photosynthesis but they also use some of that stored energy to drive their own life-sustaining internal processes by means of respiration. The total rate at which a plant or a plant community stores solar energy by means of photosynthesis is called *gross photosynthesis or gross primary production* (GPP). The figure obtained by subtracting from gross photosynthesis the amount of energy used by the plants in respiration (R) is called *net photosynthesis or net primary production* (NPP). In abbreviated form, then, the relation is GPP - R = NPP. Several

interchangeable units are used in the biological literature for the measurement of these quantities: calories or kilocalories per unit of time, watts or kilowatts (different units for measuring the same thing -- energy flow), grams of carbon fixed into organic compounds per unit of time, moles of carbon fixed per unit of time, or grams of dry organic matter produced per unit of time. The relations among these units are discussed in Box 3-2.

A wide range of estimates of global net primary production and the associated standing crop of living plants (*phytomass*) have been published. [15] One recent review indicates that the estimates of net primary production are converging on a value around 160 billion (1.60×10^{11}) metric tons per year for the globe. [16] Global phytomass was estimated in the same review as about ten times larger -- 1840 billion metric tons, dry weight -- and gross photosynthesis was estimated to be about twice as large as net production (that is, half of gross photosynthesis is consumed in plant respiration and half remains as net production). The estimates for phytomass and net primary production, separated into terrestrial and oceanic components, are presented in Table 3-4.

The roughness of these estimates deserves emphasis. The range of recent (1970 or later) estimates of land phytomass, for example, is from about half the value given in Table 3-4 to 30 percent larger; the range of published values of ocean phytomass is from twenty times smaller than the value in Table 3-4 to three times larger. [17] The factor-of-60 range of informed opinion with respect to oceanic phytomass is especially remarkable. The range in recent published estimates of oceanic net primary production is only ± 10 percent from the value in Table 3-4, and the range in terrestrial net production is from 15 percent less to 60 percent more than the value in the table. [18] The fraction of gross primary production consumed in plant respiration is known to vary between 20 percent and 75 percent, depending on type of plant and region, but the global average is unlikely to differ much from 50 percent. [19]

BOX 3-2 Units for Energy and Material Flow in the Carbon Cycle

For the purpose of reconciling estimates of annual production presented in grams of carbon, grams of dry organic matter, and kilocalories, one widely used convention assumes that 10 kilocalories of energy are stored per gram of fixed carbon and that dry organic matter contains 45 percent fixed carbon by weight. * (The actual range of values for different kinds of dry organic matter extends roughly ± 15 percent from these nominal figures.) Thus, measurements in grams

or metric tons (1 MT = 106 g) of carbon can be converted to grams or metric tons of dry organic matter by multiplying by 2.2, and 1 gram of dry organic matter can be taken to represent 4.5 kilocalories of stored energy. Useful conversions following directly from this convention are that I gram of dry organic matter per day corresponds to an average energy flow of about 0.2 watts; 1 gram of carbon per day, to about 0.5 watts; and one metric ton of dry organic matter per year, to about 600 watts. Also, 1 metric ton of dry organic matter contains 37,500 moles of carbon.

Although we shall use the convention just described, the reader may encounter others elsewhere. If the dry organic matter were pure carbohydrate -- $(CH_2O)n$ -- which stores 112 kilocalories per mole of carbon, then the appropriate conversions would be: 3.7 kilocalories per gram of dry organic matter, 9.3 kilocalories per gram of carbon, 0.4 gram carbon per gram of dry organic matter. [Actually, CH_2O is a good approximation of the average composition of all living matter (see Deevey's formula presented earlier) because so much of the world's biomass is cellulose tied up in woody plants, and cellulose has nearly this formula. However, most of the plant material *produced* each year is not cellulose -- remember, a big pool does not necessarily mean a big flow. The annual production of organic matter contains a higher proportion of fixed carbon and higher energy content per gram than does the cellulose-dominated, slow-toturn-over standing crop.] The rounded-off value of 4 kilocalories per gram of dry organic matter is in fairly widespread use in conjunction with the figure of 10 kilocalories per gram of fixed carbon, itself a rough average among several kinds of plant matter.

These differences in conversion values are troublesome for those seeking consistency in the ecological literature, but the differences they produce in the published figures for net production are much smaller than the uncertainties of measurement and estimation.

*See, for example, R. H. Whittaker and G. E. Likens, "Carbon in the biota", in *Carbon and the biosphere*, G. H. Woodwell and E. V. Pecan, eds., pp. 281-300.

Taking the range of estimates into account, one can state several conclusions with reasonable assurance: (1) the annual NPP of the oceans is only one-third to one-half that of the continents, even though the oceans cover more than 70 percent of Earth's surface; (2) the pool, or standing crop, of living plant material on land is at least several hundred times that in the oceans; (3) the average turnover time (life expectancy) of oceanic plants must be in the range of days to weeks, in order for so small a phytomass to be associated with so large an annual production; (4) the average turnover time of terrestrial living plants, by contrast, is in the range of a decade or two; [20] (5) oceanic and terrestrial phytomasses are both so poorly known that man-induced or natural changes large enough to be very important in the long term could easily escape notice for some time. In the latter regard, although there are good reasons to suppose that the activities of civilization have diminished the terrestrial phytomass significantly, some experts consider this assertion to be debatable. [21]

Notwithstanding the uncertainties in the data, it is instructive to examine the large regional variations in plant productivity that are concealed in the global totals. Some of these figures (on which the totals in Table 3-4 are based) are summarized in Table 3-5. Of particular interest are the facts that tropical forests account for more than 40 percent of terrestrial NPP (although they cover only about 16 percent of the land area) and that up-

[20] Obviously, this longevity is strongly influenced by the high proportion of the terrestrial biomass in long-lived trees and shrubs. Most crop plants, of course, "turn over" in less than a year.

[21] See the comments in Whittaker and Likens, *Carbon*, pp. 295-297, and the group discussion stimulated by them (pp. 300-302).

TABLE 3-5
Variation and Distribution of Net Primary Production

	Range of NPP (g organic matter/m^2/yr) [a, b, c]	***Total NPP (billion MT/yr)*** [a]
Tropical Forest	1300-6000	45.3
Shrubland, Grassland, Savanna	500-3200	19.8
Temperate Forest	1200-2000	14.9
Northern Forest	600-1000	9.6
Cultivated Land	350-9400	9.1
Swamps, Lakes, Marshes	1000-1500	6.2
Desert, Tundra, Alpine Meadow	3-250	2.4

Terrestrial total		107.3
Open Ocean	50-370	42.0
Continental Shelf	370-750+	9.6
Reefs, Estuaries	1800-4900	3.6
Upwelling Regions	370-750	0.2

Oceanic total		55.4

[c] G. H. Woodwell, The energy cycle of the biosphere, *Scientific American*, September 1970 , pp. 64-74.

welling regions, continental shelves, reefs, and estuaries yield almost 25 percent of oceanic NPP while accounting for less than 9 percent of the ocean's area.

According to Table 3-4, the rate at which energy is being stored in net primary production is about 100 million megawatts, roughly two-thirds on land and one-third in the ocean. The rate of gross primary production can be assumed to be about 200 million megawatts. The net primary production is roughly twelve times the rate at which civilization used commercial energy in

1975, where commercial energy refers to energy that is sold (for example, fossil fuels, hydropower, and nuclear power, but excluding food) as opposed to energy that is gathered by the user (for example, most wood, dung).

Very little of the solar energy that reaches Earth's surface is captured by photosynthesis. The net primary production is about 0.1 percent of the incident solar energy at the surface-0.25 percent of what strikes the land and 0.05 percent of what strikes the ocean. Some of the reasons these percentages are so small are obvious. Plants do not by any means cover all of Earth's surface; in many areas of the world the growing season lasts only part of the year; and in some circumstances, as already noted, plant growth is limited by lack of one or more critical nutrients. Under favorable conditions, on the other hand -- as in a well watered and fertilized cornfield or a fertile swamp -- NPP may reach 2 percent or so of incident solar energy averaged over the growing season and as much as 6 percent or 7 percent of incident solar energy on the most favorable days. [22]

These numbers still seem low. One additional reason for this is that only about one-fourth the solar energy reaching the ground is in the part of the wavelength range that stimulates photosynthesis (blue and red light). [23] The other big reason is the large amount of water that must be evaporated through the leaves of plants to maintain the nutrient-bearing flow of water through them. Evaporating this water typically takes 40 percent or more of the energy that falls on a plant, and a much higher percentage of what is actually absorbed by the plant. [24] (For production of every ton of wet weight of many crops -- of which about one-fourth is dry organic matter -- around 100 tons of water are evaporated. This means 400 grams of water are evaporated, requiring

[23] D. Gates, *The flow of energy in the biosphere*.

[24] Ibid. ; H. Penman, *The water cycle*.

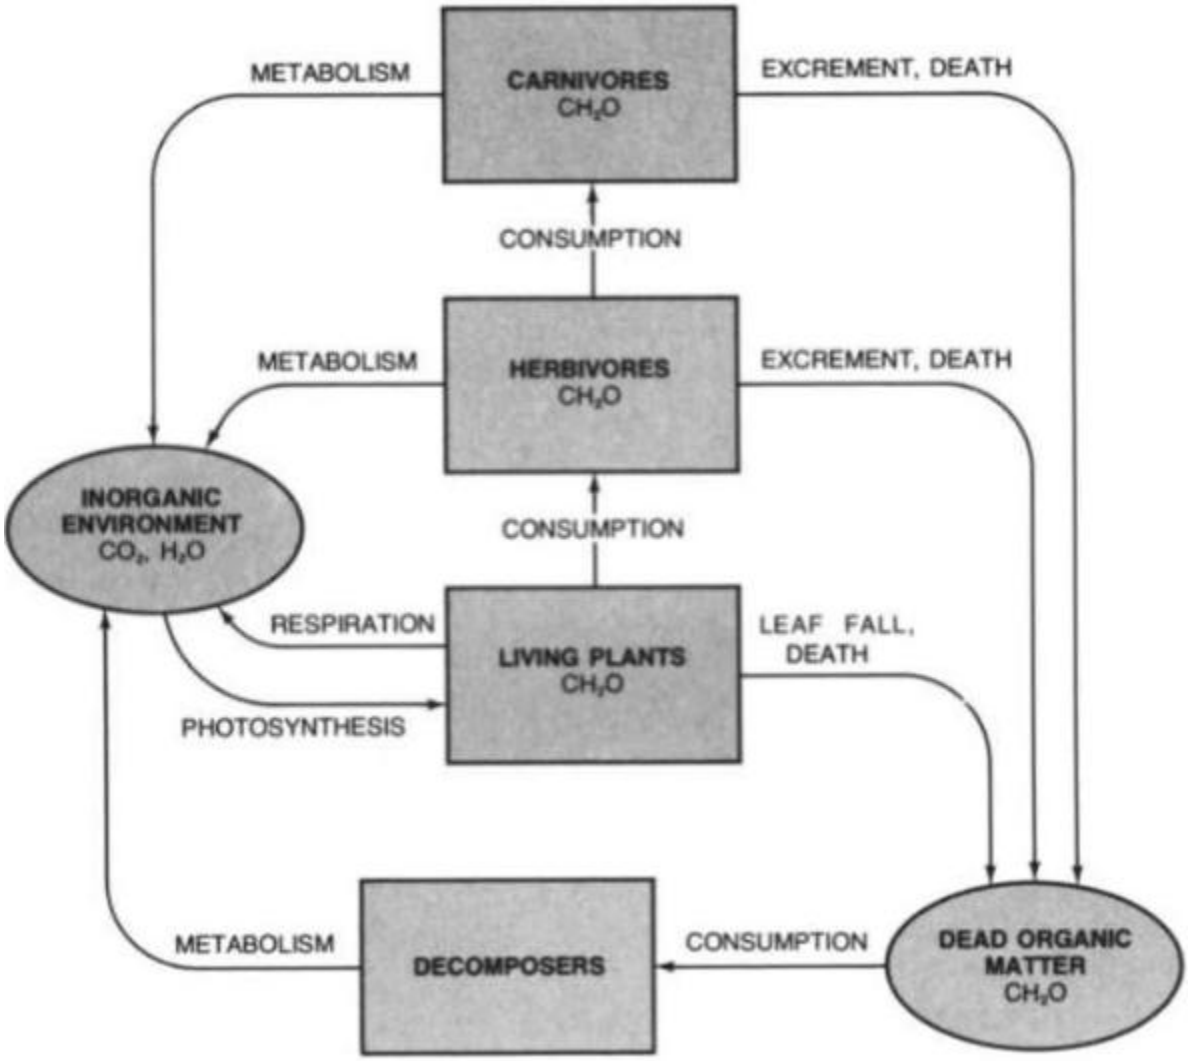

FIGURE 3-2 The cycling of carbon through organism (simplified).

about 0.6 kilocalories per gram evaporated, for every gram or 4.5 kilocalories of dry organic matter produced. The ratio in such a case is about 50 kilocalories for evaporation per kilocalorie of net primary production.)

Oxygen balance: metabolism by animals and microbes. The overall effects of the net production of plants on the cycles of carbon, oxygen, and hydrogen are as follows: (1) more oxygen, O_2, is added to the environment than is removed from it; (2) less carbon dioxide, CO_2, and water, H_2O, are added to the environment than are removed from it; (3) the CO_2 and H_2O subtracted from the environmental pools show up as additions to the pool of stored organic matter, CH_20, and to the atmospheric oxygen pool. Quantitatively, for every metric ton of dry organic matter produced, there is a net loss from the environment of 0.6 metric tons of water and about 1.5 metric tons of CO_2, and a net gain of about 1.1 metric tons of oxygen.

Why, then, is oxygen not building up continuously in the atmosphere, while water and carbon dioxide are depleted? Because plant matter is not accumulating, but rather is approximately in

steady state. It is being broken down into carbon dioxide and water again by the metabolism of animals and microbes, using up molecular oxygen just as rapidly as new plant material and oxygen are being produced.

Consider the possible fates of plant carbohydrate produced as part of net primary production (Figure 3-2). Plants either are consumed by herbivores, or they die and add their carbohydrate to the pool of dead organic matter. Of the part consumed by herbivores, some is metabolized and thereby returned to the environmental pool of CO_2 and H_2O, some is added as excrement to the pool of dead organic matter, and some is incorporated into herbivore tissue, either to be eaten by carnivores or to be added at the herbivore's death (by causes other than being devoured) directly to the pool of dead organic matter. The same fates await the carbohydrate that reaches the carnivores. The cycle is closed by the action of decomposers--both animals and microbes (bacteria)--which by metabolizing the fixed carbon in dead

organic matter return CO^2 and H^2O to the environmental pools.

There are some important side pathways in the carbon cycle not shown in Figure 3-2, in which the initial products of decomposition include methane and carbon monoxide (CH_4 and CO) in addition to carbon dioxide. The main reactions are:

$$2\,CH_2O \longrightarrow CH_4 + CO_2$$

$$2\,CH_2O + O_2 \longrightarrow 2\,CO + 2\,H_2O$$

The CH_4 and CO may then be oxidized in the soil or in the atmosphere according to the following reactions:

$$2\,CH_4 + 3\,O_2 \longrightarrow 2\,CO + 4\,H_2O$$

and

$$2\,CO + O_2 \longrightarrow 2\,CO_2$$

The details concealed by these simple formulas can be quite complex.

In steady state, the metabolism of carbohydrate by herbivores, carnivores, and decomposers returns to the environment exactly as much CO_2 and H_2O as the production of the carbohydrate by photosynthesis originally removed. And it consumes exactly as much oxygen as the photosynthesis produced. There is therefore no long-run buildup (or depletion) of oxygen in the environment as a result of this cycle, unless net photosynthesis and metabolism get out of balance.

The sequestering of fixed carbon. How did oxygen accumulate in the atmosphere in the first place? The biogeochemical evidence suggests that molecular oxygen in the atmosphere is of biological origin, there having been essentially none before the evolution of photosynthetic organisms, perhaps 2 billion years ago. [25] For oxygen produced by photosynthesis to have accumulated over the long term, part of the carbon fixed by this process must have been withdrawn from the cycle illustrated in Figure 3-2, escaping the oxidation step back to carbon dioxide. Indeed, it is precisely such a break in the carbon cycle that produced the fossil fuels. They originated as plant material that escaped breakdown by decomposers, in many cases by being buried in swamps and bogs under conditions in which both oxygen and anaerobic decomposer organisms were absent. Hundreds of millions of years of burial under considerable pressure and heat converted these plant materials into the hydrocarbon fossil fuels--coal, petroleum, and natural gas. The oxygen released when the carbon in these fuels was first fixed by photosynthesis remained in the atmosphere. [26]

The different ranks of coal--lignite, subbituminous, bituminous, anthracite--represent different ages (listed here from youngest to oldest) in terms of the origin of the plant material they derived from, and somewhat different chemical compositions. [27] Peat is the partially decomposed organic matter that is the precursor of coal. Petroleum, natural gas, oil shale, and tar sands are the results of different histories of biogeochemical transformation, but all originated, like coal, with dead organic matter.

Not all of the fixed carbon that has been sequestered out of reach of natural oxidative processes is in deposits as concentrated as the fossil fuels. A much larger amount, in fact, is dispersed in sediments whose hydrocarbon content is on the order of 1 part per 1000 (1 g of hydrocarbon material per kg of sediment) or less. [28]

Since the oxygen reservoir in the atmosphere has been built up by the sequestration of fixed carbon in various forms, could it be jeopardized by any forseeable activities of civilization that would cause the oxidation of these fixed-carbon pools? Deforestation, for example, could lead to the oxidation of part of the standing crop of fixed carbon in living organic matter, and combustion of fossil fuels oxidizes those pools. Yet, examination of the best estimates of the sizes of the fixed-carbon pools shows little cause for concern in the short term (see Table 3-6). Removal and oxidation of the entire terrestrial biomass would deplete atmospheric oxygen by at most 0.2 percent. Combustion of all the conventional fossil fuels (coal, petroleum, natural gas--of which about 90 percent is coal) thought to be recoverable ever by human effort would deplete atmospheric oxygen by 1.8 percent. This

---

[25] Cloud and Gibor, *The oxygen cycle*.

[26] Contrary to a rather widely held misconception, fossil fuels did not come mainly from dinosaurs or other animals. Because of the inefficiency of energy transfer up food chains and other factors (which are treated in Chapter 4), the rate at which fixed carbon was incorporated in animal tissues was much smaller than the rate at which it was incorporated into plant tissues.

[27] See P. Averitt, *Coal*; and Chapter 8 of this book.

[28] See, for example, T. H. McCulloh, *Oil and gas*.

TABLE 3-6 Sizes of Pools of Fixed Carbon (1015 moles reduced carbon)

Oceanic Biomass [a, b]	0.1-0.6
Terrestrial Biomass [a, b]	40-70
Dead Organic Matter, terrestrial [a, b]	60-750
Dead Organic Matter, dissolved and suspended in oceans [a, b]	60-250
Recoverable Coal, Petroleum, Natural Gas [c]	500
Oil Shale [c]	24,000
Reduced Carbon, dispersed in sediments [a]	1,000,000
Molecular Oxygen, in atmosphere [a, d]	38,000

[d]For comparison.

would reduce the oxygen content of the atmosphere at sea level to what it now is at an elevation of 150 meters. The 1975 global rate of fossil-fuel combustion would amount to a depletion of atmospheric oxygen by about 0.001 percent per year--far below the threshold of detectability with existing measurement techniques. On the other hand, the amount of reduced carbon thought to be present in oil shales is sufficient, if it were ever totally recovered and oxidized, to consume more than half the atmospheric oxygen pool. Some observers believe that most of the oil shales are too dispersed an energy resource ever to be economically attractive (see Chapter 8). But, in the event this view is not correct and civilization commences to use oil shale at a very high rate--say, ten times the rate at which all forms of energy were consumed worldwide in 1975--it would still take many centuries for the resulting depletion of atmospheric oxygen to become serious.

The oxygen situation is made more complicated than indicated in the foregoing paragraphs by the existence of important pools of oxygen elsewhere than in the atmosphere. It is apparent from the information in Table 3-6 that other oxygen pools must exist, because the number of moles of oxygen in the atmosphere is much smaller than the number of moles of reduced carbon in the sediments and elsewhere. The oxygen produced when all that carbon was fixed and sequestered was tied up with the oxidation of ferrous oxide (FeO) to ferric oxide (Fe_2O_3) and sulfur to sulfate ($-SO_4$) in sedimentary rocks. It may also have been tied up in the oxidation of carbon of inorganic origin (such as carbon monoxide from volcanoes) to carbon dioxide and carbonate ($-CO_3$). Although all these reactions are slow, they can account for the necessary enormous amounts of oxygen if they are assumed to have operated over geologic time spans. [29] Similarly, alterations in conditions governing the reaction rates could lead to significant changes in atmospheric composition over very long periods. On shorter time scales, however, organic carbon pools and associated reactions are almost certainly more important, and they are unlikely to produce significant changes in atmospheric oxygen in less than centuries.

Carbon dioxide. Although atmospheric oxygen depletion evidently is not a short-term threat, buildup of atmospheric carbon dioxide is. Every mole of oxygen removed from the atmosphere

means a mole of carbon dioxide added. Since the number of moles of CO^2 in the atmosphere is 700 times smaller than the number of moles of O^2, a change of a specified number of moles has 700 times the effect on the CO^2 concentration as on the O^2, concentration. The combustion of fossil fuel that depletes oxygen by 0.001 percent per year augments the atmospheric CO^2 by 0.7 percent per year--not an insignificant increment.

Not all of the added CO^2 remains in the atmosphere, however. Some is absorbed by the oceans, and it is conceivable that some is being taken up in an increase in biomass. (Recall from the earlier discussion that the size of the biomass is not known with sufficient accuracy to

[29]See, for example, Cloud and Gibor, *The oxygen cycle*.

detect even rather substantial changes.) An increase in the concentration of CO_2 in the atmosphere should increase the rate of net photosynthesis (where other nutrients are not limiting), and this would produce a growing biomass if the rate of oxidative metabolism by consumers and decomposers did not increase correspondingly.

Accurate measurements of atmospheric CO_2 have been made since about 1957. They have been coupled with indirect evidence to produce a model of the rise of atmospheric CO_2 from about 280 molecular parts per million in preindustrial times to around 325 parts per million in 1975. [30] The possible climatic effects of this increase and its continuation are discussed in Chapter 11.

An additional kind of evidence that can shed some light on the sources and fate of the CO_2 added to the atmosphere is the abundance of radioactive carbon-14 relative to the amount of nonradioactive carbon-12 in various pools. Carbon-14 is produced naturally by bombardment of nitrogen by cosmic rays in the stratosphere and also by civilization when nuclear bombs are detonated in the atmosphere; it then mixes throughout the atmosphere and is incorporated, along with other carbon, into plant matter. Since the half-life of carbon-14 is only 5770 years, the carbon-14 buried for millions of years in fossil fuels has decayed away entirely. [31] Thus, the CO_2 added to the atmosphere by the combustion of fossil fuels contains no carbon-14, whereas CO^2 added from pools with faster turnover does contain carbon-14. The reduction in the 14C/C ratio in the atmosphere because of the combustion of fossil fuels is called the Suess effect. The use of data on the Suess effect, combined with other information needed to help interpret it (such as the way the rate of natural and artificial 14C production has varied over time), has allowed development of the estimate that about half of the $C0^2$ ever added to the atmosphere by combustion of fossil fuels has stayed there. [32] The same work indicates that the land biomass should have increased between 1 percent and 3 percent since preindustrial times, having absorbed some of the industrial CO_2, while the oceans absorbed the rest. This change in land biomass is much too small to measure, and the exact amount is a matter of controversy.

Global carbon cycle. Figure 3-3 presents an internally consistent picture of the pools and flows of the global carbon cycle. We caution the reader once more that substantial uncertainties exist about many of the numbers, as noted in detail earlier, and that further research might therefore alter the picture considerably. In this diagram, the pools of living and dead organic matter on

land and in the oceans are assumed to be in equilibrium. Half the CO_2 added to the atmosphere by combustion of fossil fuels is assumed to dissolve in the surface layer of the oceans. The fossil-fuel pool shown here is somewhat larger than the figure in Table 3-6 suggests, because the latter indicated only the part of the fossil fuels estimated to be recoverable eventually. (Some will remain forever in the ground, as discussed in Chapter 8.)

Of the carbon added to the atmosphere by the respiration of animals and microbes, only a few percent is in the form of methane (CH_4) and carbon monoxide (CO), while the rest is carbon dioxide. [33] Still, the natural sources of carbon monoxide--incomplete decomposition of organic matter and partial oxidation of methane in the atmosphere--exceed man-made carbon monoxide from fossil-fuel combustion severalfold. Methane is apparently not toxic at any concentrations that occur in natural environments, and carbon monoxide is toxic only at concentrations on the order of 100 times the global atmospheric average or more. [34]

Nitrogen

The nitrogen cycle is chemically the most intricate of the major nutrient cycles, and it is probably the least well understood scientifically. The several chemical forms of nitrogen to be encountered in this discussion are identified in Table 3-7. The crucial role of nitrogen in all proteins makes this element essential to life, but most

TABLE 3-7 Chemical Forms of Nitrogen

Formula	Name	Oxidation number*	Comments
NH_3	Ammonia	-3	Major nutrient form
NH_4^+	Ammonium ion	-3	From NH_3 dissolved in water
NH_2^+	Amino group	-1	Constituent of protein
N_2	Nitrogen gas	0	Bulk of atmosphere
N_2O	Nitrous oxide	+1	Laughing gas, controls natural ozone cycle
NO	Nitric oxide	+2	Combustion product
NO_2^-	Nitrite ion	+3	Link in N cycle
NO_2	Nitrogen dioxide	+4	From NO oxidized in atmosphere
NO_3^-	Nitrate ion	+5	Principal nutrient form

Formula	Name	Oxidation number*	Comments

*Negative oxidation numbers denote more-reduced forms, and positive oxidation numbers, more-oxidized forms.

organisms can assimilate and use nitrogen only in specific chemical forms. Only a relatively few species of bacteria and algae can convert gaseous molecular nitrogen (N_2) into the more complex compounds that can be used by plants and animals. The principal usable forms are ammonia (NH_3) and nitrates ($-NO_3$), of which the latter is needed in greater quantity by most plants. The conversion of N_2 to ammonia and nitrate is called *nitrogen fixation*, and the species that can accomplish this conversion are called nitrogen-fixing organisms. Thus, although the atmosphere represents an enormous reservoir of molecular nitrogen, the continuation of life on Earth depends absolutely on the activities of these tiny, inconspicuous organisms.

Organisms and nitrogen. The best known of the nitrogen-fixing organisms are the bacteria (genus *Rhizobium*) associated with the special nodules on roots of legumes, which are plants of the pea family. In a symbiotic relationship, the bacteria obtain from the plants the energy they need to carry out the nitrogenfixing reaction

$$2N_2 + 6H_2O \rightarrow 4NH_3 + 3O_2,$$

and some of the ammonia, in turn, is made available to the plants for the synthesis of amino acids, for example,

$$2NH_3 + 2H_2O + 4CO_2 \rightarrow$$
$$2CH_2NH_2COOH + 3O_2.$$

(In this example the amino acid is glycine.) The capacity of such legumes as alfalfa, beans, peas, and clover to fix nitrogen in large quantities has led to their widespread use in crop-rotation schemes to replenish in the soil the nitrogen depleted by other crops.

Although nitrogen fixation by the legume-bacteria symbiosis is thought to be responsible for most natural nitrogen fixation, the fixation step is also carried out by some bacteria that have looser associations with plants, including the free-living *Azotobacter* (aerobic) and *Clostridium* (anaerobic), and by various species of blue-green algae. [35] Blue-green algae are apparently responsible for maintaining the fertility of rice paddies in much of Asia, which are subjected to intensive cropping without the use of nitrogen fertilizers.

The amino acids used by all organisms as the building blocks of protein are synthesized not only from ammonia but also from nitrate produced from ammonia by processes collectively called *nitrification*. The nitrification reactions yield energy, which supports the life processes of the nitrifying bacteria (*Nitrosomonas, Nitrobacter*). The actual synthesis of amino acids is carried out by bacteria (which differ widely in how many amino acids they can synthesize), by plants (which can synthesize all the amino acids needed for making proteins), and by animals (which, again, differ in the variety of amino acids they can produce). [36]

Vertebrates--including human beings--cannot synthesize all the amino acids they need and must obtain intact in the food they eat the ones they cannot synthesize. The amino acids an animal must get from its diet are called *essential amino acids*; those it can synthesize are called *nonessential*. (This terminology is unfortunate, because both essential and nonessential amino acids are needed--the distinction concerns only whether the organism can synthesize them itself.)

Fixed nitrogen that has been incorporated into organisms returns to the soil in animal wastes and in dead organisms (microbes, plants, animals) or parts of organisms (for example, leaves). Animal wastes are rich in urea--$(NH_2)_2CO$--which is the principal product of the metabolism of proteins in many organisms. The proteins of dead organisms are broken down into amino acids and other residues by bacteria and fungi of decay. The latter compounds--urea, amino acids, and other breakdown products of protein--are then converted into ammonia by yet another group of bacteria. This step is called *ammonification*. (The chemical reaction for the ammonification of an amino acid is just the opposite of aminoacid synthesis.)

So far we have described how nitrogen is fixed by living organisms and how the fixed nitrogen is further processed by them. A logical question at this point is: How is nitrogen *unfixed*? For without a mechanism for

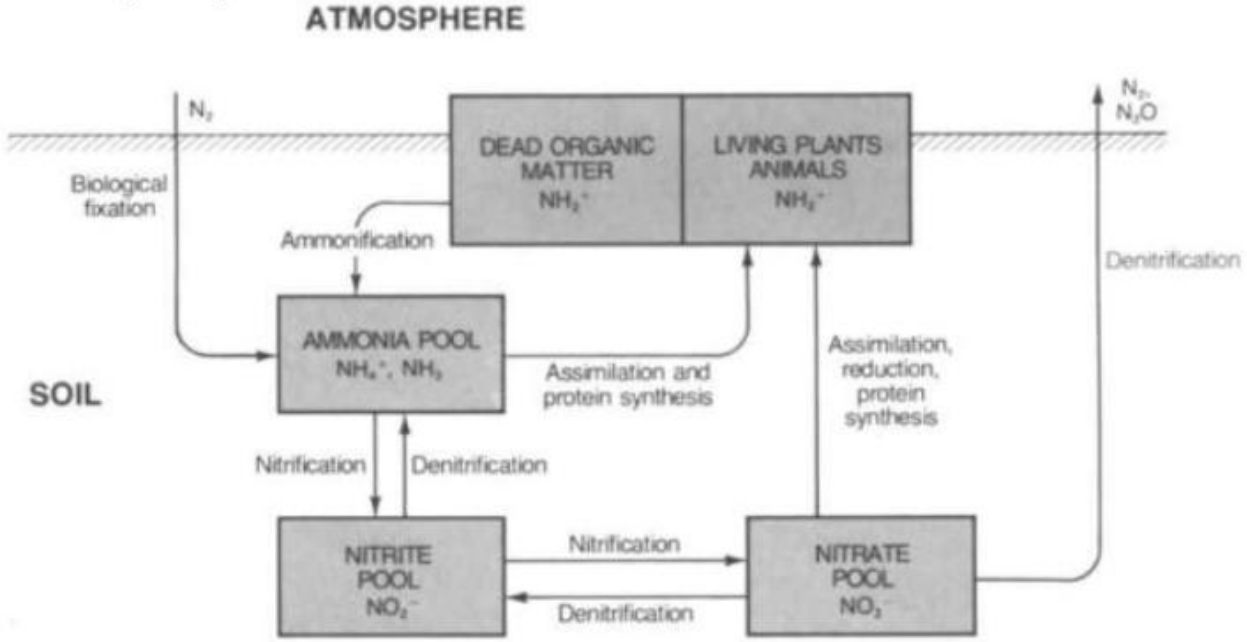

FIGURE 3-4 Biological processes in the terrestrial nitrogen cycle.

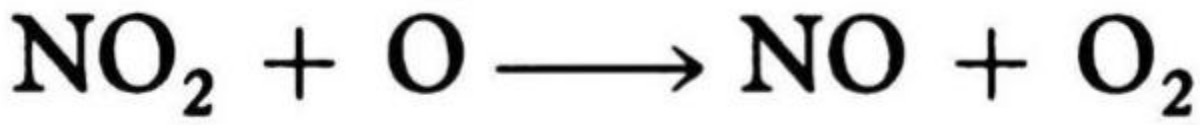
returning nitrogen to its molecular form (N_2), even the vast reservoir of this compound that exists in the atmosphere would have been depleted long ago; much of the nitrogen would be tied up as nitrates in soil, in the oceans, and in sediments. [37] The mechanism that has prevented this outcome by closing the atmospheric loop of the nitrogen cycle is the action of a relatively few groups of *denitrifying bacteria* that make their living converting nitrate to nitrous oxide (N_2O) and N_2. (These transformations release energy.) The nitrous oxide is reduced to N_2 by further

bacterial action, or in the atmosphere by photochemical reactions. Another set of denitrifying reactions, also carried out by bacteria, transforms nitrate to nitrite and nitrite to ammonia.

The chemistry of the main steps in the nitrogen cycle that are mediated by bacteria is summarized (in an illustrative, not exhaustive way) in Table 3-8. For each reaction, the "energy" column indicates whether energy must be supplied to accomplish it ("in") or whether the reaction makes energy available ("out"). The part of the terrestrial nitrogen cycle directly associated with organisms is represented schematically in Figure 3-4. The oceanic cycle is substantially similar, relying both on bacteria and algae. [38]

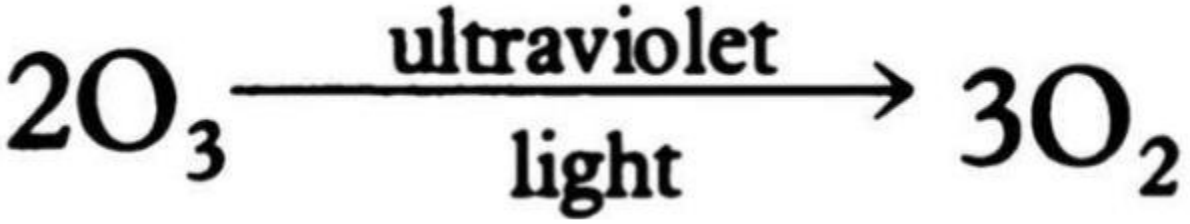
[37] See the discussion in Deevey, *Mineral cycles*, p. 141.
[38] See especially Burns and Hardy, *Nitrogen fixation*.

Inorganic processes. Some important flows and transformations in the nitrogen cycle take place without the active participation of organisms. For example, some of the ammonia produced by the decomposition of organic materials enters the atmosphere by outgassing from Earth's surface. Highly soluble in water, the ammonia dissolves in atmospheric water vapor to form ammonium ion, which combines with sulfate and nitrate ions and rains out as ammonium sulfate and ammonium nitrate. Possibly, the ammonium ion is also partly removed from the atmosphere by oxidation to N_2. [39]



Nitrous oxide, produced by denitrifying bacteria, is the second most abundant form of nitrogen in the atmosphere, after N_2. No sinks for this gas are known in the troposphere--that is, no process has been identified in the troposphere that converts N_2O to other compounds--but one may yet be discovered. The presently known sink for N_2O is in the stratosphere, where it is both photochemically reduced by ultraviolet light to produce N_2 and O, and oxidized by contact with atomic oxygen to produce nitric oxide (NO). [40] The net result chemically is

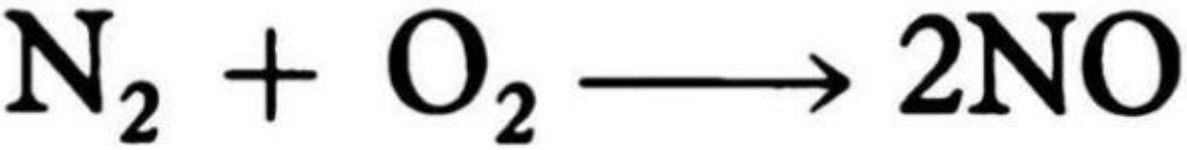
$$2N_2O \longrightarrow N_2 + 2NO$$



Nitric oxide (NO) is a very effective catalyst for the destruction of ozone (O_3) in the stratosphere. The reactions are

$$NO + O_3 \longrightarrow NO_2 + O_2$$

$$O_3 \xrightarrow[\text{light}]{\text{ultraviolet}} O_2 + O$$



from which the net effect is

Thus, there is a connection between the rate of biological nitrous oxide (N_2O) production in the soil and the rate of ozone destruction high in the stratosphere. This link is examined more closely in Chapter 11.

Nitric oxide is also produced in or added to the troposphere by several processes. One is the so-called juvenile addition of nitric oxide by volcanoes. Another is fixation from atmospheric nitrogen gas by lightning, where the lightning discharge supplies the high energy needed to drive the reaction:

The same reaction takes place as the result of combustion of fossil fuels by industrial society in automobiles, aircraft, electric power plants, and other processes. Nitric oxide, from whatever source, is oxidized in the troposphere to give nitrogen dioxide (NO_2), which in turn reacts with atmospheric water, giving nitric acid and reproducing the NO:

The nitric acid falls in rain as HNO_3 or reacts with other atmospheric constituents (such as NH_4^+) to produce other nitrate compounds. The end result in either case is to supply fixed nitrogen to the surface.

In addition to the inadvertent production of fixed nitrogen through the combustion of fossil fuels, industrial society fixes atmospheric nitrogen intentionally for use as fertilizer. The basis of this industrial fixation process is a method invented by Haber and Bosch in 1914, in which nitrogen and hydrogen react under high pressure and in the presence of a catalyst to form ammonia. The source of the hydrogen for this process is usually methane in natural gas. Some of the ammonia produced is reacted with carbon dioxide to produce urea, and some is reacted with oxygen to

form nitric acid. The nitric acid is reacted with more ammonia to make ammonium nitrate--along with urea, a widely used fertilizer. [41] These materials are often referred to as *inorganic fertilizers*, to distinguish them from the ammonia, urea, and nitrates of organic origin that are often used as fertilizer in the form of manure or plant material. (There is no chemical distinction between, say, nitrate ion of organic origin and nitrate ion produced in a fertilizer plant, but important differences in soil quality may result from the different ways in which the nitrate is actually made available to the soil in organic and inorganic fertilization. See Chapter 11 for further discussion.)

[39]Garrels, Mackenzie, and Hunt, *Chemical cycles*, p. 95.

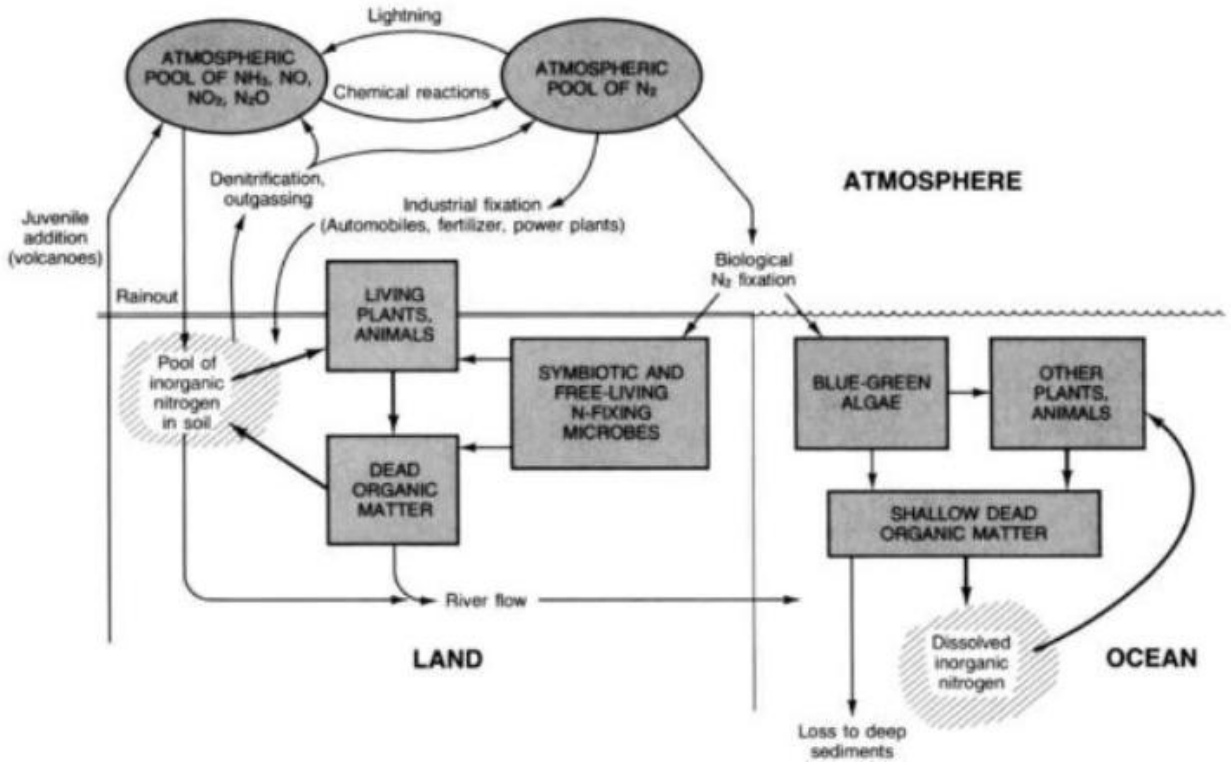

FIGURE 3-5 The global nitrogen cycle. The largest flows are denoted by the heavier arrows.

Nitrate compounds, whether put in the soil by biological processes or by rainout from the atmosphere or by application of inorganic fertilizers, are usually quite soluble; thus, those that escape uptake by plants or bacterial denitrification may be transported far and wide by the flow of surface water, or they may accumulate in the much more slowly moving reservoirs of groundwater.

Global nitrogen cycle. The biologic and inorganic steps in the global nitrogen cycle are depicted together in Figure 3-5. Estimates of the sizes of some of the major flows are summarized in Table 3-9, with an indication of the approximate uncertainties in those figure. [42]

Note that industrial nitrogen fixation may have been equal to half of natural fixation already in 1975, a very significant perturbation in a global process. It is unlikely that natural denitrification processes are keeping pace with the increased load of fixed nitrogen (although the data are far from adequate to prove this). If this is the case, fixed nitrogen must be accumulating in one or more of the pools: biomass, dead organic matter, inorganic pools in soil and oceans, or groundwater. How much increase in global river flow of nitrates has increased because of industrial fixation is quite uncertain--and controversial (see Chapter 11). Also very unclear is the partitioning between N_2O and N_2 of gas flow to the

[42] The ranges of uncertainty are from the workshop summarized by the Institute of Ecology (TIE) in *Man in the living environment*, and from comparisons of some of the principal published reviews of nitrogen cycle data and estimates, namely Garrels, Mackenzie, and Hunt, *Chemical cycles*; chapter 8; Delwiche, *The nitrogen cycle*; Deevey, *Mineral cycles*; Burns and Hardy, *Nitrogen fixation*. A set of estimates giving natural fluxes around 10 times greater than the central values presented here for some fixed-nitrogen forms appears in E. Robinson and R. C. Robbins, Gaseous atmospheric pollutants from urban and natural sources, in *Global effects of environmental pollution*, S. F. Singer, ed. Those estimates apparently were not considered credible by those attending the TIE workshop.

TABLE 3-9 Magnitudes of Flows in the Global Nitrogen Cycle

	Magnitude (10^{12} moles N/yr)	*Approximate uncertainty*

To Land	5	÷ × 2
To Ocean	2	÷ × 2
RIVER FLOW OF FIXED NITROGEN (TOTAL)	2	÷ × 2

[a]The symbol ÷ × 2 means the value could be from 0.5 to 2 times the magnitude given.

[b]The figures for assimilation of fixed nitrogen by terrestrial and oceanic plants are derived from the net primary production (carbon) estimates of Table 3-4, using the molecular carbon/nitrogen ratios of 41/1 for terrestrial plant production and 5.7/1 for oceanic plant production (TIE, *Man*, p. 71). The figure for terrestrial plants differs from the molecular carbon/nitrogen ratio in the terrestrial pool of plants (about 90/1, according to Deevey, *Mineral cycles*) because the pool is mostly wood, whereas the annual production contains a much higher proportion of leaves.

Sources: C. C. Delwiche, *The nitrogen cycle*; R. M. Garrels, F. T. Mackenzie, and C. Hunt, *Chemical cycles and the global environment*, chapter 8. The Institute of Ecology (TIE), *Man in the living environment*, chapter 3. R. C. Burns and R. W. F. Hardy, *Nitrogen fixation in bacteria and higher plants*.

atmosphere from denitrification, and what factors control the partitioning. [43]

Perhaps the most striking feature of the data in Table 3-9 is the margin by which the rate of uptake of fixed nitrogen for incorporation into protein by plants, fungi, and bacteria exceeds the rate of new fixation by both natural and industrial processes (roughly a factor of 35). The internal loops of the nitrogen cycle, which can be summarized as uptake/synthesis → excretion/death → decomposition → uptake/synthesis (with the nitrogen remaining in the fixed state at all times), thus embody a great deal more of the cycle's total activity than do the external loops, wherein nitrogen enters and leaves the atmospheric pool of N_2 (see Figure 3-5). Among other things, this suggests that disturbances directly affecting the strong internal loops would lead much more

quickly to large-scale consequences than would disturbances affecting fixation of atmospheric nitrogen.

Estimates of the sizes of some of the pools of nitrogen in the global cycle appear in Table 3-10. A significant contrast with other biogeochemical cycles considered here is the large fraction of the total reservoir of nitrogen that is tied up in the atmospheric pool; for all other

[43]For a synopsis of such insights as are available, see Burns and Hardy, *Nitrogen fixation*.

nutrients, the pools in sediments and sedimentary rocks are largest.

From the information on pools in Table 3-10 and that on flows in Table 3-9, some important characteristic times can be deduced, albeit with substantial uncertainties. For example, the assimilation of fixed nitrogen by terrestrial plants "turns over" the nitrogen in the combined dead organic matter and inorganic soil nitrogen pools roughly every 100 to 600 years; assimilation of fixed nitrogen by ocean plants turns over the corresponding ocean pools every 40 to 350 years. The stock of nitrogen in the main terrestrial and oceanic loops (biomass, dead organic matter, fixed nitogen in soil and water) is replenished by natural fixation every 1200 to 35,000 years-turnover times that apparently would be cut by 50 percent by the addition of the 1975 rate of industrial fixation. The atmospheric pool of N_2 is turned over only once every 15 million to 60 million years by natural fixation. By contrast, N_2O has an atmospheric residence time of perhaps ten to thirty years (unless its production and destruction rates have been badly misjudged), and NH_3/NH_4 and NO/NO_2 have residence times of a month or two. The shortest residence time among atmospheric nitrogen forms is that of NO_2-and NO_3- -- perhaps a day.

Clearly, human interventions in the nitrogen cycle cannot possibly influence the atmospheric concentration of N_2 on any time scale of practical interest. On the other hand, the concentrations of other atmospheric forms of nitrogen could be influenced on time scales of a few months to a few years, and the sizes of the major pools of fixed nitrogen in the soil and surface water could be influenced in a matter of a few to a few tens of human generations. Significant local disruptions in soil and surface water can of course occur more quickly, and they have (see Chapter 11).

Phosphorus

Phosphorus, while absolutely essential to life, is required in quantities only about one-tenth as great as nitrogen. [44] Nevertheless, phosphorus probably is the

TABLE 3-10 Sizes of Pools in the Global Nitrogen Cycle

Pool	Size (10^{12} moles N)
LAND	
Biomass (99% in plants) [a]	400-1,000

Pool	Size (10^{12} moles N)
Dead Organic Matter [a]	5,000-60,000
Inorganic Fixed Nitrogen in Soil [b, c]	5,000-15,000
OCEANS	
Biomass (80% in plants?) [a, c]	10-300
Dead Organic Matter [a, d]	9,000-60,000
Dissolved Inorganic Nitrogen in Oceans [b, c]	4,000-50,000
Dissolved N_2 in Oceans [d, e]	1,500,000 ± 10%
SEDIMENTS [c, d]	29,000,000-70,000,00
ATMOSPHERE [c, d, f]	
N_2	282,000,000
N_2O	90 ± 50%
NH_3, NH_4^+	2 ± 50%
NO, NO_2	0.4 ± 50%

[a] Based on the range of values for carbon pools in Table 3-6, with carbon/nitrogen ratios as follows: land biomass, 90/1 (Deevey, "Mineral cycles"; Garrels, Mackenzie, and Hunt, *Chemical cycles*); land, dead organic matter, 12/: (Woodwell and Pecan, eds., *Carbon*, p. 369); ocean biomass and dead organic matter, 6.6/1 (Garrels, Mackenzie, and Hunt, *Chemical cycles*).

limiting nutrient in more circumstances than any other element because of its scarcity in accessible form in the biosphere.

Two chemical properties of phosphorus are responsible for this natural scarcity, which is much more acute than one might expect from the size of the total phosphorus pool in sedimentary rocks. One is that phosphorus does not form any important gaseous compounds under conditions encountered in the environment. [45] The second is the insolubility of the salts formed by the phosphate anion $PO_4 \equiv$ and the common cations Ca^{++}, Fe^{++}, and Al^{+++}. The lack of gaseous compounds deprives the phosphorus cycle of an atmospheric pathway linking land and sea and thus slows the closing of the cycle to the almost inconceivably sluggish pace of

[44] N/P atom ratio is 9/1 in land plants, according to Deevey, *Mineral cycles*, and 16/1 in marine plants, according to Garrels, Mackenzie, and Hunt, p. 67.

[45] Phosphene gas produced in swamps is negligible in quantity. See, for example, Institute of Ecology, p. 50.

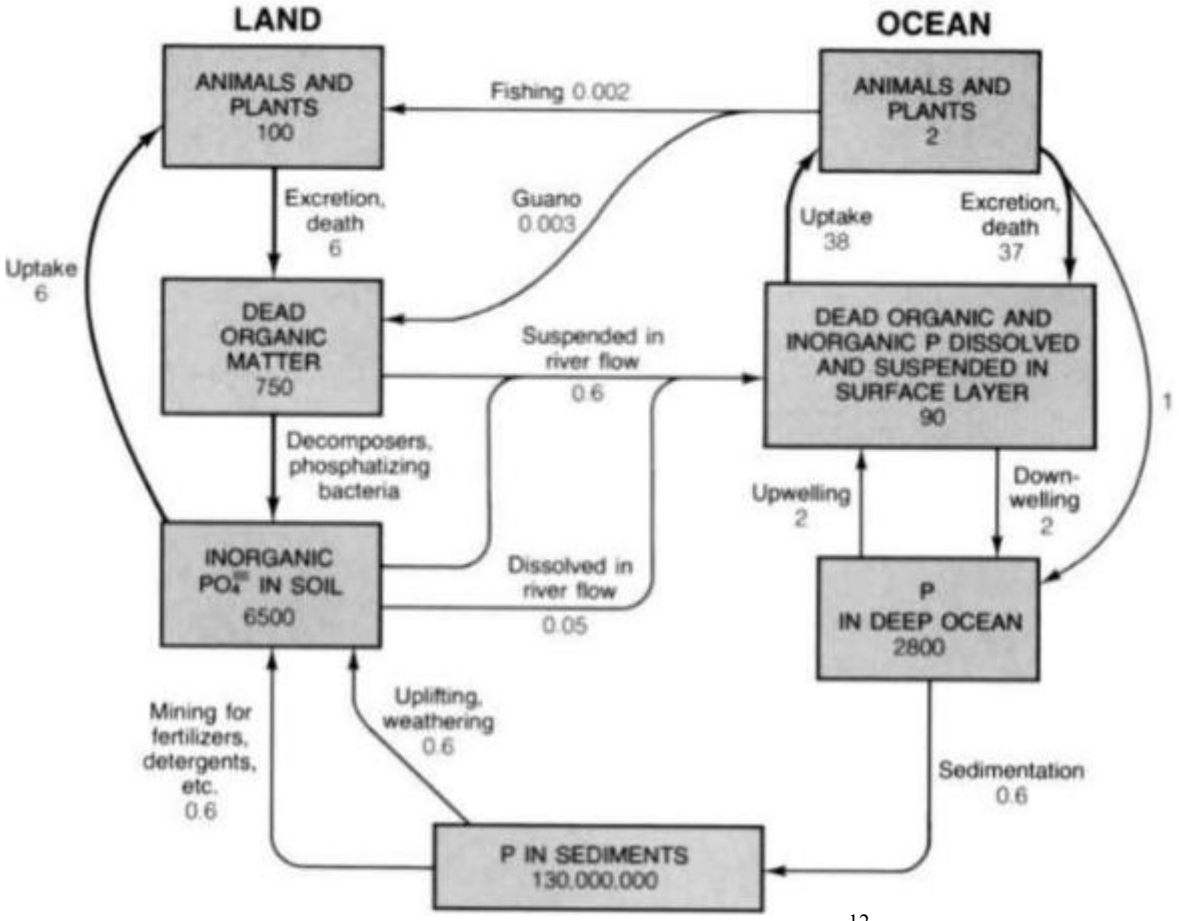

FIGURE 3-6 The global phosphorus cycle. Pools are in units of 10^{12} moles; flows, in units of 10^{12} moles per year.

sedimentation, uplift, and weathering. That phosphate forms insoluble compounds with constituents of most soils retards its uptake by plants and slows its removal and transport by surface water and groundwater.

The main characteristics of the global phosphorus cycle are indicated in Figure 3-6. The numbers given there for the organic pools and flows are based on the carbon-cycle estimates summarized in Figure 3-3, combined with the carbon/phosphorus ratios for different kinds of organic matter, as discussed above. These phosphorus numbers, therefore, should not be considered any more precise than the carbon numbers (roughly ± 50 percent in the flows, and multiplicative factors of 2 or 3 larger or smaller in the pools). In fact, they may be less precise than this, because of inaccuracy in the estimates of carbon/phosphorus ratios on a global basis.

As in the nitrogen cycle, the inner loops between living material and the soil (or ocean) pool of decomposition products appear to contain most of the flow in the phosphorus cycle. Also in analogy to the nitrogen cycle, a group of bacteria (phosphatizing bacteria) makes a living converting the phosphorus compounds characteristic of living tissue into inorganic phosphate.

The links between the terrestrial and oceanic parts of the phosphorus cycle are very weak. Little dissolved phosphorus is carried by rivers, because of the low solubility of phosphorus salts (the amount carried in suspended soil particles by erosion is about ten times as large). Aside from the slow link provided by the sedimentary cycle, the only sea-to-land transport is in fish and shellfish harvested from the sea and consumed on land, and in the excrement that fish-eating seabirds deposit on land. These flows together amount to about one-hundredth of the erosion loss. The idea that the sedimentation rate roughly balances the river flow and is balanced in turn by the rate of uplifting and weathering is an assumption, not an experimentally determined fact. The assumption amounts to supposing that the

various pools have reached a natural equilibrium over geologic time and that the extra phosphorus now being mobilized by civilization's mining of phosphate rock is not yet reaching the rivers in appreciable quantities. [46] Quite possibly, the acquisition of more data shedding light on historical and contemporary phosphorus loads in rivers will change this picture.

Worldwide mining of phosphate rock amounted to 94 million metric tons in 1972, which corresponds to the 0.6 trillion moles of phosphorus represented under "mining" in Figure 3-6. [47] Seventy to 80 percent of this amount is added to the land as fertilizer -- mostly in the forms of ammonium phosphate [$(NH_4)_3PO_4$], triple phosphate [$Ca(H_2PO_4)_2$], and superphosphate, which is a mixture of triple phosphate and gypsum [$CaSO_4 \cdot 2H_2O$]. [48] Phosphorus is also used in detergents (three-quarters of the nonfertilizer use), animal-feed supplements, pesticides, medicines, and a host of industrial applications. [49] It seems reasonable to assume that most of these uses eventually lead to the deposition of the phosphorus in the environment.

Over the long term, civilization's mobilization of phosphorus by mining phosphate rock must certainly be considered a significant perturbation in the cycle. The time in which mining at the level of the mid-1970s would double the pool of phosphate in the soil (assuming the additions all remained there, which is unlikely) would be around 10,000 years. There are some reasons to think that this very long-term problem should not be our primary worry about the phosphorus cycle, however. One is that the local perturbation of adding phosphorus to agricultural land is far greater than these global-average numbers indicate and can be important much sooner (see Chapter 11). A second is that known and suspected *minable* phosphorus resources -- as distinguished from those too dispersed to recover -- could not support a drain of 0.6 trillion moles of phosphorus per year for 10,000 years (see Chapter 9); this situation suggests, especially in the face of a demand for phosphorus that is not constant but, rather, is doubling about every fifteen years, that exhaustion of the concentrated supplies of phosphorus is more imminent than overloading the cycle globally. These aspects of civilization's effect on the phosphorus cycle are, of course, closely related. It is largely because society breaks the main internal loop of the phosphorus cycle on agricultural land (by "exporting" from the land the phosphorus-containing crops and crop residues and not returning the sewage that in time receives this phosphorus) that the heavy supplement of mined phosphorus is required.

Sulfur

The sulfur cycle is important, chemically complicated, and not yet well understood quantitatively. Its importance has several dimensions: the essential role of sulfur in the structure of proteins; the circumstance that the main gaseous compounds of sulfur are toxic to mammals; the fact that sulfur compounds are important determinants of the acidity of rainfall, surface water, and soil; and the possibility that sulfur compounds may play a role in influencing the amount of molecular oxygen in the atmosphere in the very long term. [50] The complexity of the sulfur cycle, like that of nitrogen, arises mainly from the large number of oxidation states the element can assume. Some of the principal compounds and groups in which sulfur participates are listed in Table 3-11.

Many transformations among the different oxidation states of sulfur are carried out by bacteria. Which of the several kinds of sulfur bacteria (and, hence, which reactions) prevail in a given situation depends on the presence or absence of oxygen and light and the acidity or alkalinity of the environment. [51] The principal biologic sulfur transformations are summarized in Table 3-12. Essentially all of the bacterial activity probably takes place in wet media -- moist soil, swamps, the muds of lakeshores and estuaries, and (to an uncertain degree) the

TABLE 3-11 Chemical Forms of Sulfur

Formula	Name	Oxidation number	Comments
H_2S	Hydrogen sulfide	-2	"Rotten egg" gas, extremely toxic
HS-	Hydrosulfide ion	-2	Constituent of amino acids
S=	Sulfide ion	-2	Forms insoluble compounds with metals
S_2=	Disulfide ion	-1	Plays crucial role in stiffening protein
S_2,S_6,S_8	Elemental sulfur	0	Crystalline solid
SO_2	Sulfur dioxide	+4	Colorless, toxic gas
H_2SO_3	Sulfurous acid	+4	Weak acid from SO_2 plus water
SO_3	Sulfur trioxide	+6	Gas from oxidizing SO_2 in air
H_2SO_4	Sulfuric acid	+6	Strong acid from SO_3 plus water
SO_4=	Sulfate ion	+6	Forms many compounds in atmosphere and soil

TABLE 3-12 Sulfur Chemistry of Biologic Assimilation and Decomposition

Transformation	Mechanism
$SO_2, SO_4^{=} \longrightarrow$ organic S	Assimilation and synthesis by plants
Organic S $\longrightarrow H_2S$	Many anaerobic and aerobic bacteria
Organic S $\longrightarrow SO_4^{=}$	Most plants and animals, many bacteria
$SO_4^{=} \longrightarrow H_2S$	Anaerobic bacteria (*Desulforvibrio*, *Desulfotomaculum*)
$H_2S \longrightarrow S$ $\longrightarrow SO_4^{=}$	Aerobic bacteria (*Thiobacillus*), photosynthetic bacteria (*Chromatium*, *Chlorobium*)

open water of lakes and oceans. [52] The presence of dissolved oxygen favors decomposition of organic sulfur to form sulfates; the absence of oxygen favors decomposition to form sulfides.

Reactions involving the oxidation of sulfur also take place without the intervention of bacteria. Hydrogen sulfide that has been produced by bacterial decomposition is readily oxidized chemically by dissolved oxygen in water, producing sulfite and sulfate. (The mean lifetime of H_2S in water containing appreciable dissolved oxygen appears to be on the order of tens of minutes.) [53] Hydrogen sulfide emitted to the atmosphere is oxidized to sulfur dioxide (SO_2) by atomic oxygen (O), molecular oxygen (O_2), and ozone (O_3). These reactions are too slow in clean, dry air to account for the observed atmospheric residence time of H_2S of only a few hours; possibly most of the action takes place when the reacting gases are dissolved in atmospheric water droplets or absorbed on the surfaces of suspended particles. [54] Sulfur dioxide is further oxidized in the atmosphere to form sulfur trioxide and various sulfates, including sulfuric acid. Photochemical oxidation of SO_2 exists but is too slow (0.1 percent per hour) to account for the observed lifetime of SO_2 in the atmosphere (minutes to days). Much more important, apparently, is the dissolving of SO_2 in atmospheric cloud and water droplets to form sulfurous acid (H_2SO_3), followed by the oxidation of this sulfurous acid to sulfuric acid (H_2

SO_4). The oxidation is sped up by various metal salts dissolved in the droplets, which serve as catalysts. [55]

The global sulfur cycle is represented in schematic and simplified form in Figure 3-7. The estimates given there

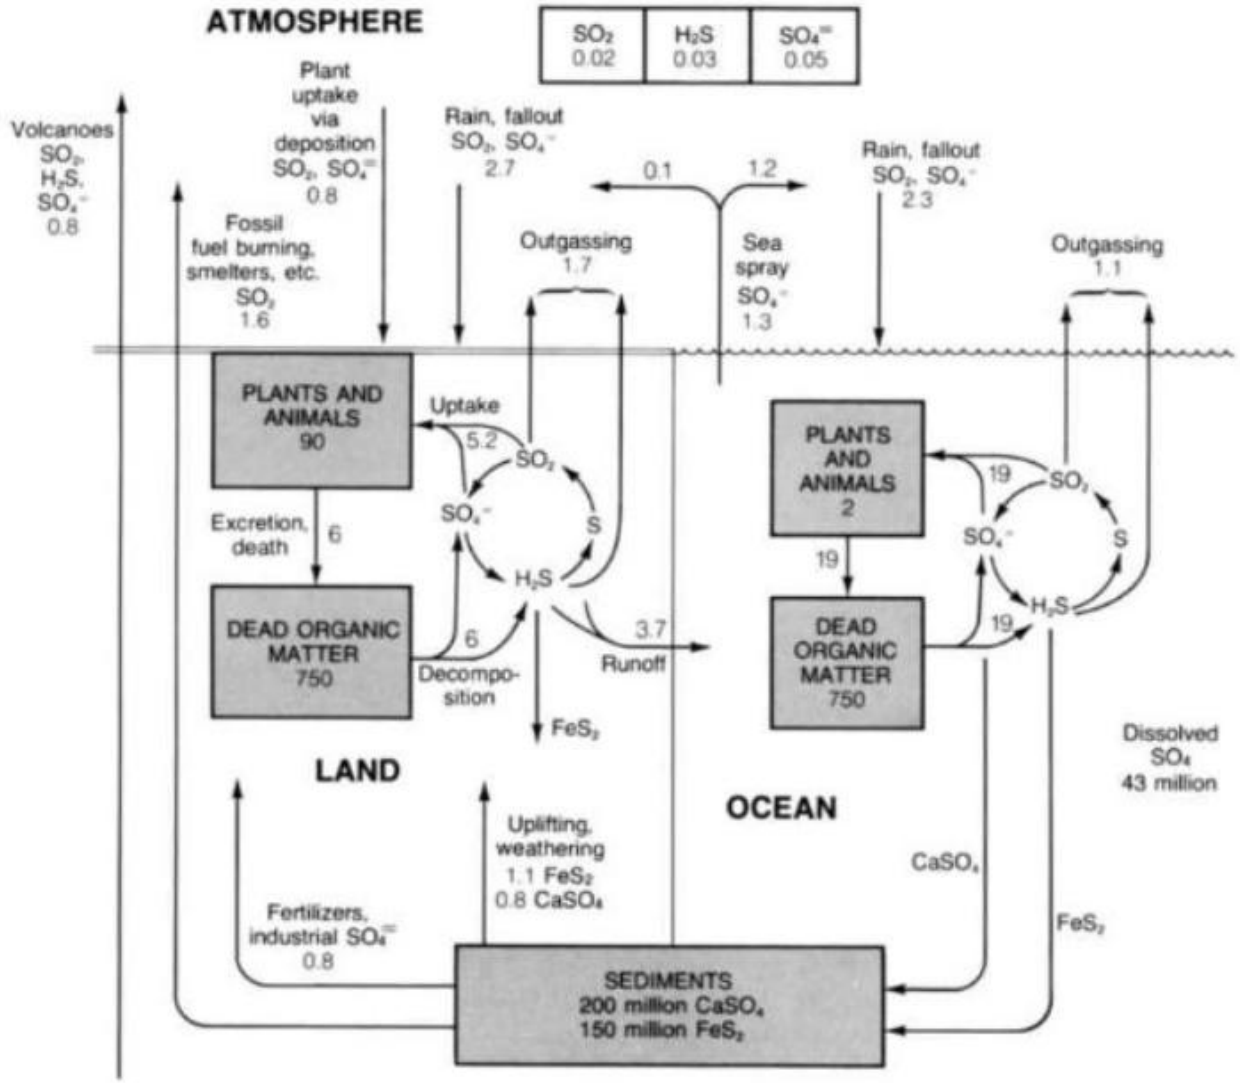

FIGURE 3-7 The global sulfur cycle. Pools are in units of 10^{12} moles of sulfur; flows, in units of 10^{12} moles per year.

for the magnitudes of pools and flows contain all the uncertainties encountered in the carbon, nitrogen, and phosphorus cycles, and more. The pools in organic matter were computed from the carbon estimates given in Figure 3-3, together with carbon/sulfur atom ratios of 800/1 in living terrestrial plants and 106/1 in marine plants and dead organic matter. [56] Uptakes were computed from the phosphorus figures in Figure 3-6 (in turn, based on carbon) with phosphorus/sulfur atom ratios of 1/1 for land plants and 2/1 for ocean plants. [57] The global average sulfur content of organic matter is not considered as well established as the carbon, nitrogen, and phosphorus contents, however.

The values for the flows to the atmosphere of SO_2 and H2S originating in bacterial decomposition were *chosen* in Figure 3-7 to produce a balance between inputs and outputs of sulfur to the atmosphere; there are at this writing no adequate data with which to support or reject those values for the SO_2 and H_2S flows, nor are measurements of the atmospheric pools of H_2S, SO_2, and SO_4 = accurate enough to determine whether they are really constant at present or not. The apparent mean lifetime of sulfur in all forms in the atmosphere (about 10^{11} moles of sulfur altogether) is about one week. The main pathways by which sulfur leaves the atmosphere are dry fallout and rainout of SO_2 and sulfates [the latter largely as H_2SO_4 and neutral ammonium sulfate, $(NH_4)_2SO_4$] and uptake of SO_2 and sulfates directly from the atmosphere by plants. [58]

---

[56] Ratios are from Garrels, Mackenzie, and Hunt, *Chemical cycles*, p. 67.

[57] The land-plant ratio is based on date for uptake by crops in M. B. Jones , Sulfur in agricultural lands, in *Sulfur*, Missouri Botanical Garden, pp. 141-168; the ratio for ocean plants, from Garrels, Mackenzie, and Hunt, *Chemical cycles*, p. 67, assuming high turnover tends to make P/S ratio the same in uptake as in the pool.

[58] See, for example, J. G. Severson, Jr., Sulfur and higher plants, in *Sulfur*, Missouri Botanical Garden, pp. 92-111.

Sulfates and sulfuric acid that fall on the land can usefully restore nutrient sulfur that has been removed by cropping, or they can acidify soil and surface water with possible adverse effects on ecosystems, depending on the circumstances. The human input of sulfur to the atmosphere had reached a magnitude of about half of the natural inputs by the early 1970s (if the estimates of the natural flows in Figure 3-7 are roughly correct) and had apparently caused an increase in the acidity of rainfall over large regions (see Chapter 11). The human perturbation in the sulfur cycle appears all the more significant when the additions to land and surface water of sulfur fertilizer and industrial sulfuric acid are reckoned in, since they amount to about half as much as the human sulfur inputs to the atmosphere. Figure 3-7 indicates an annual excess of 0.8×10^{12} moles of sulfur accumulating in the soil or terrestrial vegetation and leaves open the possibility that the other 1.6×10^{12} moles of the annual human sulfur input are accumulating in the oceans. Again, these are little more than educated guesses; knowledge of the magnitude of the relevant pools

and flows is inadequate to determine what really is happening in this much detail. We simply know the extra sulfur must go somewhere.

Potentially capable of altering the atmospheric oxygen pool over the very long term -- tens to hundreds of millions of years -- is the balance or imbalance between weathering and sedimentation of highly insoluble iron sulfide (FeS_2). Weathering of FeS2 produces sulfate, which under some circumstances can be precipated into sediments as gypsum ($CaSO_4 \cdot H_2O$) before being reduced back to sulfide. The precipitation of gypsum, of course, takes the oxygen in the sulfate (which was extracted from the atmosphere during the weathering of the FeS_2) with it. If more sulfur is added to sediments as gypsum than is removed from sedimentary rocks as gypsum -- that is, if there is an increase of sedimentary $CaSO_4 \cdot H_2O$ at the expense of FeS_2 -- then a steady drain on atmospheric oxygen could result. There is evidence that this phenomenon was actually occurring during the Permian period about 250 million years ago, but how much oxygen depletion occurred is unclear and controversial. [59]

One rather powerful analytic technique offers hope of resolving some of the important uncertainties about the sulfur cycle, in both its short-term and long-term aspects. The technique exploits the existence of two stable isotopes of sulfur -- ^{32}S and ^{34}S -- the relative proportions of which differ in sulfur compounds of different origins. The average abundance ratio of ^{32}S atoms to 34S atoms in nature is thought to be about 22.2/1, but sulfur in seawater has 2 percent more ^{34}S than this, biologically produced hydrogen sulfide has between 2.3 percent less and 0.6 percent more, and so on. [60] Since instruments are now available that can measure this ratio with great precision, in a sample it is possible to determine, for instance, the fraction of a given flow of sulfur that comes from different pools (if they have different ratios). This technique has been used successfully to determine the origins of pollutant sulfur in several places around the world, and to investigate the fate of sulfur in the sedimentary cycle in earlier geologic eras. Discrimination on the basis of isotope ratios also has great potential for untangling some of the complexities of the carbon, nitrogen, phosphorous, and other cycles.

OTHER NUTRIENTS AND GEOGRAPHICAL VARIATIONS

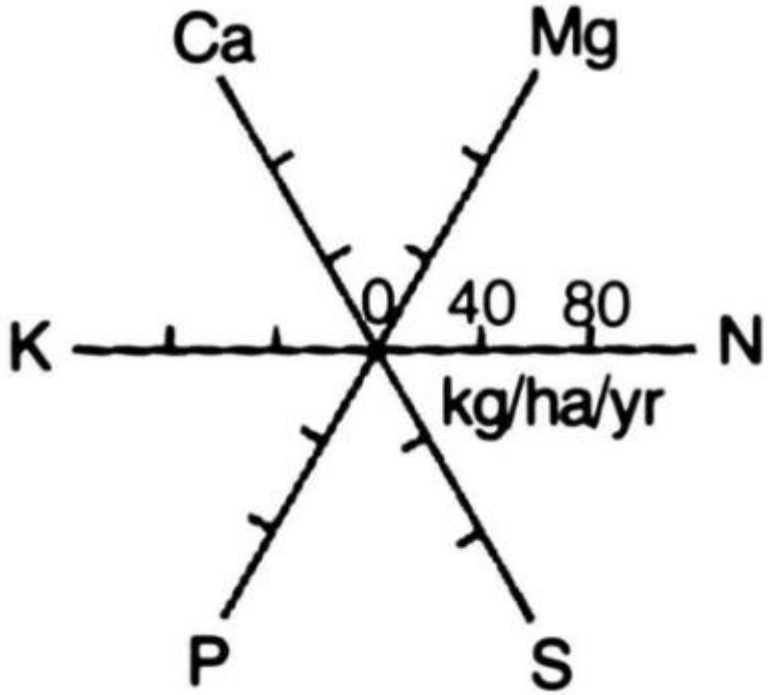
The nutrients just considered in detail are, of course, not the only important ones, nor are the quantitative relationships shown for global averages uniformly valid in different kinds of biological communities (or even in the same general kinds of communities in different places). We chose carbon-oxygen-hydrogen, nitrogen, phosphorus, and sulfur either because of their quantitative importance globally (C-O-H and N) or because of special characteristics of their biochemical roles and environmental behavior (P and S), and because a larger literature exists on these nutrients than on the others.

Other nutrients mobilized and used in large quantities include calcium, magnesium, and potassium. All of these are present in seawater in large amounts (see Table 2-7) and in rainwater and surface water in much smaller

---

[59] Garrels, Mackenzie, and Hunt, *Chemical cycles*, pp. 87-89.

[60] For a thorough discussion, see B. D. Holt, "Determination of stable sulfur isotope ratios in the



environment", *Progress in nuclear energy, analytical chemistry*, vol. 12, no. 1 (1975), pp. 11-26.

amounts, and are added to the soil by rock weathering as described above in the discussion of the sedimentary cycle. In some circumstances, dust raised by the wind and deposited as dry fallout elsewhere forms an important additional link in the cycling of these nutrients, and in other circumstances the mobilization rate from rocks is increased by the rock-splitting action of deep tree roots in the weathering process. [61]

The cycling of the macronutrients nitrogen, phosphorus, sulfur, calcium (Ca), magnesium (Mg) and potassium (K), in various kinds of biological communities -hardwood forests, jungles, deserts -- has been extensively studied since the 1960s, and a large body of data is accumulating. [62] The enormous variety in the nutrient budgets of different communities in different places is indicated graphically in Figure 3-8, which summarizes some of these studies. The differences among communities of the same type (for example, the temperate hardwood forests) result from differences in soil, quantity of rainfall, local rainwater chemistry, dry fallout characteristics, and detailed species composition. (All these factors, of course, interact.)

One respect in which the presentation of global nutrient flows may be particularly misleading is in failing to reveal what part of the soil pool of nutrients is actually accessible to plants. This factor varies widely from one region to another, but it is known that in many important biological communities, such as tropical jungles, the actual availability of soil nutrients is very low. Such a cycle, in which nutrients spend a long time in a large pool of living and dead organic matter and a short time in a small pool of accessible inorganic nutrient forms, is called a tight cycle. The opposite situation, with a large pool of accesssible inorganic nutrient forms compared to the organic pool, is called a loose cycle. [63]

Another important distinction left out of the global estimates is between agricultural and nonagricultural systems. Although the human inputs of nitrogen, phosphorus, and sulfur fertilizers are already noticeable perturbations in these cycles on a global basis, their effects in the agricultural systems where they are applied are much larger than the global figures indicate. Much more extensive local studies are needed to resolve the questions that these magnified local perturbations raise (see Chapter 11).

CHAPTER 4
Populations and Ecosystems

One of the penalties of an ecological education is that one lives alone in a world of wounds. Much of the damage inflicted on land is quite invisible to laymen. An ecologist must either harden his shell and make believe that the consequences of science are none of his business, or

he must be the doctor who sees the marks of death in a community that believes itself well and does not want to be told otherwise.

-- Aldo Leopold, *Round River*

Humanity shares the physical vehicle of Earth with an enormous diversity of other living things--plants, animals, and microorganisms. There may be as many as 10 million different kinds--*species*--of organisms alive today. In turn, each species consists of one or more *populations*, a population being a group of individuals more or less isolated from other populations of the same species. [1] This diverse array is not static. Populations of organisms change continually in size and genetic composition in response to changes in their physical environments and in response to changes in other populations. The populations of plants, animals, and microorganisms of Earth, or of any area of Earth, make up a *biological community*, a community bound together by an intricate web of relationships. Of course, this living web is embedded in the physical environment, interacts with it, and modifies it.

The interdependence that characterizes the physical and biological elements of the environment has led ecologists to coin the term *ecosystem* (short for ecological system) for the functional unit that includes both *biotic* (living) and *abiotic* (nonliving) elements. In order to understand humanity's role in ecosystems, it is necessary

[1] The reader interested in some of the complexities of the definitions of *population* and *species* should refer to Paul R. Ehrlich, R. W. Holm, and D. R. Parnell , *The process of evolution*, chapters 5 and 13.

to have some grasp of the functioning of both biotic and abiotic elements in these systems and of their properties in combination. You have already been introduced to the major abiotic features of the environment. In this chapter the biotic elements are discussed, starting with the properties of populations and then moving on to the integration of populations into ecosystems.

POPULATION DYNAMICS

The study of changes in population size-*population dynamics*--is of enormous practical importance to humankind. People are continually in the position of wishing to predict or influence the sizes of populations of other organisms or of some group of *Homo sapiens* or of humanity as a whole. Will there be a spruce budworm outbreak next year? Are peregrines threatened with extinction? Can the present harvest of sei whales or Peruvian anchovetas be sustained? How many people will be living in the United States in the year 2000? Answering any of these questions would require some knowledge of population dynamics.Although the details of population dynamics can be endlessly complex, the essence of analyzing changes of numbers is relatively straightforward. A number of points should be kept clearly in mind throughout the discussion.

The analysis basically amounts to keeping track of inputs and outputs in a population (Box 2-2).

The inputs are natality and immigration. (*Natality* is used instead of births because individuals that hatch from eggs or grow from seeds are not normally said to have been

"born.")
The outputs are mortality (deaths) and emigration.
In most discussions in this chapter, migration is ignored, and the analyses focus on natality and mortality.
In populations with overlapping generations (such as human populations), the *age composition*--that is, the proportion of individuals in various age classes--has a substantial effect on the future course of population growth. In populations where adults of one generation invariably die before their offspring mature (like many insects), the generations do not overlap, and the analyses are greatly simplified.

Although the mathematics of human population dynamics is identical to that of other animal populations with overlapping generations, [2] a subtle difference in approach has developed between ecologists, who are mainly interested in nonhuman populations, and the social scientists known as demographers, who study the dynamics of human populations alone.

Demographers concern themselves primarily with factors that influence natality--that is, the birth rate. They assume that death rates in *Homo sapiens* will reach a low point and remain there as diseases and other threats are conquered, and they therefore concentrate on the interesting and important questions of how and when birth rates may change in response to social or environmental pressures.

In contrast, ecologists--especially those who work with invertebrates--tend to focus on mortality. The reproductive rates of most nonhuman organisms can change dramatically only over evolutionary time (hundreds or thousands of generations). Ecologists have considered populations to have a rather fixed *reproductive potential* (a term no longer in vogue) and have viewed varying mortality rates as the prime determinants of population size. To oversimplify, demographers have viewed the populations they study as having varying inputs and fixed outputs, whereas ecologists have viewed theirs as having fixed inputs and varying outputs. The differences of approach in the two scientific disciplines are quite interesting and can be seen by comparing this discussion with that in Chapter 5, which deals with demography.

In the remainder of this section of text, the discussion centers primarily on the dynamics of nonhuman populations, although most of the points apply to human beings as well. The treatment varies considerably in depth and complexity. The most basic concepts of population dynamics--for example, instantaneous birth and death rates, exponential growth, growth with restraint, age composition, population structure--are introduced at a

[2] For a more thorough introduction to the mathematics of population dynamics, see: C. J. Krebs, *Ecology: The experimental analysis of distribution and abundance*; R. W. Poole, *An introduction to quantitative ecology*; R. E. Ricklefs, *Ecology*; J. Roughgarden, *Theory of population genetics and evolutionary ecology, an introduction*; and E. O. Wilson and W. H. Bossert, *A primer of population biology*, Sinauer, Stamford, Conn., 1971. Only a brief outline is given here.

BOX 4-1 Symbols Used in Population Dynamics

N population size

$N(t)$ population size at time t. Some texts use N_t.

$N(0)$ population size at time zero (starting population size)--sometimes written N_0.

t time in any units

T length of a generation

$\frac{dN}{dt}$

instantaneous rate of change of population size

IRI instantaneous rate of increase in population size

b birth rate

d death rate

r intrinsic rate of increase (instantaneous rate of increase per individual)

r_m maximum intrinsic rate of increase

λ lambda, the finite rate of increase, N_1/N_0

e the base of natural logarithms (approximately 2.718)

ln natural logarithm (*l*og *n*atural)

K carrying capacity (the maximum number of individuals that can be supported in a given environment)

c a constant

α alpha, a competition coefficient

β beta, a competition coefficient

x age as a variable

lx the proportion or number of survivors of a birth cohort at age x.

m_x the average number of female offspring produced by a female of age x

Σ sum of . . .

$$\sum_0^\infty$$

sum from zero to infinity of . . .

R_0 net reproductive rate,

$$\sum_0^\infty l_x m_x$$

NRR net reproductive rate

${}_nq_x$ in life tables, the proportion of persons alive at the beginning of an age interval who die during that interval

${}_nd_x$ in life tables, the number of persons from a given birth cohort dying during an age interval

${}_nL_x$ in life tables, the number of persons in an age interval in a hypothetical stationary population supported by 100,000 annual births and subject to the actual l_x schedule of the population

T_x in life tables, the total number of persons in the stationary population in an age interval and all subsequent age intervals. Equals

$$\sum_x^\infty {}_nL_x$$

level that assumes no prior familiarity with the field. For the more ambitious reader, however, there are also some excursions into subtleties and details at a somewhat more mathematical level. This material (much of it displayed in boxes) can be skipped without loss of continuity but will repay the scrutiny of those who wish a clearer picture of what the study of population dynamics really entails. The notation used in this discussion is summarized in Box 4-1.

Instantaneous Rate of Increase

A logical beginning is to consider the problem of measuring the rate of change in a population--that is, the rate of increase or decrease--*at a given moment*. An average rate is easy to calculate. Suppose at the beginning of a year a population of mice contains 100 individuals and at the end of the year it contains 220. The population has grown at an average rate of 10 individuals per

month, or 120 per year. This is analogous to, say, calculating the average rate of speed of an automobile trip by dividing the distance between start and finish by the time it consumes. Thus, if the car progresses 200 miles in 10 hours, the average rate of speed is 20 miles per hour (note that rates are always expressed in terms of a unit of time).

Of course, the growth of the mouse population might have been the result of 30 female mice all having litters in a single month, together with some deaths scattered evenly over the rest of the year, just as the average speed of 20 miles per hour might have been achieved by driving 80 miles an hour for a 3-hour spurt and backing up slowly for the other 7 hours. In other words, the instantaneous rate of change in both cases may have been high and positive for a brief period and negative for the rest of the time.

What we will calculate now is the *instantaneous rate of increase* (IRI) for a population--a quantity analogous to the readout on a speedometer, which tells how fast the car

is going at a given instant. The IRI will be positive when the population is growing and negative when it is shrinking--a negative IRI being analogous to a speedometer reading when the car is backing up.

It is reasonable to expect that the rate of change in the size of a population (let the size be *N*) in the course of time (*t*) will itself depend on the population size. (A mathematician would say the rate of change of *N* is a *function* of *N*.) Whatever the average individual's contribution to population growth, it must be multiplied by the population size in order to determine the amount of change in the population as a whole. These simple relations, expressed in the notation of calculus, yield the most basic equation of population dynamics: [3]

instantaneous rate of increase	=	average individual contribution to population growth	multiplied by	population size
$\frac{dN}{dt}$	=	r	$\times$	N $= rN$

Here *dN/dt* is the conventional notation for instantaneous rate of change of *N* with *t*. The average individual contribution (r) is the *instantaneous rate of increase (per individual)*, usually called the intrinsic rate of increase by biologists. [4] Thus, at a given moment, if a population contains a million individuals (*N*) and is growing at that moment at the rate of 100,000 individuals per year (*dN/dt*), then *r* would be 0.10. In other words, the growth rate amounts to one-tenth of an individual per individual per year. In recent years the human population has been growing with an *r* of about 0.02; that is, roughly one-fiftieth of a person has been added per person per year to the total population.

The factor *r* is more easily understood if it is split into its input and output components. If input is *b* (the instantaneous birth rate) and output is *d* (the instantaneous death rate), then *r* is seen to be simply *b* minus *d*. (We are ignoring migration.) If more individuals are being born at a given instant than are dying, the population is growing, and r is positive. If more are dying than are being born, the population is shrinking, and *r* is negative.

Exponential Growth

The equation $dN/dt = rN$ relates the IRI to population size itself. It does not, however, show explicitly how the size of a population (growing according to this relationship) at one time is related to the size at another time. Consider, for instance, a population whose size at an initial time ($t = 0$) is known and is denoted $N(0)$. How can one calculate the size t units of time later [$N(t)$]? [5] The answer can be derived from the equation for IRI by elementary calculus. For the case when r itself does not vary with time, one obtains:

$$\left\{\begin{array}{c}\text{Size after}\\ t \text{ time}\\ \text{units}\end{array}\right\} = \left\{\begin{array}{c}\text{initial}\\ \text{size}\end{array}\right\} \text{ multiplied by } \left\{\begin{array}{c}e \text{ raised to the}\\ \text{power of the}\\ \text{IRI per capita}\\ \text{multiplied by } t\\ \text{time units}\end{array}\right\}$$

$$N(t) = N(0) \times e^{rt}$$

Here *e* is the base of the natural logarithm; it is approximately equal to 2.7183. When the quantity *e* is raised to a power that is a variable--for example, the product *rt*--the result is called the *exponential function*. It is sometimes also written, "exp(*rt*)." This function has unique mathematical properties that cause it to arise naturally in the mathematical representation of many physical and biological processes. Its presence in the growth equation just presented is the basis for calling this particular process *exponential growth*.

Consider the application of the exponential growth equation to human population growth in India. The population of India in 1975 was about 620 million persons. How large would it be in 2025-fifty years later--if it continued to grow at the 1975 rate (an *r* of roughly 0.026 per person per year)? Using the above formula: [6]

$N(0) = 620$ million

$t = 50$ yr; $r = 0.026$; $rt = 1.30$

$e^{rt} = 2.7183^{1.30} = 3.67$

$N(t) = N(50) = N(0)e^{rt}$ = 3.67 X 620 million

= 2275 million

---

[3]Some familiarity at least with the notation and fundamental approach of calculus is helpful for what follows. For an introduction or review, see E. Batschelet, *Introduction to mathematics for life scientists*, 2d ed. (Springer-Verlag, New York, 1975), or a basic calculus text.
[4]This quantity is also sometimes called *the innate capacity for increase*.
[5]The alternate notations N_0 and N_t are used in many biology texts.
[6]The symbol = means, "approximately equal to."

BOX 4-2 Interest and Growth Rates

If $N(0)$ dollars is placed in a bank at a 2-percent rate of interest, compounded semiannually, the principal plus the interest at the end of t years will be $N(t) = N(0)(1.01)^{21}$.

More generally, if the interest rate is expressed as a decimal r (where $100r$ = interest rate as a percent) and interest is compounded x times a year, then

$$N(t) = N(0)\left(1 + \frac{r}{x}\right)^{xt}$$

. (1)

If interest is compounded continuously, then $x \to \infty$. Expression (1) may be rewritten, substituting $y = r/x$ $N(t) = N(0)(1 + y)^{rt/y} = N(0)[(1 + y)^{1/y} = e$. (2)

Those who have had calculus will understand that as $x \to \infty$, $y \to 0$, and in the limit

$$\lim_{y \to 0} (1 + y)^{1/y} = e$$

The base of natural logarithms (e) is approximately equal to 2.718. Therefore, when interest is compounded continuously, (2) becomes the familiar equation of exponential population growth $N(t) = N(0)e^{rt}$.

Given the growth rate, the doubling time may be computed by setting N(t)/N(0) = 2. Then $2 = e^{rt}$.

Taking the natural logarithm, (ln) of each side (and remembering that ln e = 1) gives ln 2= rt or

$$\frac{\ln 2}{r} = t$$

or

$$\frac{0.6931}{r} = t$$

.

For example, if the annual growth rate is 2 percent, then 1.02 = e^r and r = 0.0198, and

$$t = \frac{0.6931}{0.0198} = 35 \text{ yr}$$

The doubling time can be closely approximated by dividing seventy years by the annual growth rate in percent. (The approximation becomes less accurate as annual growth rate gets larger, however; above a rate of 10 percent it can be significantly in error.)

Thus, in the year 2025 India's population would have grown to 2275 million (or 2.275 billion) persons--well over half the 1975 population of the entire Earth!

A quantity growing exponentially increases in any given period of time by a fixed percentage of its size at the beginning of the period. A savings account at a bank where interest is compounded grows exponentially. The interest becomes part of the balance and, in turn, earns more interest. As time goes on, the balance gets bigger and the additions in the form of interest get bigger, in proportion. When growth is exponential, as it approximately is now in the human population, each addition becomes a contributor of new additions. The relationship between compound interest and population growth rates is made explicit in Box 4-2, as is a derivation of e.

If the percentage of exponential growth of a population in two successive periods is the same, the absolute growth in the second period is larger. Between 1960 and 1970, growing at about 2 percent per year, world population increased by some 650 million persons; if the 2 percent annual rate of growth persisted through the 1970s, the population increase for that decade would be about 800 million.

Exponential growth at a constant annual percentage increase can be characterized by the time it takes for any given quantity to double. The doubling time for a population growing at 2 percent per year is about 35 years. Consumption of energy--a useful index both of resource consumption and of a population's impact on the environment--is growing worldwide at roughly 5 percent per year, corresponding to a doubling time of only 14 years. (The general relation is: doubling time is approximately equal to 70 years divided by the annual percentage increase. See Box 4-2.)

Use of the concept of doubling time emphasizes what for our purposes is the most important property of exponential growth--the rapidity with which such growth can exceed a given limit after seeming safely small for a long time. To understand this phenomenon, imagine a large aquarium with filter and aeration systems adequate

to the needs of 1000 guppies. Suppose we start with 2 guppies in the tank and that the number grows exponentially with a doubling time of I month. It takes 8 doublings, or 8 months, for the guppy population to reach half the carrying capacity of the tank (2 → 4 → 8 → 16 → 32 → 64 → 128 → 256 → 512). For this entire period, the population seems safely small; no crisis seems imminent. Symptoms of impending disaster are unlikely to appear until the population is well over half the tank's capacity. The critical phase of the growth, when the population zooms from 512 to more than 1000, occurs within the ninth month, when the last 100 guppies are added in less than 5 days. After 265 days of apparent prosperity, exponential growth carries the population from 90 percent of capacity to a disastrous excess in less than a week.

If the subject is human beings instead of fish in an aquarium, the limits are not so obvious, but the treacherous properties of exponential population growth are just as relevant. *A long history of exponential growth does not imply a long future of exponential growth.*

Increase Without Restraint

Restraints on the growth of a population include predators, disease, and shortages of resources such as food and water. When all such restraints are removed--when there are no predators or disease and there are superabundant resources--r reaches a theoretical maximum, symbolized as r_m (*m* for "Malthusian"). Actually, r_m for a given species is not a single number but has a range of values, depending on temperature, humidity, and other conditions. For a specified set of such conditions, then, the maximum possible exponential rate of growth is the corresponding maximum intrinsic rate of increase multiplied by the population size:

$$\left(\frac{dN}{dt}\right)_{\max} = r_m N$$

Suppose, for instance, that a grain beetle has established a population of 100 individuals in a bin of wheat in which the temperature is 29°C and the moisture content of the wheat is 14 percent. Assuming growth without significant restraint and an $r_m = 0.75$ per individual per week, how many beetles would you expect to find after 3 weeks? The calculation is of the same form as that done for population growth in India, above--although the *r* for the Indian population was not the theoretical maximum (r_m) for the temperature and humidity of India!

In the grain beetle case: $N(0) = 100$; $r_m = 0.75$; and $t = 3$. And $N(t)$ [= $N(3)$] is to be calculated.

After t weeks,

$$N(t) = N(0)e^{r_m t}$$

.

After 3 weeks, $N(3) = 100e^{(0.75)(3)} = 100e^{2.25} = 949$.

Thus, one would expect to find 949 beetles after 3 weeks of unrestrained growth. After 10 weeks there would be 180,804 beetles; and in 20 weeks, 326,901,737 beetles. Essentially unrestrained growth obviously cannot continue for 20 weeks unless the wheat bin is large, since at that point more than 300 million beetles would be competing for the remaining grain. Indeed, unrestrained growth for a year would lead to:

$N(52) = 100e^{(0.75)(52)} = 100e^{39}$

$N(52) = 8{,}659{,}340{,}042{,}000{,}000{,}000 = 8.7 \times 10^{18}$.

If each beetle weighed 10 milligrams on the average, the entire mass of beetles would weigh 8.7 X 10^{11} metric tons. After 82 weeks there would be 6.1 x 10^{28} beetles, and their weight of 6.1 X 10^{21} metric tons would be equal to that of Earth! A general rule about long-continued exponential increase is that it leads to preposterous numbers with surprising speed. [7]

Remember, in the more general case of exponential growth, where predators and disease are not eliminated (or in human populations, where some limitation of births is almost always practiced), r is substituted for r_m. Hence, growth may be exponential at a rate below the theoretical maximum. For instance, the human population is now growing roughly exponentially with r = 0.02 per person per year, whereas r_m for human beings in most environments would probably be in the vicinity of 0.04 to 0.05. Exponential growth produces characteristic curves when numbers are plotted against time (Figure 4-1). These curves transform into a straight line if the population size is plotted on a logarithmic scale (Figure 4-2), which is why it is often called logarithmic growth.

[7] The r_m conditions in this example approximate those calculated for the grain beetle *Calandra oryzae* by L. C. Birch in Experimental background to the study of the distribution and abundance of insects, pt. 1, *Ecology*, vol. 34, pp. 698-711.

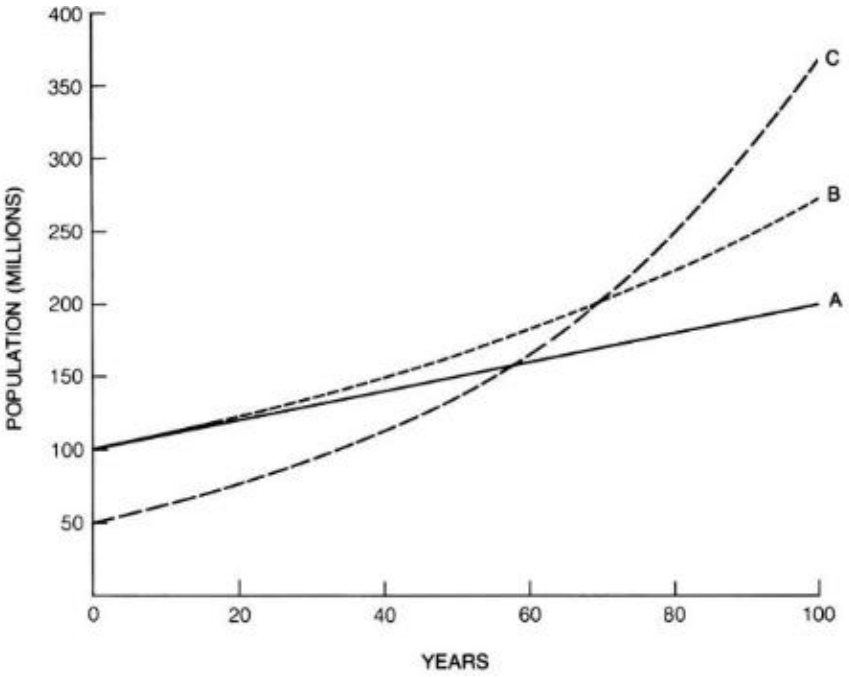

FIGURE 4-1 Exponential growth and arithmetic growth. A. Initial population of 100 million growing arithmetically at 1 million per year. B. Initial population of 100 million growing exponentially at I percent per year. C. Initial population of 50 million growing exponentially at 2 percent per year. Compare A and B: The difference is negligible at first, then grows dramatically. This is the effect of compound interest. Compare B and C: A higher exponential growth rate soon compensates for a smaller initial population.

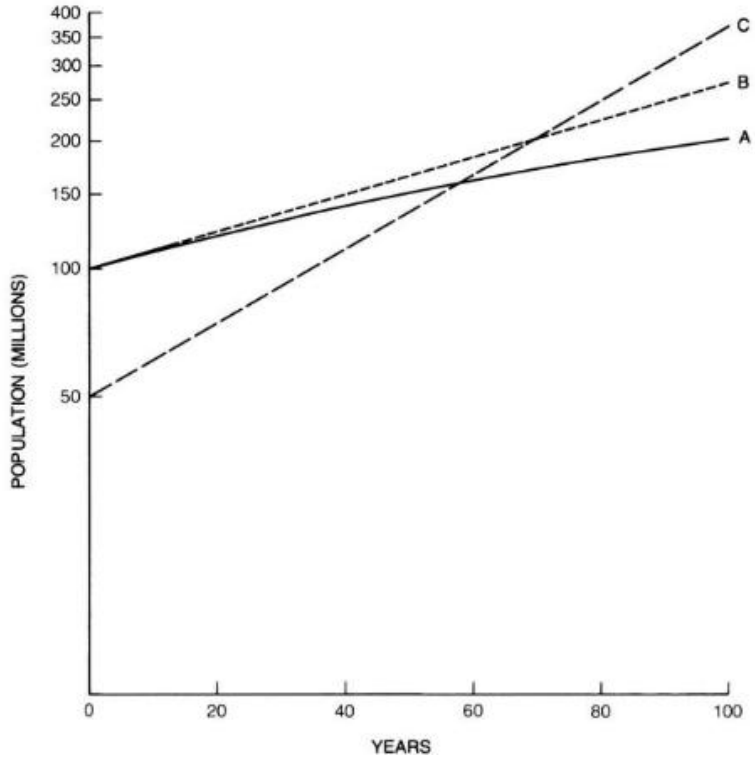

FIGURE 4-2 Curves from Figure 4-1, replotted using a logarithmic scale on the ordinate. Note that only the previously straight arithmetic growth line, A, is now curved.

It is important to keep in mind both the properties of exponential growth curves and the assumptions underlying them. Remember especially that the intrinsic rate of increase (r) is assumed to be constant and that the rate of change of population size (derivative of size with respect to time, dN/dt) is this constant, r, multiplied by the size at a particular time. Thus, when the beetle population was just 1000 individuals, the instantaneous growth rate was:

$$\frac{dN}{dt} = rN = 0.75(1000) = 750 \text{ individuals per week}$$

The human population in 1975 was some 4 billion persons and was growing approximately exponentially at about 2 percent per year. Hence, the midyear instantaneous growth rate was roughly 0.02 X 4 billion = 80 million per year. The relation between true instantaneous rates of change and the *finite rates* that can be computed from data generally available is explored in Box 4-3.

Growth with Restraint

Suppose that, instead of being constant, an individual's reproductive contribution varies with the size of the population. Now the basic equation becomes:

$$\left\{\begin{array}{c}\text{Instantaneous} \\ \text{rate of} \\ \text{increase}\end{array}\right\} = \left\{\begin{array}{c}\text{function} \\ \text{of} \\ \text{population size}\end{array}\right\} \times \text{population size}$$

$$\frac{dN}{dt} = f(N) \times N$$

$$= r \times N,$$

where $f(N)$ stands for a function of N--that is, for r, which now varies with N.

The simplest mathematical model we can make of this situation is one in which r decreases linearly as N increases. That is, in this model r is not a constant but rather is given by the expression:

$$r = r_m\left(\frac{K - N}{K}\right)$$

Here K is the *carrying capacity* (the maximum number of individuals that can be supported in a given environment). According to this relation, at the beginning of the growth process (when $N = 0$), r is equal to r_m, the Malthusian rate of increase. Later, as N approaches the carrying capacity (K), r approaches zero.

The differential equation for this simple model of growth is:

$$\frac{dN}{dt} = r_m\left(\frac{K - N}{K}\right)N$$

This can be rewritten in the form:

$$\frac{dN}{dt} = r_m N\left(\frac{K - N}{K}\right) = N\left(r_m - \frac{r_m}{K}N\right)$$
$$= N(a - bN)$$

where $a = r_m$ and $b = r_m/K$. By integrating this differential equation (expressing population size as a function of time), we obtain the following solution:

$$N(t) = \frac{K}{1 + ce^{-r_m t}}$$

where $c = [K -- N(0)]/N(0)$.

This equation is that of the logistic curve (Figure 4-3)--the archetypal presentation of density dependence in ecology. Note in this figure that the growth rate of the population at each point in time depends on its density (size). Growth starts off slowly and then accelerates

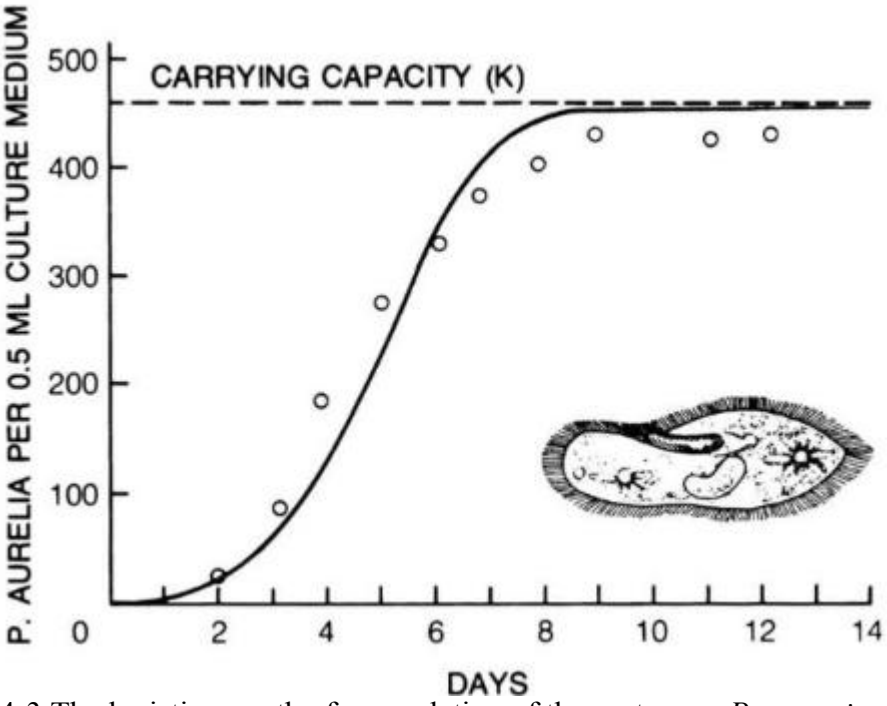

FIGURE 4-3 The logistic growth of a population of the protozoan *Paramecium aurelia* in culture. Data show observed values that are quite close to the calculated logistic curve. (Adapted from Andrewartha and Birch, 1954.)

BOX 4-3 Finite and Instantaneous Rates

Finite birth and death rates are computed by dividing the number of births (or deaths) in a period by the average population size in that period (the sum of the initial and final sizes divided by 2) or by the size of the population at the midpoint of the period. These finite rates are estimates of the instantaneous rates, and the difference between the finite birth and death rates is an estimate of *r*, the instantaneous rate of increase per individual.

Consider a population of rodents. Suppose there were 11,250 births and three-fourths as many (8,438) deaths in the population during a period in which the average population size was 11,250. The finite birth rate would be 1 per individual per period, and the finite death rate would be 0.75 per individual per period. The instantaneous rate of increase per individual during that period in that case can be estimated to be 0.25 individuals per individual during the period--from which one could estimate that the final population would be 1.25 times the starting size (the original number of individuals plus one-quarter of an additional individual for each of the original individuals).

The factor by which the size of a population is multiplied *during a given period* is the finite rate of increase per individual, or, simply, the *finite rate of increase* (conventionally symbolized by the Greek letter lambda, λ) for that period. Thus, if N1 is the population size at the end of the period and N0 is the size at the beginning,
$N_1 = \lambda N_0$ and

$$\frac{N_1}{N_0} = \lambda$$

.

What would λ be in our example? To find out, we must establish the initial population size (N_0) and the final size (N_1). There were 11,250 births and 8,438 deaths, so 11,250 minus 8,438, or 2,812, rodents were added to the population. We know the average population size during the period was 11,250, so the starting size (N_O) must have been 11,250 minus half the growth, or 9,844, and the final size (N_1) must have been 11,250 plus half the growth, or 12,656. Thus:

$$\lambda = \frac{N_1}{N_0} = \frac{12{,}656}{9{,}844} = 1.29$$

What accounts for the discrepancy between 1.29 and 1.25? The basic answer is that when a population is growing, the rate per individual gives a continuously varying total rate of increase because *the number of individuals is steadily growing*. Thus, an IRI per individual of 0.25 will multiply our hypothetical population by more than a factor of 1.25 in a given finite period because the IRI per individual is applied not just to the original population of 9,844, but to a continuously growing population.

The ratio λ is known if the population sizes N_0 and N_1 are known, or it can be estimated by adding I to the difference between the finite birth and death rates for an interval, if those are known or can be estimated. In most theoretical work, such as mathematical models of population dynamics, one works not with λ but with *r*, so it is necessary to know the relation between those two quantities. This relation can be obtained easily from the solution of the exponential growth equation. If the length of the time in question is one unit, we obtain:

$$\frac{N_1}{N_0} = \lambda = e^r$$

In the example given here, λ = 1.29, so
$r = \ln\lambda = \text{In}(1.29) = 0.255$.

Note that the estimate of $r = 0.25$, made by subtracting the finite birth rate from the finite death rate, differs from the exact value by only 0.005. When dealing in periods of time that are short in comparison with the doubling time of the population (that is, when finite rates of increase are very small), the instantaneous rate can be approximated by subtracting I from the finite rate. For example, rounded to two places:

Estimate of *r*, λ - 1	**True *r***
1.01 - 1 = 0.01	0.01
1.02 - 1 = 0.02	0.02
1.03 - 1 = 0.03	0.03
1.05 - 1 = 0.05	0.05
but	
1.20 - 1 = 0.20	0.18
1.40 - 1 = 0.40	0.34
2.00 - 1 = 1.00	0.69
3.00 - 1 = 2.00	1.10
10.00 - 1 = 9.00	2.30

Therefore, when considering annual rates for humanity (where the finite rate is always below 1.05), the difference between finite birth and death rates is a good estimator of the average *r* for the year.

rapidly. The first part of the curve is sometimes called the log phase because, when plotted with N on a logarithmic scale (Figure 4-2), it approximates the straight line of exponential growth. Then the curve rapidly flattens out, approaching *K* asymptotically (that is, the difference between *N* and *K* becomes infinitesimally small as *t* gets very large).

There are many simplifying assumptions in the logistic equation. One is that all individuals are presumed to be alike ecologically (there is, for instance, assumed to be no change with age in the likelihood of giving birth or being eaten). There is assumed to be no time lag between a change in the environment and the reactions of the organisms--a very unrealistic assumption. Very low

densities are presumed not to hinder mate-finding. And, most important, there are the assumptions that the carrying capacity (*K*) is constant and that r is directly proportional to *K* -- *N*.

Despite these simplifications, the logistic curve has proven to be remarkably close to observed patterns of population growth in laboratory cultures of organisms such as yeasts, protozoa, and fruit flies. Indeed, the recent history of human population growth might represent the log phase of a logistic pattern. It is not, however, known exactly what the carrying capacity is for the global human population, although it certainly is *not* a constant. As we discuss later, any determination of the carrying capacity for *Homo sapiens* must include the question of how long that carrying capacity is expected to persist.

The question of changes in carrying capacity must be considered for any organism, although in laboratory experiments this may often be ignored. In nature, for instance, fruit flies may well show a logistic pattern of growth. A fertile female fly finds a suitable habitat--say, a pile of rotten fruit--and lays her eggs. The population then grows in a roughly logistic manner, but when the food is exhausted the population "crashes"--it is reduced to a very low level or goes extinct. This type of outbreakcrash population cycle is common in organisms that exploit temporary habitats. The species persists because dispersing individuals can find other suitable habitats. But *Homo sapiens*, as a whole, cannot follow this pattern, for there is only one known suitable habitat!

The logistic model has also proven to be a valuable building block for the construction of multispecies models, which are a means of studying interactions among different organisms. For example, a simple model can be constructed for the growth of a pair of competing species, a and b, with two differential equations:

$$\frac{dN_a}{dt} = r_{ma} N_a \left(\frac{K_a - N_a - \alpha N_b}{K_a} \right)$$

$$\frac{dN_b}{dt} = r_{mb} N_b \left(\frac{K_b - N_b - \beta N_a}{K_b} \right)$$

The subscripts a and b indicate the intrinsic rates of increase, carrying capacities, and populations of species *a* and *b*. The Greek letter alpha (*a*) represents the degree to which the resources of species a are reduced by each individual of species *b*. The letter beta (α) is the degree to which the resources of *b* are reduced by each individual of *a*. In this model, *a* and β are constants and are called *competition coefficients*. Depending on the relationship of K_a, K_b, α, and β, logistic competition can result in one species or the other wiping out its competitor or in the two species coexisting, depending on the initial proportions of the two populations. A considerable body of

competition theory deals with such questions as the definition of ecological *niche* (the role an organism plays in an ecosystem), the degree of similarity possible between organisms in competition, and the circumstances under which they coexist or exclude one another. [8]

Age Composition and Population Growth

The assumption that all individuals are ecologically identical--equally likely, for instance, to give birth or die--is not even approximated in most animal populations and clearly is not the case in human populations. Understanding the effects of the age compositions of these populations (and changes in those compositions) on birth and death rates is critical to understanding their dynamics, especially when populations have overlapping generations.

Consider the input side of the equation first. Given the requisite information, one can construct a schedule of age-specific birth rates for a population. In bisexual

[8]These matters are beyond the scope of this book but are dealt with in fine texts by Pianka and Roughgarden. (E. Pianka, *Evolutionary ecology*; J. Roughgarden, *Theory of population genetics*.)

organisms, this schedule is the maternity function, mx (m for maternity, *x* for age). It is normally presented in terms of the number of female offspring per female. Such a function is plotted in Figure 4-4 for women in the United States. The shape of the curve is rather typical for human females--a rapid rise from the midteens to the late twenties, and then a sharp tapering-off around fortyfive. In populations in less developed countries, the entire curve extends farther to the left (reproduction starts earlier), and the peak usually is considerably higher because the average woman has more babies (Figure 4-5).

To make statements about population growth, however, we need to know more than what the number of female offspring per female will be in each age class. We also need to know how many females there are in each age class. For this, it is necessary to know the probability that an individual will survive to any given age (lx, in which l denotes living) which can be obtained from the age-specific death rates. Again, the pattern is similar for females of most human populations. As can be seen from the plot of age-specific death rates in Figure 4-6, there is a burst of infant mortality, followed by low death rates through childhood and young adulthood, with a gradual increase starting in the late twenties. The basic U-shape of the curve holds for all human populations, but in less developed countries infant and child (ages 1-5) mortalities are considerably higher, and the high death rates of old age begin earlier.

Conventionally, however, death-rate data are presented in terms of l_x, defined either as the number of individuals surviving or the proportion of individuals surviving. Most animal populations show survivorship curves, (l_x) of one of three types (Figure 4-7). Human populations in developed countries come close to having a Type I curve, in which low early mortality is followed by a period of rapidly increasing death rates in middle age. The Type II curve, in which a constant proportion of the population dies in each age interval, is approximated

by adults of some butterflies, adult fishes, some adult birds, and adults in primitive human groups (all of these organisms have high juvenile mortalities). Type III curves are probably the most common in natural animal populations: extremely heavy early mortality followed by a gradual die-off of the survivors. Most marine invertebrates, fishes, and insects show this general pattern.

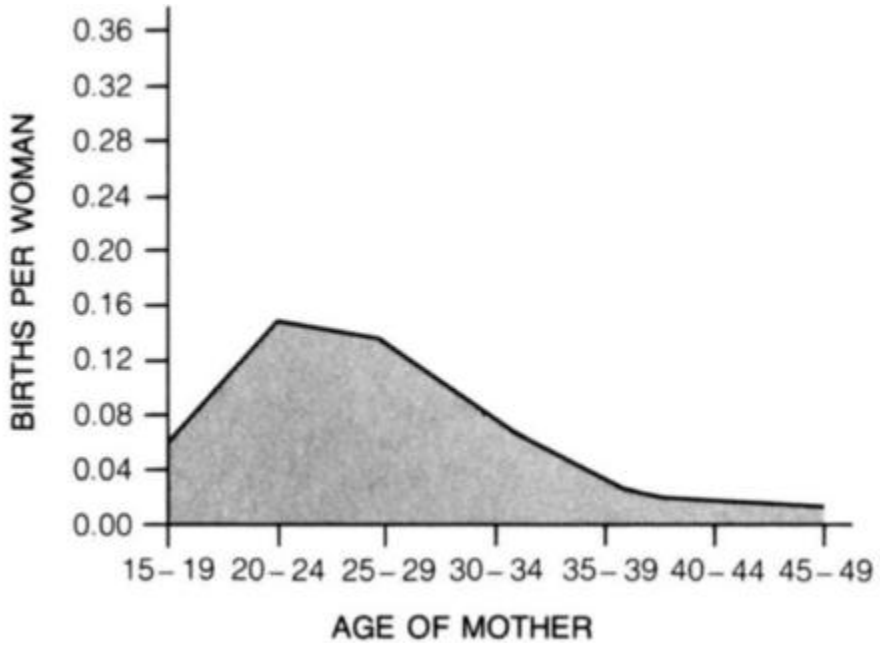

Figure 4-4 The maternity function for American women, 1971. The ordinate indicates the number of offspring produced by an average woman in each period. Thus an average American woman reproducing at the 1971 rate would have 0.15 children between the ages of 20 and 24. (Data from U.S. Agency for International Development.)

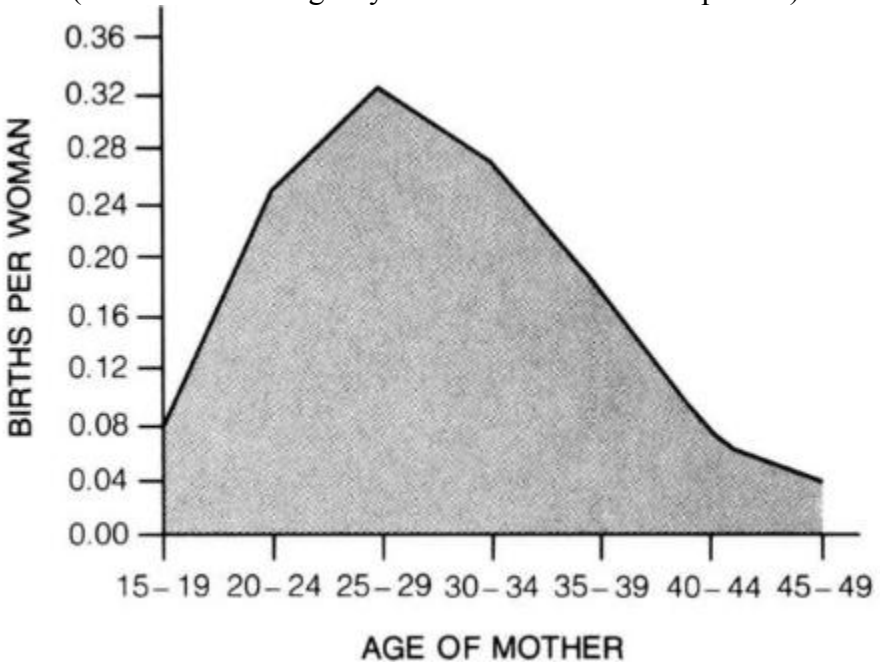

FIGURE 4-5 The maternity function for Peruvian women, 1969. If data were available, this curve would extend farther to the left than the one in Figure 4-4. (Data from U.S. Agency for International Development.)

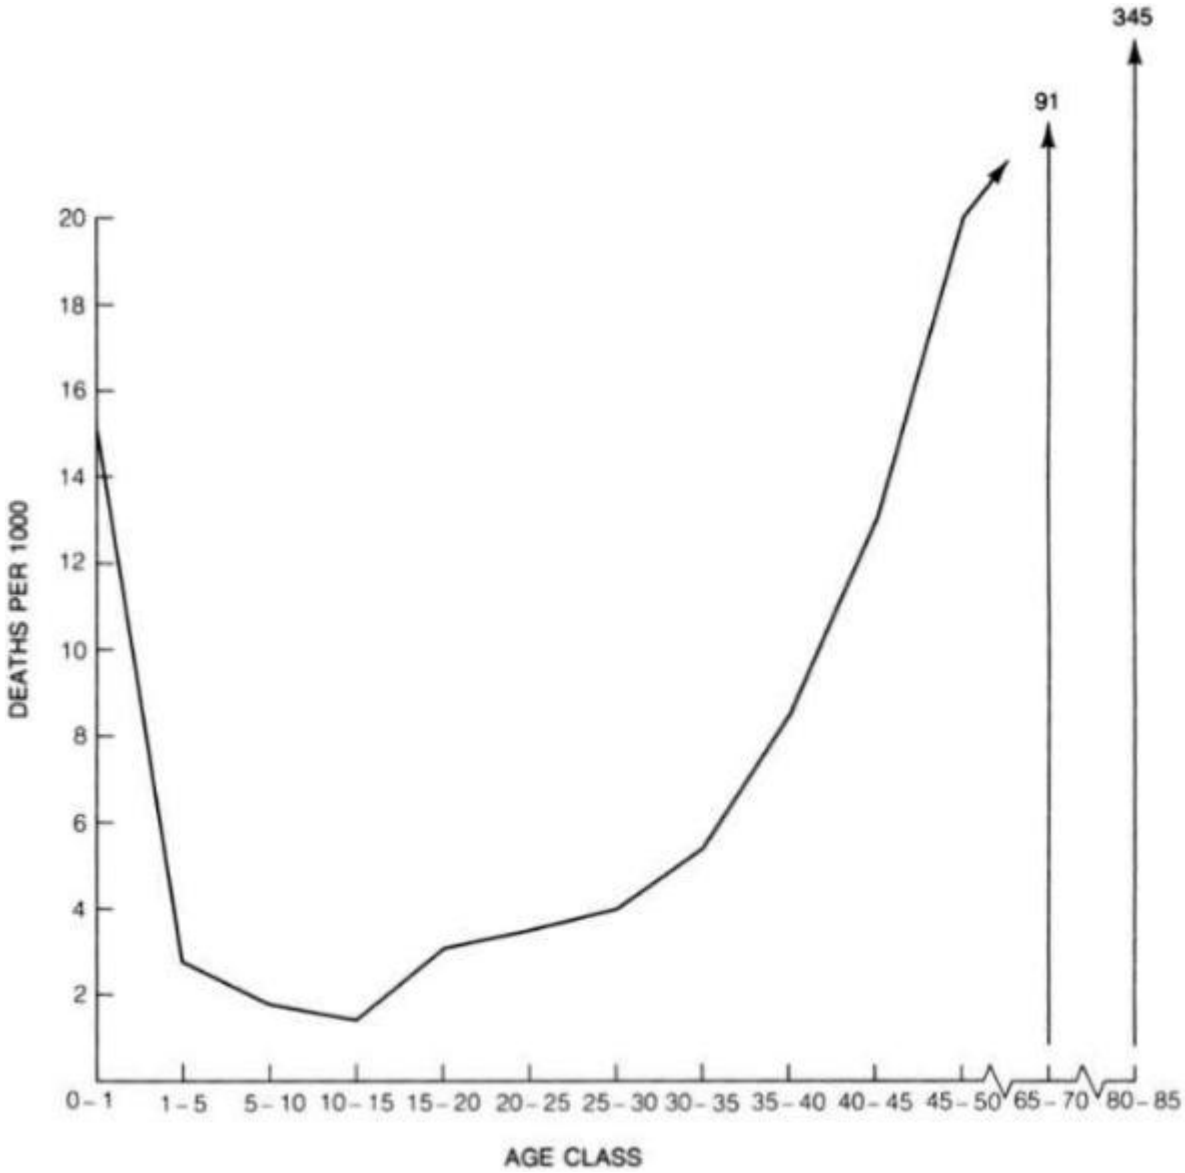

FIGURE 4-6 Age-specific death rates of American women, 1973. Only the prereproductive and reproductive years, critical to calculation of population reproductive rates, are shown in detail.

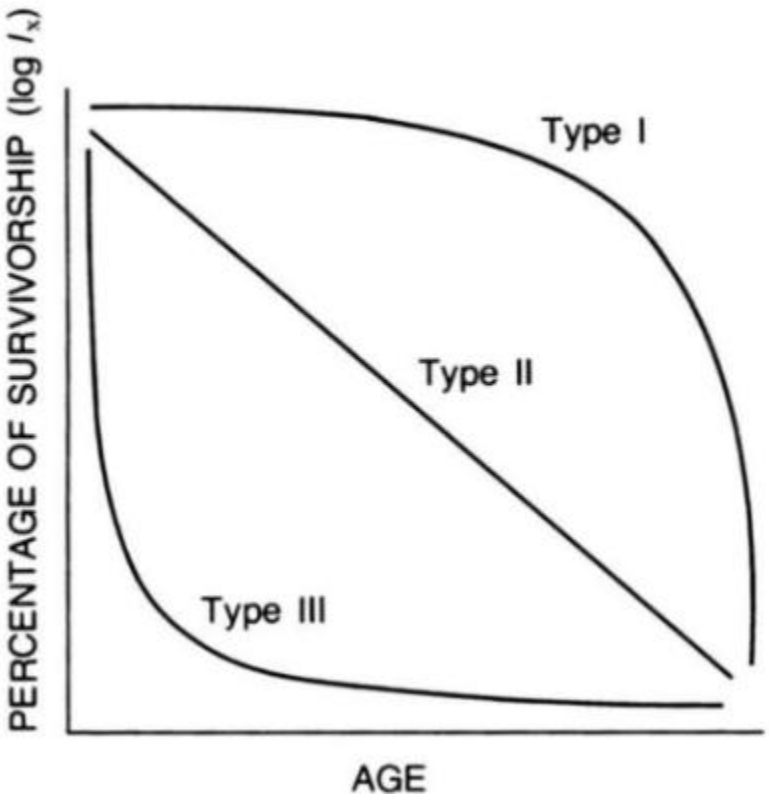

FIGURE 4-7 Three types of survivorship curve. Only the general shape of the curve is important here, not the scale.

			1.00

If age-specific death- and birth-rate (l_x and m_x) data are available, it is possible to combine them in order to make some statements about population dynamics. Let us look at a single newborn female cohort (a group of females born at the same time) of a hypothetical animal. A version of a *life* table called an $l_x m_x$ table can be constructed for the cohort by observing the pattern in which it reproduces and dies. In Table 4-1, x is the designator of the age class (x - 1/2) to (x + 1/2) -- that is, if x is 5 years, all individuals 4 1/2 to 5 1/2 years old are in Class 5. In the same table, l_x,

is the proportion of the cohort surviving to age x, and m_x is the age-specific female birth rate. The key column is the right-hand one, the product of l_x and m_x. The sum of that column,

$$\sum_0^\infty l_x m_x$$

, tells the average number of female offspring produced per female of the original cohort. This sum is designated R_0 and is known as the net reproductive rate (NRR).

If $R_0 = 1$, as it does in this example, it means that the original female cohort has exactly replaced itself; for 1000 females in generation n, there are 1000 females in

generation $n + 1$. If $R_0 = 2$, then in generation $n + 1$ there are 2000 females. If $R_0 = 0.5$, there are 500 in generation $n + 1$. If generations do not overlap -- that is, if all the parents die before any of their offspring nature (as in an insect with one generation per year) -then R0 indicates whether the population is growing, shrinking, or *stationary* (not changing in size). If R_0 is greater than 1, the population is growing; if R_0 is less than 1, the population is shrinking; if R_0 is exactly 1, the population is stationary.

If generations overlap, however, no statement about population growth at a given moment can be made on the basis of a calculation of R_0 alone. It is necessary also to know the *age composition* of the population. The way R_0 is calculated in a population with overlapping generations is analogous to that of the preceding hypothetical example. Age-specific female birth- and death-rate schedules are determined for a given period of time; and those schedules are applied mathematically to a hypothetical cohort in order to calculate R_0. The age composition of the actual population at the time of determination of the birth-rate and death-rate schedules is not taken into consideration.

Suppose that R_0 in a human population is found to be 1. Suppose further that almost half the women in the population are below reproductive age. Even if R_0 remained 1 and each *generation* were just reproducing itself, the population would continue to grow for some time because the proportion of females in their childbearing years would be increasing (raising the overall birth rate, b) more rapidly than the ranks of the elderly were increasing (raising the overall death rate, d). Remember that, ignoring migration, it is the relationship of these overall rates (not the age-specific rates) that determines whether the population is growing, shrinking, or stationary.

The relationship between R_0 and r is discussed further in Box 4-4. Confusion of the net reproductive rate (R0) with the instantaneous rate of increase has, for example, led to many erroneous statements about population growth in the United States. When in the early 1970s the NRR was very close to 1, many commentators declared that the United States had reached ZPG (zero population growth, a stationary population). Unfortunately, this was not so (see Chapter 5).

What $R_0 = 1$ for a growing human population does mean is that if the age-specific vital (birth and death) rates that result in $R_0 = 1$ are maintained, the population will eventually reach ZPG (in about a lifetime). That is, if the NRR in the United States remained equal to 1 for some seventy-five years, and if there were no migration, the population would stop growing at the end of that time (ZPG, $r = 0$), and the size of the United States population at ZPG would be about 280 million persons.

The reason for the continued growth with NRR equal to 1 is that the age composition of the U.S. population in the early 1970s was not in a steady state. If the schedule of age-specific birth and death rates (and thus the NRR) subsequently remain constant, the *age composition* (or *age distribution*, as it is often called) will change gradually into what is known as a *stable age composition* or a *stable age distribution*. [9] When a stable age composition is reached, recruitment into each age class (births for the youngest, aging for the rest) is compensated by departures (mortality plus aging into the next older class) so the proportion of the population in each age class remains constant and each age class has exactly the same r as the entire population. This stability of age composition would be achieved in any population with constant vital rates; accordingly, a population with a stable age composition may be growing, shrinking, or stationary.

Sometimes a population with such an age composition is referred to as a *stable* population. This should not be confused with a *stationary* population. A stationary population does not necessarily have a stable age composition (although, without a stable age composition, vital rates must keep changing in complex ways if the population is to *remain* stationary). Again, stable populations are not necessarily stationary, and stationary populations are not necessarily stable.

It takes about the average life expectancy (symbolized e_0°) for the age composition of a population to stabilize. The life expectancy can be calculated from a life table. Table 4-5 in Box 4-5 shows this calculation for the female population of the United States in 1973. Since $e_0^\circ = 75.3$, obviously it would take about seventy-five years for the population of the United States to reach a

[9] A. J. Lotka, "The stability of the normal age distribution", *Proceedings of the National Academy of Sciences*, vol. 8 (1922), pp. 339-345.

BOX 4-4 Generation Time and Calculation of r

Given a $l_x m_x$ table, and *assuming a stable age distribution*, r can be estimated easily. If T is the average length of a generation (that is, the average time between the birth of mothers and the birth of their female offspring), then the size of the female population after a generation of growth can be calculated:

$N_t = N(0)e^{rt}$, *becomes* $N_T = N(0)e^{rT}$

$$\frac{N_T}{N_0} = e^{rT} = \text{(by definition) the ratio of female births in two successive generations}$$

$= R_0 = NRR.$

Therefore, $R_0 = e^{rT}$, $1nR_0 = rT$, and $r = 1nR_0/T$.

Thus, all that is required to estimate r is R_0 and an estimate of T, the generation time.

How is the generation time estimated? It may be approximated from the information in the $l_x m_x$ table by the formula:

$$T = \frac{\sum x l_x m_x}{\sum l_x m_x} = \frac{\sum x l_x m_x}{R_0}$$

.

In this expression, $xl_x m_x$ is the age of the female times the average reproductive contribution for that age class. The total of the product divided by the total reproduction of that generation (R_0) gives the average age of females reproducing, weighted by the amount of reproduction of each age class. The value of T can now be used in the expression $r = 1nR_0/T$ to calculate r.

It is possible to get a more accurate estimate of the r associated with any $l_x m_x$ schedule by substituting trial values of r until a solution is found to Euler's formula:

$$\sum_{x=0}^{\infty} l_x m_x e^{-rx} = 1$$

.

This involves calculating an e^{-rx} value for each age class (x), multiplying by the lxmx value, and summing the products. The procedure for getting an estimate of T and then r, and then using the latter as a starting point for trials for getting a more accurate r is shown in Table 4-2. The data are for a hypothetical organism with overlapping generations, an R_0 of 1.85 and a generation time of about one and a half months. Only the first trial calculation is shown in the table (Columns 5 and 6). The calculated value for r (0.408) will, of course, only be realized when the age composition of the population is stable.

Note that the more precise estimate of r obtained with Euler's formula now permits a more accurate estimate of the generation time (T):

$$r = \frac{\ln R_0}{T} =$$

$$0.408 = \frac{0.615}{T}$$

$$T = 1.51 \text{ (0.10 months shorter than the original estimate, 1.61).}$$

The relationships of R_0, r, and T permit us to say something about the effects of age of reproduction on population growth. If reproduction occurs earlier, T becomes shorter; if reproduction is delayed, T naturally becomes longer. But how much effect this has on r depends on the magnitude of $1nR_0$. When R_0 is larger, a shift in generation time from, say, 20 years to 30 years greatly reduces r (slows population growth). As R_0 approaches 1, however, $1nR_0$ approaches 0, and the influence of an increase of T from 20 to 30 years is minimal. This can be seen in Table 4-3, which shows the difference between r for 20and 30-year generation times and different values of R_0.

From this result it can be seen that delaying the onset of reproduction (increasing T) may be a useful strategy for slowing the growth of a rapidly growing population; but the closer a population is to ZPG, the less effective this strategy will be.

BOX 4-5 Life Tables

Age-specific death rates in a population -- especially a human population -- are often presented in the form of life tables. Such tables are of great interest to the actuaries employed by insurance companies and to government planners. Also, as described in the text, if the l_x data in a life table are combined with the mx data of a fertility table, the net reproductive rate R0 is easy to calculate.

The 1973 life tables for males and females in the United States are given in Table 4-4 and Table 4-5. The source of the data is the United States National Center for Health Statistics. The explanation of the columns that follows is from the same source, slightly modified. Note, in particular, how the key variable, the life expectancy $e + \mathring{x}$, is calculated.

Column 1, "Age Interval" (x-x + n). Column 1 gives the interval between the two exact ages indicated. For instance, "20-25" means the fiveyear interval between the twentieth birthday and the twenty-fifth.

Column 2, "Proportion Dying" (nqx). This column shows the proportion of a cohort who are alive at the beginning of an indicated age interval who will die before reaching the end of that age interval. For example, for males in the age interval 20-25, the proportion dying is 0.0111. Of every 1000 males alive and exactly 20 years old at the beginning of the period, 11.1 will die before reaching their twenty-fifth birthdays. The nqx values represent probabilities that persons who are alive at the beginning of a specific age interval will die before reaching the beginning of the next age interval. They are the age-specific death rates. The "Proportion Dying" column forms the basis of the life table; the life table is so constructed that all other columns are derived from it.

Column 3, "Number Surviving" (lx). This column shows the number of persons, starting with a cohort of 100,000 live births, who survive to the exact age marking the beginning of each age interval. The lx values are computed from the nqx values, which are successively applied to the remainder of the original 100,000 persons still alive at the beginning of each age interval. Thus, of 100,000 male babies born alive, 98,022 complete the first year of life and enter the second; 97,674 begin the sixth year; 96,405 reach age 20; and 13,662 live to age 85. In life tables the lx schedule is often given as the probability of reaching an age interval (the proportion of individuals reaching that interval), as in Table 4-1.

Column 4, "Number Dying" (ndx) shows the number dying in each successive age interval out of 100,000 live births. Of 100,000 males born alive, 1978 die in the first year of life, 348 in the succeeding four years, 1068 in the five-year period between exact ages 20 and 25, and 13,662 die after reaching age 85. Each figure in Column 4 is the difference between two successive figures in Column 3.

Columns 5 and 6, "Stationary Population" (nLx and Tx). Suppose that a group of 100,000 individuals is born every year and that the proportion that dies in each such group in each age interval throughout the lives of the members is exactly that shown in Column 2. If there were no migration and if the births were evenly distributed over the calendar year, the survivors of those births would make up a population that is both stationary and stable. It is stationary because in such a population the total number of persons is constant, and stable because the number of persons living in any given age group is constant. When an individual leaves the group, either by death or by growing older and entering the next higher age group, that person's place would immediately be taken by someone entering from the next lower age group. Thus, a census taken at any time in a stationary and stable community would always show the same total population and the same numerical distribution of that population among the various age groups. In such a stationary population, supported by 100,000 annual births, Column 3 shows the number of

persons who, each year, reach the birthday that marks the beginning of the age interval indicated in Column 1, and Column 4 shows the number of persons who die each year in the indicated age interval. The sum of Column 4 must of course be 100,000, or the population would not be stationary.

Column 5 shows the number of persons in the stationary population in the indicated age interval. For example, the figure given for males in the age interval 20-25 is 479,389. This means that in a stationary population of males supported by 100,000 annual births and with the proportion dying in each age group always in accordance with Column 2, a census taken on any date would show 479,389 persons between exact ages 20 and 25.

Column 6 shows the total number of persons in the stationary population (Column 5) in the indicated age interval and all subsequent age intervals. For example, in the stationary population of males referred to in the discussion of Column 5 preceding, Column 6 shows that there would be at any given moment a total of 4,808,611 per-

85+	1.0000	13,662	13,662	65,682	65,682	4.8

sons who had passed their twentieth birthdays. The population at all ages 0 and older (in other words, the total population of the stationary community) would be 6,756,651.

Column 7, "Average Remaining Lifetime" (e_x°). The average remaining lifetime (also called expectation of life) at any given age is the average number of years remaining to be lived by those surviving to that age, calculated on the basis of a given set of age-specific rates of dying. In order to arrive at this value, it is first necessary to observe that the figures in Column 5 of the life table can also be interpreted in terms of a single lifetable cohort without introducing the concept of the stationary population. From this point of view, each figure in Column 5 represents the total time (in years) lived between two indicated birthdays by all those reaching the earlier birthday among the survivors of a cohort of 100,000 live births. Thus, the figure 479,389 for males in the age interval 20-25 is the total number of years lived between the twentieth and twentyfifth birthdays by the 96,405 (Column 3) males (of the 100,000 born alive) who reached the twentieth

birthday. The corresponding figure in Column 6 (4,808,611) is the total number of years lived after attaining age 20 by the 96,405 reaching that age. This number of years divided by the number of persons surviving (4,808,611 divided by 96,405) gives 49.9 years as the average remaining lifetime of males at age 20.

stable age composition once the vital rates became constant. And, *with NRR = 1*, population growth would not cease until the age composition stabilized.

Furthermore, only when there is a stable age composition is a population growing truly exponentially, that is, according to the equation

$N(t) = N(0)e^{rt}$.

In many human populations, growth is close enough to exponential that if you know *r* -- that is, *b* -- *d* -- you can calculate a doubling time (Box 4-2) without significant error. Where the age composition is far from stable, however, the calculated r and doubling time would be very misleading. For instance, in the United States in the early 1970s, there was a sudden change in net reproductive rate, and the age composition was very different from the stable composition that ordinarily would be associated with the new NRR. Thus, while the difference between birth rate and death rate in 1974 (about 0.6 percent) indicated a doubling time of approximately 120 years, in fact, if the NRR remained constant, population growth would have stopped in about seventy-five years with less than a 50 percent increase in population.

If you read Box 4-3, you saw that the finite rate of increase (λ) can in theory vary from zero (when the population goes extinct) to plus infinity (the population size is increasing infinitely rapidly). Between zero and one the population size is shrinking; at one it is stationary (neither growing or shrinking); and above one it is growing. By contrast, the instantaneous rate of increase r is between zero and plus infinity if the population is increasing, zero and minus infinity if it is decreasing, and zero if it is stationary (if it has reached ZPG).

Population Structure

Very frequently ecologists wish to know what factors are influencing population size. They may need the information to design a system for exploiting a valued resource such as a stock of food fishes. Or they may wish to manipulate the population sizes of other economically important organisms -- for instance, to suppress a dangerous crop pest or a vector of disease, or to increase the population size of a pollinator or a predator on pests. Whenever the dynamics of an organism is to be investigated for any reason, some of the most important data are those giving information on population structure. In the most general sense, population structure is simply all the factors that influence the way in which matings occur in a population. It includes such elements as age composition, mating preferences, and the patterns of distribution and movement. The latter patterns are considered in this section.

Suppose the populations of two species, the white rhinoceros of Africa and the Sumatran rhinoceros of Southeast Asia, were reduced to seventy-five individuals each. Which would have the best chance of survival? Everything else being equal, you would have to bet on the white rhino because of its population structure. It lives in herds, so mates would have little problem in finding one another (often a difficulty when a population size drops below a critical point). By contrast, the Sumatran rhino lives alone in territories, and mating apparently occurs by chance encounter during an annual period of wandering over huge areas. [10] Thus, reduction in population size is bound to have more serious consequences for this rhino than for the white rhino. Indeed, this species is severely threatened today -- its numbers have been reduced to perhaps between 100 and 170 individuals, scattered over much of Southeast Asia, where expansion of human populations has led to a rapid destruction of suitable habitat. Furthermore, like other Asian rhinoceroses, the Sumatran rhino is still hunted because of the use of its horn, hide, most organs, and even urine, by Chinese pharmacists. (Many Chinese, who make up a substantial portion of the Southeast Asian population, hold a traditional belief in rhinoceros horn as a potent aphrodisiac.) [11]

It is not uncommon to find many different population structures in the same group of organisms. In California one kind of checkerspot butterfly, *Euphydryas editha*, tends to divide into many rather small populations that rarely exchange individuals. A nearly indistinguishable species occurring in the same area, *Euphydryas chalcedona*, moves around more, and its populations occupy larger areas. [12] Both of these species have small, restricted populations, however, in contrast to a nearly ubiquitous subalpine butterfly of the Rocky Mountains, *Erebia epipsodea*. Populations of *E. epipsodea* cover such enormous areas that individuals separated by more than 10 kilometers may be members of the same interbreeding unit, whereas individuals of *E. editha* separated by only 0.5 kilometers may belong to different units. [13]

A totally different pattern has been found in the longlived tropical butterfly *Heliconius ethilla*. The temperatezone butterflies mentioned above apparently wander more or less at random over areas where nectar sources for the adults and food plants for the larvae are widely distributed. The *Heliconius*, by contrast, have relatively ritualized daily movements. Much of their time is spent moving among widely scattered plants from which the adults collect pollen. The pollen provides amino acids which allow the butterflies to live for several months as adults. Individual Heliconius set up "trap lines" and move in patterns determined by whatever plants are blooming at a given time. Population units seem to consist of clus-

ters of more or less circular trap lines, and movements of more than 400 meters are apparently rare. [14]

The patterned movements of *Heliconius* butterflies are also characteristic of some tropical bees with widely scattered pollen resources. But such movements are much more common among vertebrates, where an individual concentrates its activities within a single area, the *home range*. Frequently the home range, or a portion of it, is defended against other members of the same species or, more rarely, members of other species. The defended portion of the home range is called a *territory*. Territoriality may be a year-round phenomenon, as it is with many small pomacentrid fishes of coral reefs, individuals of which defend a small area of the reef against all comers (including human beings 25 or more times their length!) the year round. Other organisms may defend their territories for only a brief, specific period, usually the breeding season. For instance, many male birds maintain territories during the breeding season (their songs are announcements of intent to defend and readiness to breed), but they flock together peacefully when not breeding. *Homo sapiens* -- popular literature to the contrary -- does not show individual territoriality in the same sense that these other animals do. [15]

The reasons that territoriality evolved seem varied and as yet are not entirely understood. But at least one result of territoriality is clear -- it tends to space individuals more or less evenly over an area (Figure 4-8). Since most territories can only be compressed so far, this also tends to limit the maximum size of a population, often keeping it well below the limits of food resources. Much may be inferred about the behavior of particular animal populations merely by plotting their distributions (Figure 4-9). If individuals are clumped (Figure 4-9A), they are probably social; if they are overdispersed (Figure 4-9C), territoriality is likely; and if they are randomly distributed (Figure 4-9B), they probably have a minimum of interaction. There are statistical tests that can distinguish these three states, tests that are applied to counts of individuals in grid squares. If there are some squares with many individuals and many with none, it indicates social groupings;

[14]Paul R. Ehrlich and L. E. Gilbert, Population structure and dynamics of the tropical butterfly Heliconius ethilla, *Biotropica*, vol. 5 (1973), pp. 69-87.

[15]"For a discussion of territoriality in human beings and its relationship to territoriality in general, see E. O. Wilson, *Sociobiology*.

if most squares have one or a few individuals, that indicates territoriality. But the scale of the grid must be selected with care. On the scale of a single woodland, a population of tree-nesting birds might seem overdispersed; but on the scale of a state they might appear to be clumped, because woodlands are clumped.

Dispersion is the term for the three patterns of individual distribution just discussed; *dispersal* is the movement of individuals into and out of population units. Knowledge of dispersion can have practical application in interpreting the dynamics of populations that are important to humanity. Information on dispersal is important because, as we discuss later, invasions of communities by alien organisms may have a dramatic effect upon those communities, often to the detriment of humanity. The ability of organisms or of their propagules (eggs, seeds, and such) to move is their *vagility*. The chances for successful dispersal of an organism from one area to another depends on the vagility of the organism, the presence of barriers (for example, water for a terrestrial organism, lowlands for a mountain organism, dry land for a fish), and the availability of suitable habitat in the new area.

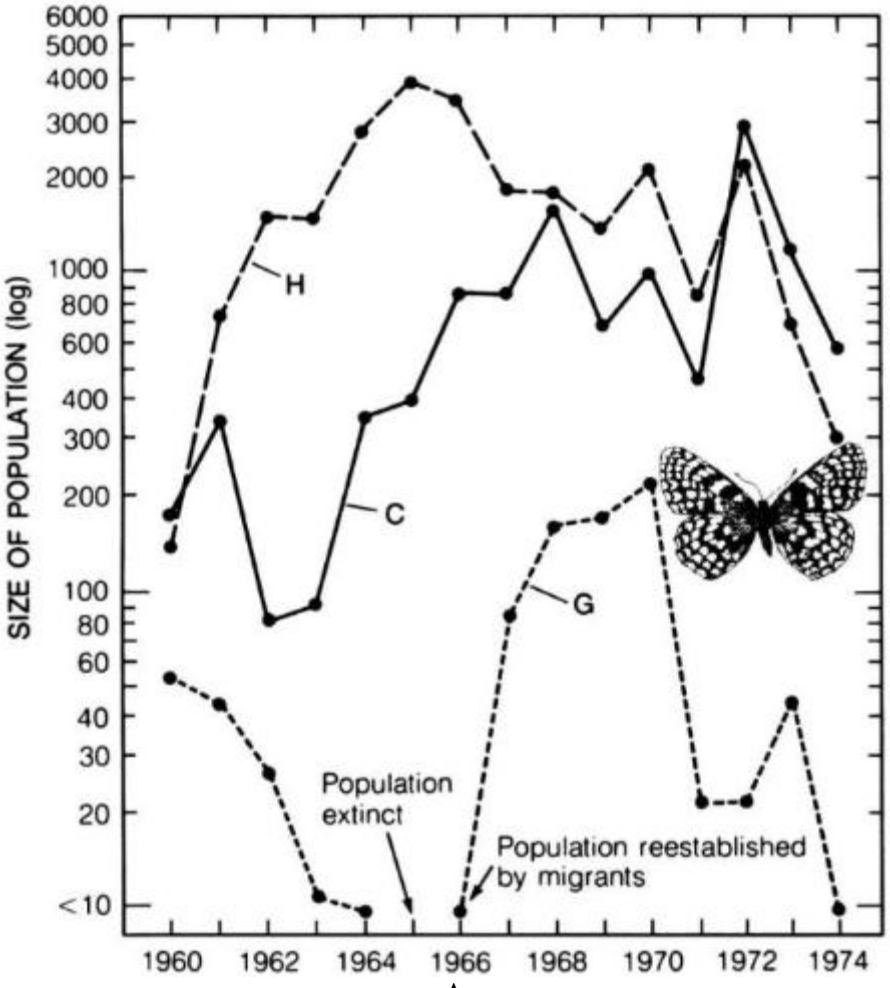
Mankind, of course, has played a major role in the dispersal of organisms, especially in the past century. Many plants have seeds that stick in the coats of passing mammals and are thus dispersed. Such seeds also tend to be dispersed readily on the clothes people wear. Other plants have moved around the world as seeds mixed in with the ballast of ships or with fodder carried for domestic animals on ships and trains. And, of course, many plants have been purposely transplanted, often carrying with them unwanted insects or other animals. People have also purposely dispersed animals, frequently with unhappy results (see "Extinction, Endangered Species, and Invasions," below).

Data on the Dynamics of Natural Populations

Unfortunately, relatively few sets of data on natural populations are useful in testing the theory of population dynamics. There are several reasons for this. First, censusing animals is usually difficult. Rarely is straightforward counting possible, so various procedures for estimating numbers must be employed. One technique used frequently is mark-release-recapture analysis. Individuals are marked in some way (with butterflies, coded numbers are put on the wings with felt-tipped pens), released, and allowed to mix back in with the population. Later a second sample group is taken. Suppose 100 individuals were captured and marked the first time, and, of a later sample of 100 captured, 10 had been marked previously. Then, assuming the equivalence of the ratios

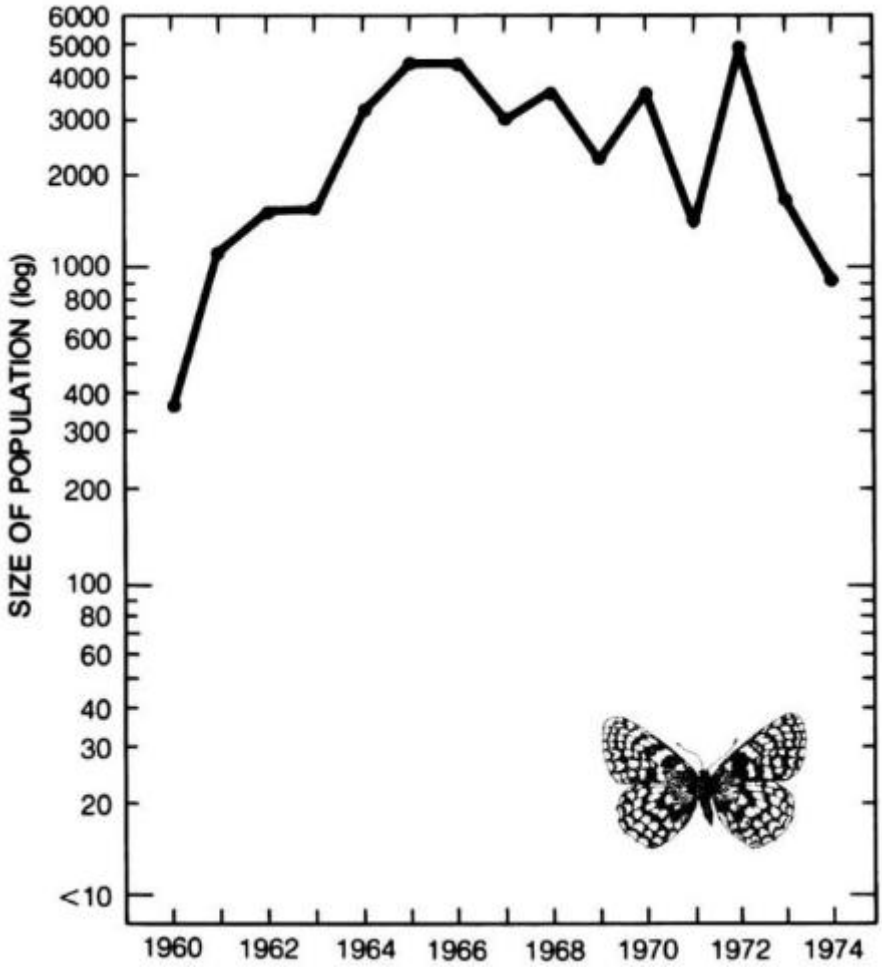
$$\frac{\text{population size } (N)}{\text{sample marked } (S_1)} = \frac{\text{second sample taken } (S_2)}{\text{number of marked recaptures } (R)}$$

we can estimate N as



$$N = \frac{S_1 \times S_2}{R}$$

Or, in our example:



$$N = \frac{100 \times 100}{10} = 1000$$

This simple estimate is based on the assumption that if 100 marked individuals (marks) made up 10 percent of a population, the population must have 1000 individuals. Of course, in real life things are not so simple -- statistical errors enter with the sampling, the marks may not mix randomly with the remainder of the population or they may be more or less readily captured than unmarked individuals, and there may be recruitment or loss to the population between the first and second samplings. Various procedures have been developed to help compensate for these problems, and despite the difficulties, mark-release-recapture analysis is widely used.

In addition to estimates of population size, this technique also provides information on population structure -- for instance, the statements about butterfly population structures made earlier were based on experiments in which many thousands of individuals were marked and released. Data obtained from these experiments can also be used to estimate survivorship and longevity. For example, while temperate-zone butterflies live as adults for an average of perhaps two weeks, the tropical *Helicoius ethilla* are much longer lived -- averaging about two months, with some surviving five months or more.

A

B FIGURE 4-10 Changes in the size of the Jasper Ridge colony of checkerspot butterflies, *Euphydryas editha*. A. Three populations (areas C, G, and H) are plotted separately. There are discrete generations, one per year. Parents and offspring never fly together. Note two extinctions and one reestablishment of G population. B. The total size of the Jasper Ridge colony (populations C, G, and H summed). The extinctions are not detectable, so important information on the dynamics of the three units is lost.

The temperate-zone species described have only one generation per year, so their generations do not overlap. The *Heliconius* do have overlapping generations; grandparents fly with their adult grandchildren.

The importance of understanding population structure when interpreting data on population dynamics can be seen by examining changes in the size of the *Euphydryas editha* populations diagramed in Figure 4-10. When studies of the dynamics of *E. editha* were begun in 1960, it was thought that there was only a single population in the Jasper Ridge biological experimental area on Stanford University's campus. A capture-recapture analysis that year revealed that what had been thought to be a single population were three quite isolated populations. These populations occupied different parts of an island of grassland surrounded by chaparral (see the discussion under "Biomes," below) and were not separated by any obvious barriers. [16] What would have happened had this structure been overlooked and die entire three-population colony been treated

as a dynamic unit? For one thing, the extinction and reestablishment of Population G would not have been detected, and for another the constancy of the overall population size would have been exaggerated (note that the line in Figure 4-10 showing changes in the total size of the colony is much smoother than that of any of the individual populations).

Why is this so important? Most of the effort in population ecology goes into attempting to understand why populations change in size as they do. Ecologists wish to understand how various environmental factors influence population size so they can predict future sizes and - where it is economically important -- manipulate factors to influence future population sizes. They wish to reduce populations of pests and increase populations of beneficial organisms. One of the main ways of finding out what affects population size is to correlate observed changes in size with observed changes in an environment. But, as with the *E. editha*, if two or more populations are lumped together, an erroneous picture of changes in population size may be drawn. This is especially critical because it is thought that the influence of environmental factors on populations size *is in part a function of popula-*

[16]Paul R. Ehrlich, The population biology of the butterfly, *Euphydryas editha*: pt. 2, The structure of the Jasper Ridge colony, *Evolution*, vol. 14 (1965), pp. 327-336.

tion size; that is, the populations respond to the environment *in a density-dependent manner*. [17] For instance, the larger an animal population is, the less likely a given individual is to have an abundant food supply or a satisfactory place to shelter from the weather. Thus the availability for each individual of both food and shelter -- as well as other resources -- may be density-dependent.

The more that environmental factors have densitydependent effects, the less variation you would expect in the size of a population. As a population increased, the life of the average individual would become increasingly precarious, reproduction would diminish, and the population size would begin to fall. When it decreased far enough, resources per individual would become abundant again, life would be more secure, and the population would tend to increase again. The more sensitive the operation of the factors to density, the less variation may occur in population size. Thus, erroneously lumping populations C, G, and H of Jasper Ridge *E. editha* would produce data much more indicative of a densitydependent "regulation" of population size than would be warranted by the actual behavior of the individual populations.

There is no more enduring controversy in population ecology than that over whether the sizes of populations are generally regulated in a density-dependent manner. [18] Ecologists who work with insects tend to believe that the feedback effect from density on population size is minimal. Those who study territorial organisms like birds are often impressed by the way availability of space for territories regulates the sizes at least of breeding populations in a density-dependent fashion. An additional complication is that populations differ genetically and may change in their genetic compositions from generation to generation. (This concept is discussed further under "Natural Selection and Evolution.") Some workers claim that there is *genetic feedback*, because the genetic makeup of a population affects its density. Changes in population density affect the

environment, which in turn (through natural selection) changes the genetic makeup of the population.

Detailed studies of *E. editha* populations indicate that, within the same species, density may have very little influence on population size in some cases, whereas in other populations it may be very important. Furthermore, there is evidence that the importance of density may change from generation to generation. [19] It seems likely that few great generalities about modes of population regulation are possible. It is obvious that at some point the growth of *any* population will be halted by factors operating in a density-dependent manner, because no resource is infinite. It is also obvious that the carrying capacity will always vary through time. But, below that point, the degree to which density at generation n will influence density at generation $n + 1$ appears to vary greatly among organisms, among populations of the same organism, and even, in some cases, between generations of the same population. Beyond that, population ecology may have to concentrate on developing procedures for investigating dynamics. [20] The reasons that populations of both Australian magpies (Figure 4-11) and *Heliconius ethilla* (Figure 4-12) are relatively constant in size may be quite different, but the approach to discovering what the critical factors are and making predictions about population sizes in the future can be very similar in both cases.

The definition of population units, for instance, is important in both cases. (This, we must repeat, is basic. For example, failure to determine whether the Peruvian anchoveta fishery is exploiting one population or two has made rational planning of that exploitation difficult.) A search for limiting factors can then be made. (It looks as if space for territories, operating in a densitydependent fashion, is the critical factor for the magpies. The situation of the *Heliconius* butterflies is more complex, but adult pollen resources appear to limit the population, also in a density-dependent fashion.)

---

[17] Population density is technically the number of individuals per unit area, but, since most populations have limited space, an increase in population size automatically means an increase in density. Thus *densitydependent* and *population-size-dependent* are usually synonymous, and the former is the accepted expression.

[18] An excellent, brief historical summary of the controversy can be found in Krebs, *Ecology*, p. 270-286.

[19] Ehrlich et al., *Checkerspot butterflies*.

[20] The landmark publication in this area is H. G. Andrewartha and L. C. Birch, *The distribution and abundance of animals*. This book is a must for all serious students of ecology. Among other things, the authors' classification of environmental factors into four components (1) weather, (2) food, (3) other animals and pathogens, and (4) a place to live was a conceptual breakthrough. A broader classification that can be used for plant populations as well appears in Ehrlich et al., *The process of evolution*, p. 84.

The broken line indicates a significant gap in sampling. (Data from Carrick, *Proceedings of the Thirteenth International Ornithological Congress*, 1963, p. 750.)

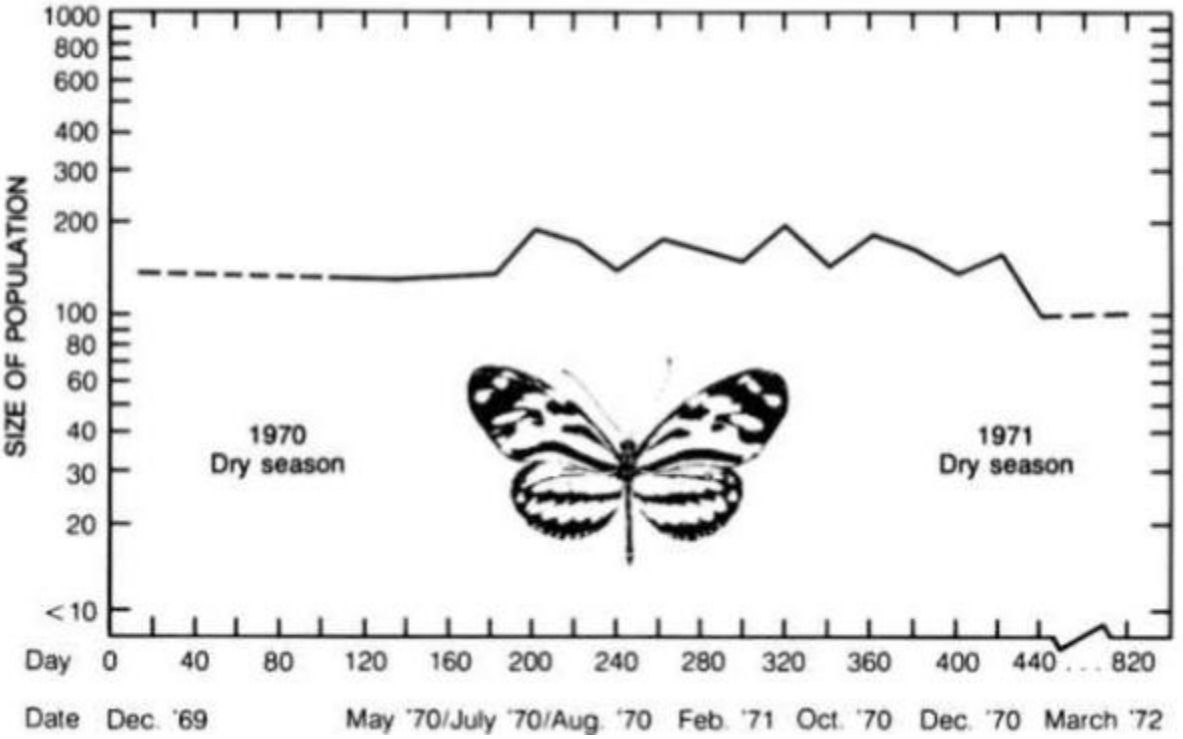

FIGURE 4-12 Changes in die size of a population of *Heliconius* butterflies, *H. ethilla*, in the mountains of northern Trinidad. Adults are long-lived (up to six months), and generations overlap; grandparents may fly alongside their grandchildren.

Multi-Species Systems

Very often population ecologists are concerned with the simultaneous behavior of two interacting populations. A great deal of attention has been paid, for example, to predator-prey systems. In part this is a response to such fascinating phenomena as the partially linked cyclic changes in the abundance of prey and specialist predators--Canadian snowshoe rabbits and lynxes, for example. In part it results from the need to understand such systems when attempting to introduce predators as biological controls of pests. Of most direct interest in human ecology are the interacting dynamics of human populations with parasites such as the plague bacterium and the influenza virus. [21]

Sometimes the dynamics of two or more populations are intertwined in a competitive situation. Competition occurs whenever two or more organisms utilize a common resource that is in short supply. Both predation and competition have been studied extensively in the laboratory, since both appear to be very important in determining the structures of natural communities. For example, competition between two species of flour beetles, *Tribolium castaneum* and *Tribolium confusum*, was stud-

[21] See K. E. F. Watt, *Ecology and resource management*, chapter 5.

ied in a series of experiments. The basic technique was to start mixed colonies in containers of flour and then see which species won the competition by eliminating its competitor under various conditions of initial density, volume of flour, temperature, humidity, the presence or absence of a parasite, and so forth. (A win invariably occurred -- the two species will not coexist.)

In experiments in which temperature and humidity were varied, it was found that under some conditions *T. castaneum* always won; under other conditions *T. confusum* always won; and in intermediate conditions the outcome was "indeterminant" -- sometimes T. castaneum won and sometimes *T. confusum*. [22] The indeterminant results proved to be caused by genetic differences in competitive ability within the species of beetles. Beetles can be selected for ability to compete; strains exist of *T. castaneum*, for instance, that invariably win in the temperature-humidity range previously thought to be indeterminant. [23] The outcome under intermediate conditions was actually determined by the genetic characteristics of the individuals used to start each culture.

One of the shortcomings of ecology in its earlier days was a tendency to ignore the genetic properties of populations under study (it was geneticists, not ecologists, who first pointed out indeterminacy as a probable cause in the flour beetle experiments). In order to understand certain key aspects of ecology, it is important to have at least a passing acquaintance with the genetic properties of populations and how they change through time -- that is, an acquaintance with natural selection and evolution.

The Dynamics of Exploited Populations

Often the ecologist interested in population dynamics is asked to recommend a pattern of exploitation of some economically valuable animal population such as a fishery. Although an extensive and complex literature exists on this topic, we can only mention a few points about it

here. [24] First of all, just what form the exploitation will take must be decided. In many, if not most cases, the problem from a biological point of view seems to be to design an exploitative program so that a *maximum sustainable yield* (MSY) is obtained. A maximum sustainable yield is the greatest amount of a population being exploited (fish, whale, deer, or whatever) that can be harvested without reducing future yields. MSY can be defined in terms of total numbers removed, total biomass removed, numbers of a particular age class removed, or biomass of some age class. Obtaining each of these would ordinarily require quite different harvesting strategies. In addition, the exploiter must choose either to maximize the productivity of the population or to minimize the loss to other causes of mortality. In the first case, harvesting might be concentrated on reproducers, minimizing competition for those remaining and inducing high productivity. In the second, harvesting might be concentrated on juvenile individuals because they are most subject to natural mortality.

Consider a simple model for the harvesting of a population following a logistic growth curve (Figure 4-13). A glance at the curve shows that *dN/dt* is maximal around the middle, where the increasing upward push of $r_m N$ is balanced by the increasing downward push of *(K -- N)/K*. (*K*. = carrying capacity.) Under this model, the MSY (numbers) could be harvested merely by removing enough individuals to keep the population size stationary at that point. A sustainable yield (SY, numbers) could be obtained by keeping the population larger or smaller, but in both cases the SY would be smaller than the MSY. Regardless of the strategy of exploitation, the MSY is always obtained by keeping populations below their maximum potential sizes, because production is higher when the population is smaller.

The model presented for MSY makes a number of biological assumptions -- such as that the stock being

[22]T. Park, Experimental studies of interspecies competition: pt. 2, Temperature, humidity and competition in two species of *Tribolium*, *Physiological Zoology*, vol. 27 (1954), pp. 177-238.

[23]I. M. Lerner and F. K. Ho, Genotype and competitive ability of *Tribolium species*, *American Naturalist*, vol. 95 (1961); pp. 329-343; J. Park , P. H. Leslie, and D. E. Mertz, Genetic strains and competition in populations of *Tribolium*. *Physiological Zoology*, vol. 37 (1964), pp. 97-162. For a fine general treatment of both competition and predation, see the Krebs text, *Ecology*, chapters 12 and 13.

[24]For example, see R. J. N. Beverton and S. J. Holt, *On the dynamics of exploited fish populations*, H.M. Stationery Office, London, 1957; or E. D. LeCren and M. W. Holdgate, eds., *The exploitation of natural animal populations*, Blackwell, Oxford, 1962. A student interested in the dynamics of exploited populations should also refer to Krebs, *Ecology*, and Watt, *Ecology*.

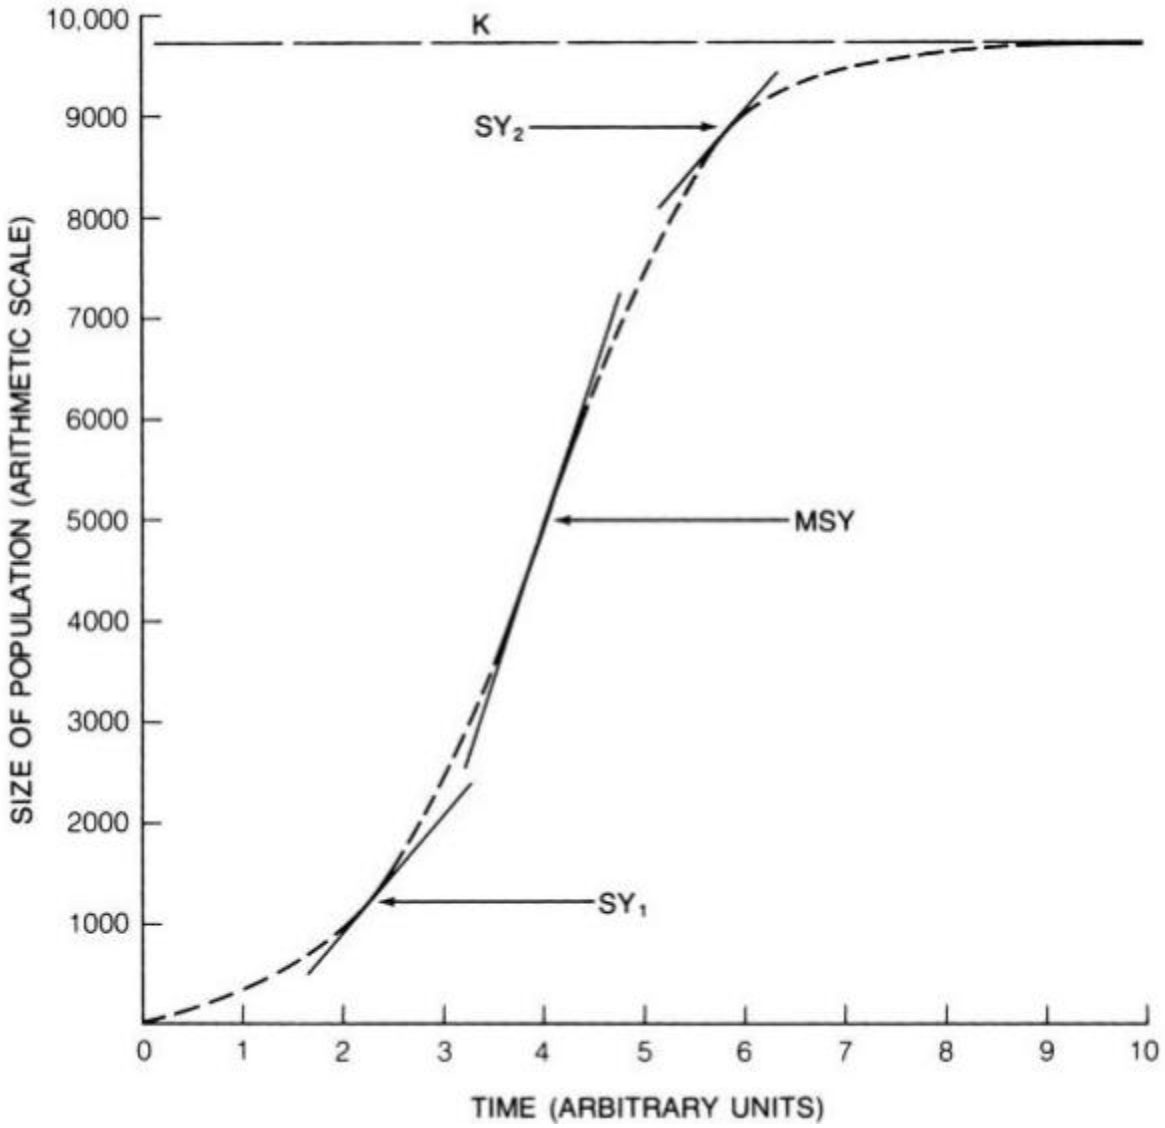

FIGURE 4-13 Sustainable yields in a hypothetical population growing according to the logistic model. The IRI (d*N/dt*) is indicated by tangents to the curve at three points SY1, MSY, and SY $_2$. Note that the maximum sustainable yield (MSY) is obtained at the point where d*N/dt* is maximum, that is, when the population consists of about 5000 individuals. Sustainable yields at lower (SY $_1$) and higher (SY $_2$) population sizes would be smaller.

exploited is relatively self-contained, that *K* is more or less constant, and that patterns of density-dependence of reproduction do not cause large fluctuations in the amount of stock. It does not consider the social organization of the exploited population or the possible effects of exploitation on the age structure of the population. When such factors are ignored, a pattern of harvesting can lead to a population crash from which no recovery occurs.

More serious, however, is the total absence from the model of economic considerations such as the costs of harvesting, the elasticity of demand for the product, and whether the population exploited is common property (as in an oceanic fishery) or controlled by an owner (a commercial

fish pond). When economic factors are included, harvesting is often pushed beyond the biological MSY, since by doing so an economic variable such as receipts can be maximized. [25]

NATURAL SELECTION AND EVOLUTION

Natural selection is the creative process in evolution. It is essentially the differential reproduction of genetic types. In most animal and plant populations and in all human populations, individuals differ because each individual has a different hereditary endowment. For instance, people differ in such traits as eye color, height, and blood type, all of which are at least partially hereditary. If people with one hereditary trait (that is, one kind of genetic information) tend to have more children than those with another, then natural selection is occurring with respect to that trait. Natural selection can cause one kind of genetic information -- for example, that producing people with a certain type of hemoglobin -- to become more and more common in the pool of genetic information (the gene pool) of a population. This might occur as a response to an environmental change in which mosquitoes carrying malaria become more common, since individuals with one kind of hemoglobin are more

[25] See, for example, J. A. Crutchfield and G. Pontecorvo, *The Pacific salmon fisheries: A study of irrational conservation*, pp. 28-36.

resistant to malaria than those with another. Changes in the gene pool of a population constitute the basic process of *evolution*.

It is evident that in the evolutionary history of humanity, for instance, there was a selective trend toward increased brain size. This is a convenient shorthand for a more complete description that might go like this:

In early human populations there was variation in brain size. This variation was largely caused by differences among individuals in their genetic endowment. Individuals with slightly larger brains were presumably better able to utilize the cultural information of the society. This permitted them readier access to mates, a better chance of surviving, or perhaps a better chance of successfully rearing their offspring; and they reproduced more than did individuals with smaller brains. The result was a gradual increase in the genetic information producing larger brains in the gene pools of human populations. In turn, this increased the capacity for storing cultural information and thus produced a selective advantage for further increase in brain size. This reciprocal evolutionary trend continued until other factors, such as the difficulty of getting the enlarged braincase of a baby through the female's pelvis (which was not commensurately enlarged) at birth, removed the selective premium on further increase in brain size.

Understanding natural selection will help to illuminate a number of points in this book. Chapter 11, for example, discusses the development of resistance to pesticides in insect populations, a process that occurs through natural selection. Individual insects often vary in their natural resistance to a pesticide, and this variation has a genetic basis. Insects that are naturally more resistant have a better chance of surviving, and thus of reproducing, than their less fortunate

fellows. In this way an entire population may become more and more resistant when sprayed repeatedly with a pesticide, as in each generation the most resistant individuals do most of the breeding.

A key concept to bear in mind is that natural selection is the differential *reproduction* of genetic types (*genotypes*, in the shorthand of geneticists). Natural selection often involves differential survival, but differentials in reproduction may occur even when the life expectancies of all genotypes remain identical. All may live the same length of time, but some may be relatively sterile while others are highly fertile. Another key point to remember is that natural selection cannot operate unless there is genetic variability in a population. If there is no variation, all individuals are genetically identical and there can be no differential reproduction of genotypes. Such a population would be unlikely to survive for long, since it would lack the ability to make evolutionary adjustments to changed conditions.

The environmental factors that lead to natural selection are called *selective agents*. Changing weather can be a selective agent, leading to an accumulation of genotypes that thrive under new climatic conditions. DDT can be a selective agent, leading to insect populations made up of genotypes resistant to DDT. (In that case, humanity was the ultimate selective agent, but the resultant evolution was undesired.)

Artificial selection occurs when human beings purposely arrange for the differential reproduction of genotypes. Artificial selection is practiced by all plant and animal breeders as they control the differential reproduction of genotypes. The idea is to develop strains in which the characteristics most valuable to society are maximized -- weight in swine, milk production in cows, egg production in chickens, shape and durability in tomatoes, height above ground for ears of corn (for ease in harvesting), beauty in flowers, and so on. These strains have undergone evolutionary processes that adapt them for a man-made environment.

Without human assistance, these strains would disappear through extinction or reversion under the countervailing pressure of natural selection. That pressure must always be reckoned with by the plant or animal breeder. Frequently, attempts to enhance a single characteristic too much upset development and diminish fertility; thus, natural selection opposes further progress under the pressure of artificial selection.

Like natural selection, artificial selection can occur only if the requisite genetic variation is present. Biologists and agronomists regard genetic variation in animals and plants as an invaluable resource that must be preserved so that new strains can be selected to meet new needs. As we discuss later, however, some of the richest

sources of that variation in important crop plants are being lost at an alarming rate (see Chapter 7).

Evolutionary forces other than natural selection also can change the gene pools of populations. *Mutation* can change one form of a gene into another and thus change the constitution of the

gene pool. Immigrants bringing genes into the pool of a population or emigrants taking them out may have genetic constitutions different from the population as a whole, and thus *migration* can change the pool. Both mutation and migration may increase the genetic variability of a population.

Furthermore, chance occurrences, which are inevitably involved in the passage of genetic information from one generation to the next, can also lead to changes in the gene pool. Without going into detail, one can think of the adults of generation $n + 1$ as possessing a sample of the genetic information present in those of generation n. Just as a sample of 100 flips of an honest coin usually will not produce exactly 50 heads because of *sampling error*, so the gene pool of generation $n + 1$ will not be exactly the same as that of generation n, because of sampling error. Because sampling error causes random changes in the frequency of genes in a pool, it is referred to as *genetic drift*.

The magnitude of genetic drift in a population is itself a function of the population's size. The smaller the population, the more important drift is (just as the fewer the flips of the honest coin, the larger the deviation from 50-50 is likely to be). In any sampling, some of the genes present in generation n may not be present in generation $n + 1$ -- that is, some of the genetic variability may be lost. Such *decay of variability* is especially severe in small populations -- making it difficult, say, to maintain the variability of crops by storing small samples of seed. [26]

If a population is greatly reduced by natural catastrophe or hunting, it is likely to suffer a decay of genetic variability. If, for instance, a given gene is represented on the average in 1 of 10,000 individuals, it is highly likely that gene will be lost if the population is reduced to 100 individuals. This loss of genetic variability may greatly reduce the chances that the population can evolve appropriately in response to environmental changes and thus enhances the probability of extinction.

Even if a population increases again in size after undergoing such a genetic bottleneck, the gene pool may remain impoverished for a considerable period. For instance, the northern elephant seal, which lives on the coast of California and Baja California, went through such a bottleneck in the nineteenth century. Its population -- now more than 30,000 individuals -- may have been reduced to as few as 20 individuals in the 1890s. Investigations of the genes controlling a variety of enzymes indicate that the genetic variability of the population is much less today than that of its subantarctic relative, the southern elephant seal, and that of other vertebrates, and it may therefore be highly vulnerable to environmental change. [27]

Although mutation, migration, and genetic drift are all evolutionary forces, it is important to remember that natural selection is the creative force in evolution. It is selection that shapes populations and species in response to changing environments. And, as will become apparent in the next section of this text, selective interactions are major forces in the evolution of communities. [28]

Coevolution

Predator-prey systems illustrate a situation in which one can expect each population to affect the evolution of the other. When two populations are ecologically intimate, each exerts selective pressure on the other. (See Box 4-6 for descriptions of some other forms of ecological intimacy.) Hence, differential reproduction induced by a predator should bring about improvement in the escape mechanisms of the prey, and, reciprocally, selection in the prey should sharpen a predator's attack.

To put it more precisely, in each generation those genetic variants among the predators that are most

---

[26]Selection can also reduce variability. Any program of maintaining living samples of organisms to preserve variability inevitably selects for individuals that culture well. This, in turn, tends to reduce variability further.

[27]M. L. Bonnell and R. K. Selander, "Elephant seals: Genetic variation and near extinction", *Science*, vol. 184 (1974), pp. 908-909 (May 24).

[28]This discussion of evolution is necessarily greatly simplified and abbreviated. Those interested in more detail may wish to consult Ehrlich et al., *The process of evolution*, especially chapters 6 and 7, which deal with population genetics.

BOX 4-6 Ecological Intimacies

A rather complex terminology has developed around various kinds of relationships between species. Some of the terms most commonly used in the literature are defined below. PREDATOR. Usually this is applied to an animal that kills and devours other animals (the *prey*). The term is increasingly being used also in place of *herbivore* (plant-eater), especially when the result is the demise of an individual plant (as in *seed-predator*). HERBIVORE. An animal that eats living plants, whether or not it kills them. PARASITE. An organism that feeds on another organism (*host*) but normally does not kill it (or kills it only very slowly). Parasites are usually much smaller than their hosts, and predators are often larger than their prey, but the dividing line between predator or herbivore and parasite is sometimes blurred. For instance, parasites usually live out their lives in or on a single host individual, but some insects are confined to a single plant and are generally called herbivores. PARASITOID. Usually this term is applied to insects that lay eggs on, in, or near other insects or spiders, which are their hosts. The young parasitoids live inside the host, inevitably killing it about the time the parasitoids form their pupae (a resting stage of many insects between larval and adult stages). Like parasites, parasitoids are smaller than their hosts, often more than one lives on a single host, and they do not kill their host quickly. Like predators, they always kill their hosts. Some parasitoids are important agents in biological pest-control programs (see Chapter 11).

MODEL. A distasteful or dangerous organism that another species mimics in order to escape from predation. Models usually have aposematic (warning) coloration that makes them obvious and "advertises" their obnoxious character. In *Batesian mimicry* the mimic is tasty or harmless. In *Mullerian mimicry* models mimic each other, presumably so that predators see the same advertisement associated with obnoxiousness more frequently. Predators then need to sample fewer prey in order to learn the meaning of the advertisement than they would if each model had

a different aposematic pattern. MUTUALISM. Any mutually beneficial association, such as that between two Mullerian mimics or that between a rhinoceros and a tick-bird (the bird gets food by cleaning ticks off the rhinoceros, and the rhinoceros gets rid of its parasites). COMMENSALISM. An association of two species in which one benefits and the other is not harmed. Tiny mites living in the facial hair follicles of most people with healthy skin are good examples of commensals. Most persons are utterly unaware of the presence of these harmless residents. SYMBIOSIS. A blanket term for parasitism, commensalism, and mutualism; in older literature it is sometimes used as a synonym for mutualism. COMPETITION. The utilization of a resource in short supply by two or more individuals or populations. Competition may be *interspecific* (among individuals of differing species) or in*traspecific* (among individuals of a single species).

successful in attacking the prey are likely to be most successful in reproducing, and thus the efficiency of the predator can be expected to increase generation by generation. This does not mean, however, that soon the predator will be so effective that the prey population will be wiped out, for the prey evolves too. In each generation, the prey individuals that escape predation are the ones to reproduce and contribute their genes to posterity.

This kind of point-counterpoint selective process was originally described in detail for butterflies whose caterpillars (herbivores) eat plants (prey). The kinds of reciprocal evolutionary changes found in that system and in similar systems (such as predator-prey, host-parasite, model-mimic, and competitor-competitor systems) were christened *coevolution*. [29] It was pointed out that in such systems the populations were often involved in a coevolutionary race in which extinction of one or the other element was a possibility. The predator, for instance, could become so efficient as to wipe out the prey -- or the prey so elusive as to starve the predator.

[29] Paul R. Ehrlich and P. H. Raven, Butterflies and plants: A study of coevolution, *Evolution*, vol. 18 (1964), pp. 586-608.

FIGURE 4-14 Stone plants (*Lithops julii var. reticulata*) growing in the desert at Karasburg, Southwest Africa. Various succulent plants of the family Aizoaceae have evolved extraordinarily effective camouflage that makes them closely resemble small stones. (Photo courtesy of Chester Dugdale.)

Understanding the coevolutionary aspects of ecological systems is extremely important to anyone interested in human welfare. The importance can be seen clearly in the relationship between plants and the organisms that attack them. Plants cannot escape their predators by running away, so they have evolved a variety of other defenses. Some, like the stone plants of African deserts (Figure 4-14), have evolved camouflage patterns that make them very difficult to see. More familiar are mechanical defenses against herbivores, especially the sharp spines of such plants as cacti and acacia trees. But the most nearly ubiquitous and seemingly most effective defenses of plants are biochemical.

Plants have evolved a vast array of compounds, such as alkaloids, terpenes, essential oils, tannins, and flavonoids, raphides (needlelike calcium oxalate crystals), and other crystals, all of whose roles appear to be to poison or otherwise discourage the animals, fungi, and bacteria that prey on the plants. These compounds are used by humanity in many ways. They are the active ingredients in spices (many essential oils), medicines (quinine, belladonna, digitalis, morphine), stimulants (caffeine), and other drugs (nicotine, marijuana, opium, peyote). Plant compounds are even used for their primeval purpose -- as pesticides (nicotine, pyrethrin).

Insects and other predators on plants have been engaged in a long coevolutionary race with the plants, evolving strategies to avoid being poisoned. Undoubtedly, some have become extinct, but many others have persisted, some running the race so well that they are able not only to eat the

poisonous plants, but in some cases even adopt the poisons as part of their own defenses against predators. For example, the monarch butterfly (*Danaus plexippus*) contains vertebrate heart poisons which it obtains from its milkweed food plants. [30] The poisons cause the blue jay predators of the monarch to vomit. Considering their evolutionary experience with poisons, it is not surprising that many wild populations of insects have become resistant to DDT and other pesticides as a result of the indiscriminate use of those poisons.

Plants have been shown to suffer heavy losses to insect predators, and yet there clearly are physiological limits to how much poison the plants can sequester without poisoning themselves or without allocating to poisonproduction too much of the energy they need for growth, maintenance, and reproduction. At least some plants have shown an interesting evolutionary response to this problem. In the Rocky Mountains of Colorado, populations of lupines and other leguminous plants suffer heavy attacks from the larvae (caterpillars) of small blue (lycaenid) butterflies. These butterflies, with a name longer than their wingspread (*Glaucopsyche lygdamus*), lay their eggs on the flower buds (Figure 4-15), and their larvae devour the flowers. Of some inflorescences (groups of flowers on a common stalk), 85 percent or more of the flowers are destroyed, with a corresponding loss in seedset. [31] Therefore, considerable selective advantage should accrue to any plant genotypes that are resistant to the insect's attack. (Remember, reproductive success is the result that counts in evolution.) By counting the eggs

[31] D. E. Breedlove and Paul R. Ehrlich, Coevolution: Patterns of legume predation by a lycaenid butterfly, *Oecologia*, vol. 10 (1972), pp. 99-104.

laid on inflorescences in several lupine populations, it was determined that the level of *Glaucopsyche* attack was much higher in some than in others. A careful analysis of the alkaloid content of plants from the various populations gave a clue to one major reason for this variability. Populations that for other reasons were unavailable to the butterflies contained small amounts of a single alkaloid. Those exposed to attack accumulated much higher amounts of alkaloids in their inflorescences. Of this exposed group, the populations that suffered heavily from predation contained a mixture of nine alkaloids that varied very little from plant to plant. The populations that were exposed but remained relatively free of attack by *Glaucopsyche*, in constrast, showed great variation from plant to plant in the mixtures of three or four alkaloids they contained and in the total quantities of alkaloid in their inflorescences. [32]

From these and related data, it was hypothesized that the variability in their alkaloid content was itself a defense mechanism against small specialized herbivores like *Glaucopsyche*. By presenting the butterfly population with a varied defense, the plants were able to retard the development of resistance to that defense. Butterflies that as larvae developed on one alkaloid type were certain to lay many of their eggs on other types. Most of the offspring of a larval generation selected by one poison regime would themselves face a different regime.

How did the plants invent such an ingenious strategy? It obviously is a result of the coevolutionary process. The more common an alkaloid type is, the more insects feed on it for several consecutive generations and thus become relatively resistant to that particular type. That type therefore suffers the heaviest seed loss and thus becomes less common in the lupine population. Thus, a *frequency-dependent* selection situation presumably is set up, in which variability is maintained because the heaviest predation is directed at the most common type.

The direct importance to agriculture of understanding this sort of coevolutionary system is obvious. It is entirely possible, for instance, that by deliberately introducing and maintaining variable biochemical defenses

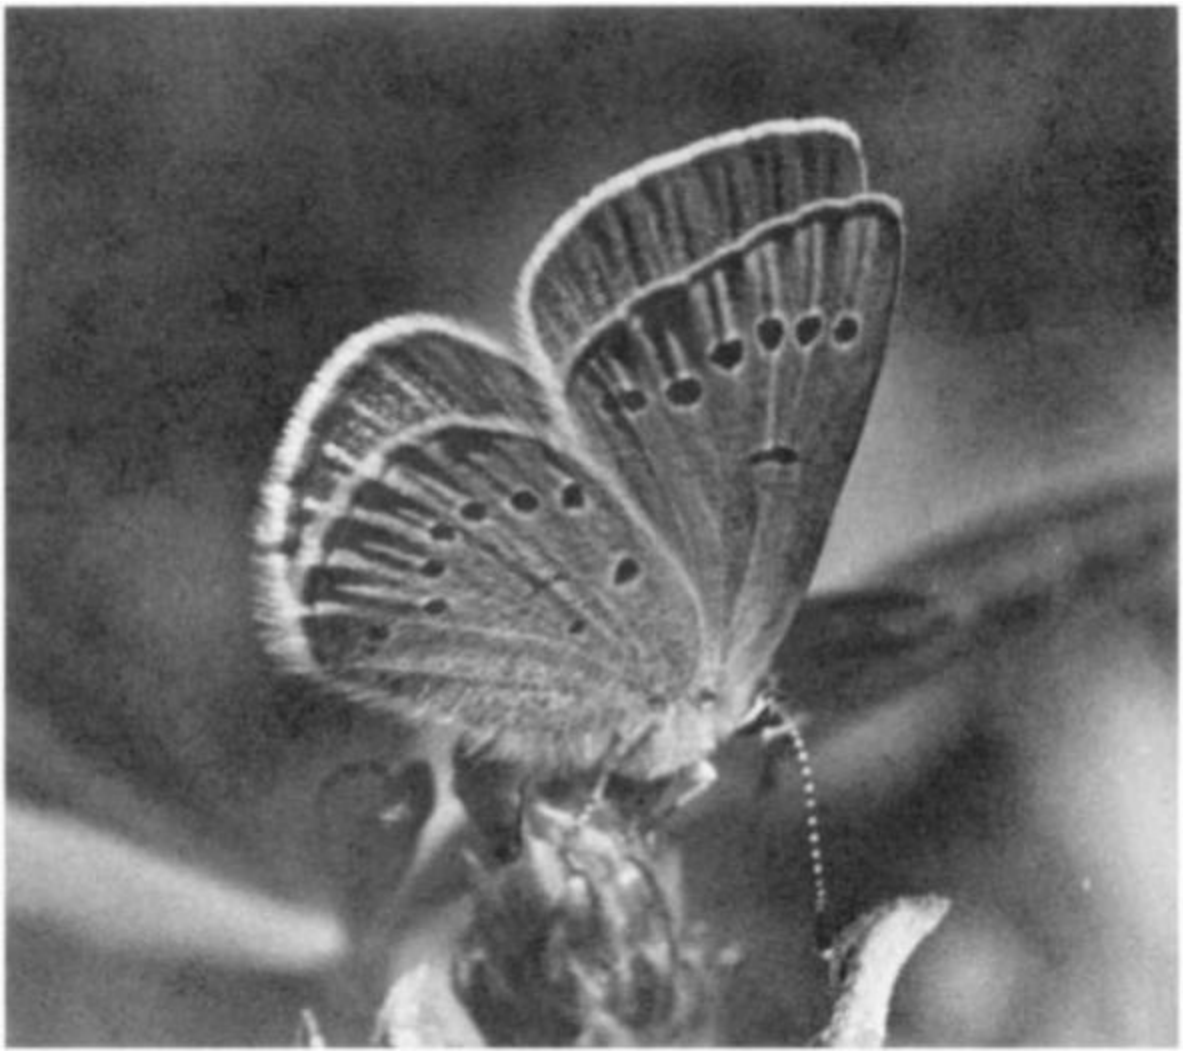

FIGURE 4-15 A lycaenid butterfly, *Glaucopsyche lygdamus*, laying an egg on a lupine bud, Gunnison County, Colorado. (The body, behind the wing, curves down at left to deposit the egg.) The larvae of this tiny butterfly (wingspread about 25 mm) are major predators on lupine plants. (Photo by P. R. Ehrlich .)

in crops, the need to use dangerous synthetic pesticides might be dramatically reduced. The potential for erecting such chemical defenses is especially high in crops like cotton, which

people do not eat (cotton is *the* major crop in terms of insecticide use). [33] But with sufficient cleverness such defenses might be adapted for some food crops.

Similarly, it is important to keep in mind the defensive functions of many, if not all, "secondary" compounds of plants -- that is, those with no obvious role in normal life processes of the plant. There is, for instance, an active research program underway to breed a strain of cotton whose seeds do not contain the poisonous compound gossypol. This would be a financial bonanza for cotton growers, since without gossypol, edible cottonseed protein could be prepared cheaply enough that the crop could probably earn a profit as a food crop, with the lint

[32] P. M. Dolinger, Paul R. Ehrlich, W. L. Fitch, and D. E. Breedlove, Alkaloid and predation patterns in Colorado lupine populations, *Oecologia*, vol. 13 (1973), pp. 191-204.

[33] About 50 percent of the pesticides used in the United States are applied to cotton and tobacco (D. Pimentel, *Extent of pesticide use, food supplies, and pollution*).

(fiber) serving as a bonus. But gossypol probably evolved as cotton's main chemical defense against insects and other pests. Without it, the already difficult pest problems of cotton might become insuperable.

Plants do not necessarily fight the coevolutionary battle with insects and other pests by manufacturing poisons. Nitrogen needed by seedlings is stored in grain seeds in the form of amino acids, the building blocks of proteins. These amino acids are essential nutrients for all animals, which must use them to make their own proteins. But the balance of amino acids in grains is not ideal for utilization by human beings and many other animals -- in grains, for example, the essential amino acid lysine tends to be in especially short supply. This makes the seeds less nutritious both for people and for other predators, and may well be the reason low-lysine seeds evolved. Work is progressing among agronomists to select new high-lysine strains of grain as a partial answer to world protein shortages. Unfortunately, these efforts may only be short-circuiting a major defense of the grains against herbivores, thus creating pest problems that might overbalance the advantages of the new strains. [34] The attempts to find new strains of both cotton and grain may be worthwhile, but in the process careful attention should be paid to possible coevolutionary constraints on their success.

COMMUNITY ECOLOGY

The plants, animals, and microorganisms that make up a biological community in an area are interconnected by an intricate web of relationships, a web that also includes the physical environment in which the organisms exist. You will recall that the interdependent biological and physical components make up what biologists call an ecosystem. The ecosystem concept emphasizes the functional relationships among organisms and between organisms and their physical environments. These functional relationships are exemplified by the food chains through which energy flows in an ecosystem, as well as by the pathways along which the chemical elements essential to life move through that ecosystem. These pathways are generally circular -- the elements pass through the system in cycles. The cycling of some elements is so

slow, however, that in the time-span of interest to society, movement appears to be one-way. An understanding of the flow of energy and the cycling of materials in ecosystems is essential for perceiving what may be the most subtle and dangerous threat to human existence. This threat is the potential destruction, by humanity's own activities, of those ecological systems upon which the very existence of the human species depends.

In Chapter 3 we discussed the physical aspects of nutrient cycling in detail, but we dealt with the biological components of the ecosystems as black boxes. Now the time has come to pry the lids off those boxes and examine the living parts of those systems. A logical place to start is with the feeding sequences ecologists call food chains.

Food Chains

All flesh is grass. This simple statement summarizes a basic principle of biology that is essential to an understanding of both ecological systems and the world food problem. The basic source of food for all animal populations is green plants -- "grass." Human beings and all other animals with which we share this planet obtain the energy and nutrients for growth, development, and sustenance by eating plants directly, by eating other animals that have eaten plants, or by eating animals that have eaten animals that have eaten plants, and so forth.

One may think of the plants and animals in an area, together with their physical surroundings, as comprising a system through which energy passes and within which materials move in cycles. Energy enters the system in the form of radiation from the sun. Through the process of photosynthesis, green plants are able to capture some of the incoming solar energy and use it to bond small molecules into the large (organic) molecules that are characteristic of living organisms. That process is often called *fixing* the solar energy. Basically, the energy from light is used in a complex process in which water and carbon dioxide (CO_2) are raw materials, and glucose (a

[34]Such problems have already been reported (see L. R. Brown, *By bread alone*, Praeger, New York, 1974, p. 165).

sugar) and oxygen are the ultimate end products. The chemical bonds of the products contain more energy than those of the raw materials; that added energy is derived from the sun. [35]

The plants themselves and the animals that eat plants break down the large organic glucose molecules and put to use the energy that once bound those molecules together. The process by which they mobilize the energy is called respiration (or, more precisely, *cellular respiration*) (see Figure 4-16). In outline, respiration is the opposite of photosynthesis -- glucose is combined with oxygen (oxidized) to produce water and carbon dioxide, and the energy thus released is trapped in chemical bonds of special molecules that transport it to other points of use. [36] The animal or plant expends some of that energy in its daily activities and uses some of it to build large molecules of animal or plant substance (for growth or repair of tissue). Animals that eat

other animals, once again break down the large molecules and put the energy obtained -- energy that originally arrived in the form of solar energy -- to their own uses.

According to the first law of thermodynamics (see Box 2-3), energy can be neither created nor destroyed, although it may be changed from one form to another (as in the change from light energy to the energy of chemical bonds in photosynthesis). The second law of thermodynamics says, in essence, that in any transfer of energy there is a loss of available energy; that is, a certain amount of the energy is degraded from an available, concentrated form to an unavailable, dispersed form. The practical expression of this law as it applies to food production is that no transfer of energy in a biological system is 100 percent efficient; some energy always becomes unavailable at each transfer. In the photosynthetic system, usually I percent or less of the sunlight falling on green plants is actually converted to the kind of chemical bond energy that is available to animals eating the plants. Usually something less than 10 percent of the energy in

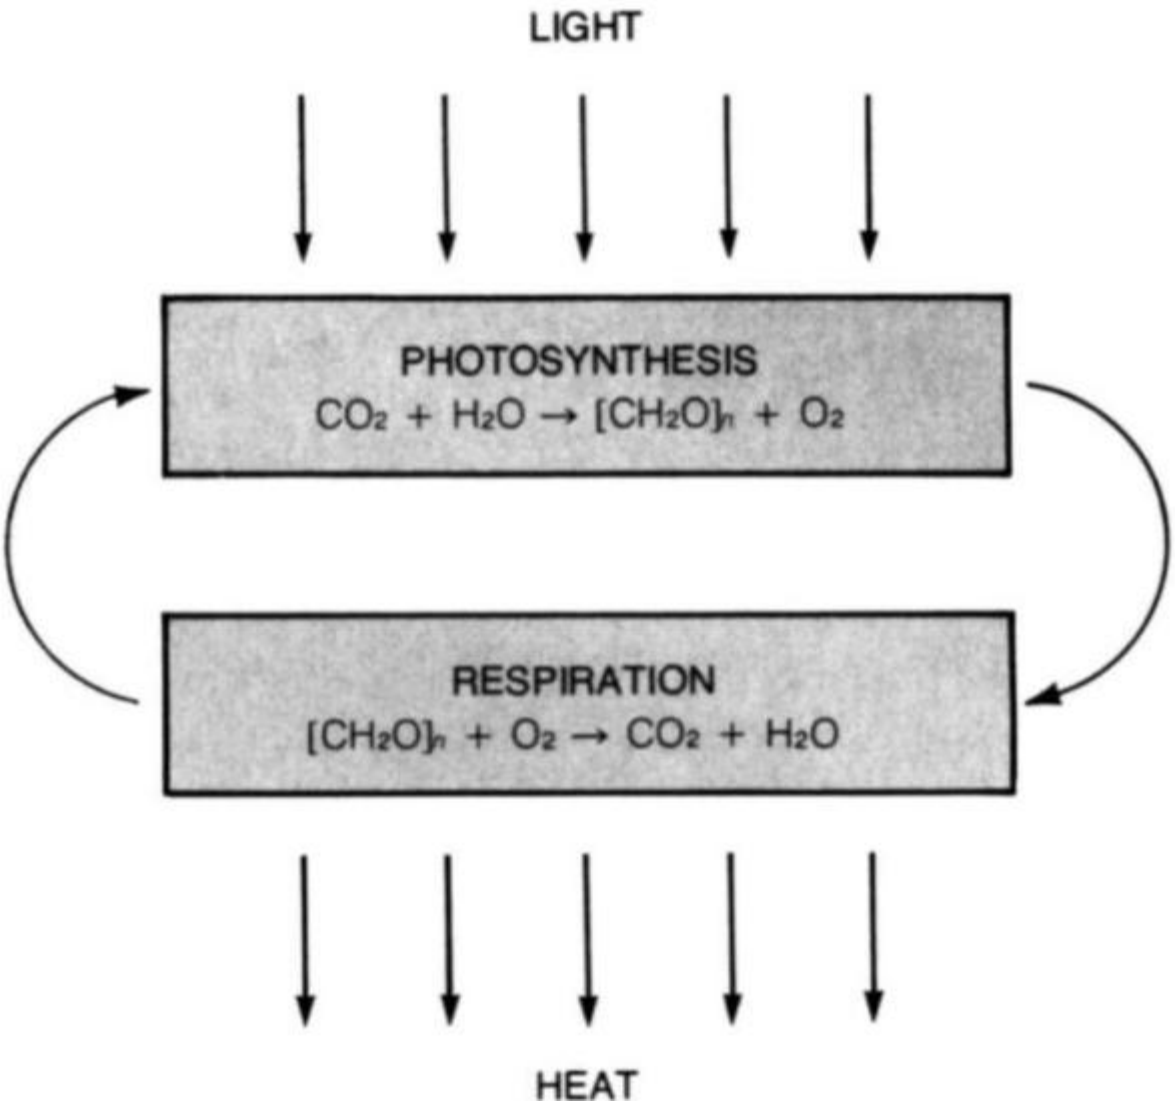

FIGURE 4-16

Photosynthesis and respiration are the basic metabolic processes of most living plants, which

obtain their energy from sunlight. In photosynthesis, energy from light is used to remove carbon dioxide and water from the environment; for each molecule of CO_2 and H_2O removed, part of a molecule of carbohydrate (CH_2O) is produced and one molecule of oxygen (O_2) is returned to the environment. In respiration by a plant or an animal, combustion of carbohydrates and oxygen yields energy, CO_2, and H_2O. (Adapted from Gates, 1971.)

the plants is converted into chemical bonds in animals that eat the plants. Roughly 10 percent of that energy may in turn be incorporated into the chemical bonds of other animals that eat the animals that ate the plants.

Thus, one may picture the flow of energy through this system as a step-by-step progression along what is known as a food chain. A food chain starts with the green plants, which are known as the *producers* or *autotrophs* (selffeeders). They are the first *trophic* (feeding) *level.* At all other trophic levels are the *heterotrophs* (other-feeders). At the second trophic level are the *herbivores* (plant-eating animals), the *primary consumers*. At the third trophic level are the *secondary consumers*, the *carnivores* (meateaters), which eat herbivores. *Tertiary consumers* are the carnivores that eat other carnivores, and so forth. Human beings play many roles in the food chains, but

[35]For a fine elementary discussion of the photosynthetic process, see P. H. Raven and H. Curtis, *The biology of plants*, 2d ed., Worth, New York, 1976. For an excellent, more detailed treatment see P. M. Ray, *The living plant*, 2d ed., Holt, Rinehart and Winston, New York, 1972.

[36]For details, see Paul R. Ehrlich, R. W. Holm, and M. E. Soulé, *Introductory biology*, McGraw-Hill, New York, 1973, or any other modern biology text.

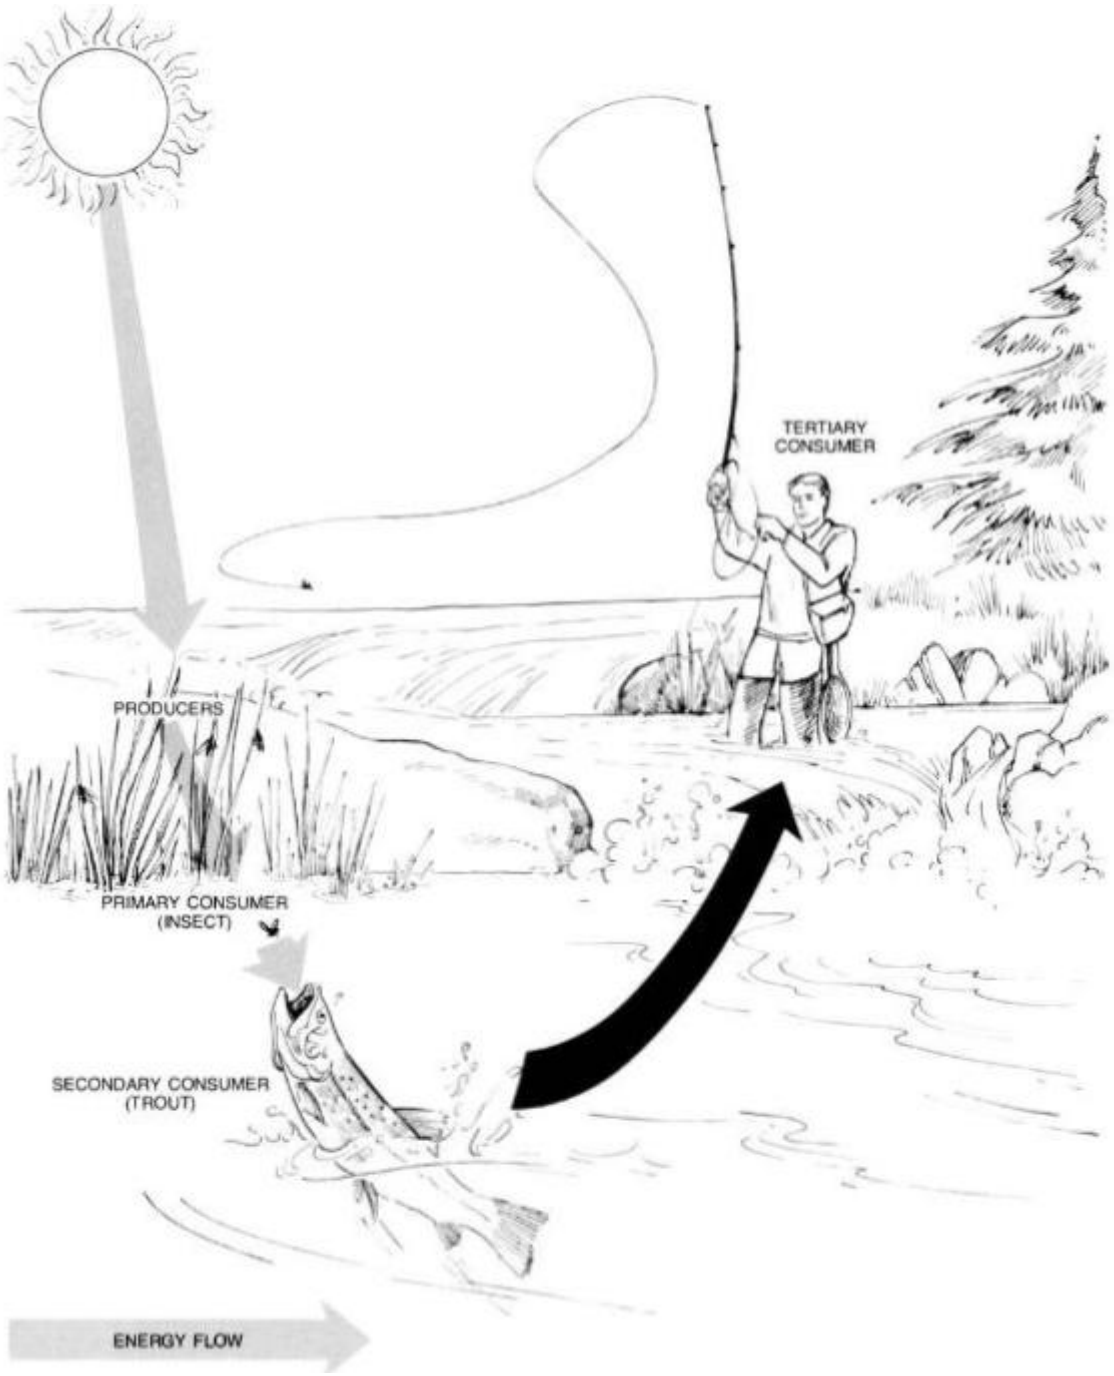

FIGURE 4-17
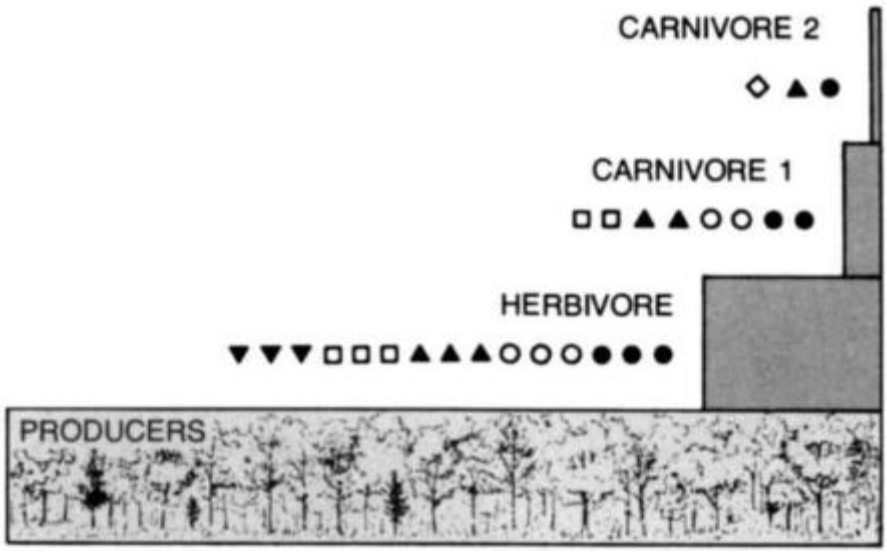
A food chain including a man. A mosquito feeding on the man would be a quaternary consumer.

their most common role is as a herbivore, since grains and other plant materials make up a very great proportion of the diets of most people. People can also be secondary consumers, as when they eat beefsteak (or the meat of any other herbivorous animal). When they consume fishes, they often occupy positions even farther along the food chain, because many fishes are tertiary or



even quaternary consumers themselves. A food chain including human beings is pictured in Figure 4-17.

At each transfer of energy in a food chain, perhaps 90 percent of the chemical energy stored in the organisms of the lower level becomes unavailable to those of the higher level (in certain situations the percentage lost may be much greater or less than this). Since the total amount of energy entering the food chain is fixed by the photosynthetic activity of the plants, obviously more energy is available to organisms occupying lower positions in the food chain than is available to those in higher positions. For instance, as an oversimplification, it might take roughly 10,000 pounds of grain to produce 1000 pounds of cattle, which in turn could be used to produce 100 pounds of human beings. By moving people one step down the food chain, ten times as much energy would be made directly available to them -- that is, the 10,000 pounds of grain used to produce 1000 pounds of cattle could be used instead to produce 1000 pounds of human beings.

It follows from this application of the second law of thermodynamics that in most biological systems the biomass (living weight) of producers is greater than that of primary consumers; the biomass of primary consumers in turn is greater than that of secondary consumers; and so forth. The weight of organisms possible at any trophic level is dependent upon the energy supplied by the organisms at the next lower trophic level; and some energy becomes unavailable at each transfer (Figure 4-18).

Productivity

Let us review for a moment two key concepts in the energetics of communities that were first discussed in connection with the carbon cycle (Chapter 3). Gross primary production (GPP) is a measure of the total

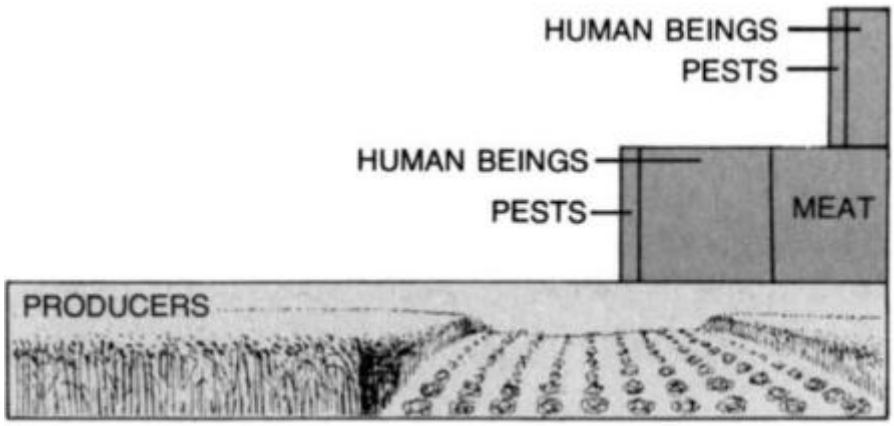


FIGURE 4-18 A. An intact natural ecosystem exemplified by a mature oak and hickory forest that supports several levels of consumers in the grazing food chain, with 10-20 percent of the energy in each trophic level being passed along to the next level. The symbols represent different herbivore and carnivore species. Complexity of structure regulates population sizes, maintaining the same pattern of energy distribution in the system from year to year. B. An agricultural ecosystem is a special case, yielding a larger than normal harvest of net production for herbivores, including human beings and the animals that provide meat for them. Stability is maintained through inputs of energy in cultivation, pesticides, and fertilizer. (Adapted from Woodwell, 1970.)

energy fixed by a community through the process of photosynthesis. Net primary production (NPP), on the other hand, is the GPP minus the energy used by the plants themselves for respiration. The GPP for the entire Earth is on the order of 1018 kilocalories. [37] The global

[37] E. P. Odum, *Fundamental of ecology*. In a concession to tradition, in this section of text we are using kilocalories (kcal) instead of kilojoules (KJ) as the units of energy. The coversion is 4.18 KJ = 1 kcal.

NPP -- the energy available to all food chains -- has recently been estimated to be about 7.2 x 10^{17} kilocalories, or roughly 720 million billion kilocalories. [38] As Table 4-6 shows, however, the NPP varies greatly from ecosystem to ecosystem.

Some additional terminology is commonly used in discussions of community energetics. *Net community production* (NCP) is calculated by subtracting from the NPP the part of that productivity used by the heterotrophs in the community. In crop ecosystems, a farmer normally tries to maximize all three kinds of productivity as well as the ratios of NPP/GPP and NCP/GPP. [39] In other words, a crop is usually selected that will fix as much solar energy as possible and use as little energy as possible in respiration. Heterotrophs other than human beings are excluded from the system insofar as is possible. Table 4-7 shows a comparison of a crop ecosystem (an alfalfa field) and a natural ecosystem (a tropical rain forest).

In grazing agricultural ecosystems, on the other hand, human beings often try to maximize the secondary productivity of some heterotrophs such as cattle. In such a case, the NPP/GPP ratio may be high, but the NCP/GPP ratio will be low. Suppose two grazing food

[38] R. H. Whittaker and G. E. Likens, *Carbon in the biota*. See also H. Lieth , *Primary productivity in ecosystems: Comparative analysis of global patterns*, for an estimate about 6 percent higher. For an estimate some 50 percent higher, see L. E. Rodin, N. I. Bazilevich, and N. N. Rozov , *Productivity of the world's main ecosystems*. Both of these papers and the volumes they are in will be very useful for those interested in the problems of evaluating productivity.

[39] The measurements, of course, are done before people, as the ultimate heterotrophs in the food chain, take their share.

chains were observed: Grass 1 → cattle → people; and Grass 2 → cattle → people. One might well be interested in the ecological efficiency with which the two chains operated. This could be calculated by determining how many kilocalories of grass were eaten by the cattle and dividing that by how many kilocalories of beef were consumed by the people. Presuming that the people in both groups ate the same portions of the cattle (and that everything else was equal), this calculation would tell which of the two grasses was best to plant. Efficiency of energy transfer between trophic levels is called a *Lindeman's efficiency* and has the general form:

$$\frac{\text{energy intake at } n\text{th trophic level}}{\text{energy intake at } (n-1)\text{th trophic level}}$$

Ecological efficiencies may also be calculated within trophic levels in the form:

$$\frac{\text{net secondary productivity at } n\text{th level}}{\text{energy intake at } n\text{th level}}$$

A rule-of-thumb figure of 10 percent has already been given as the Lindeman's efficiency. Measurements vary, however, from community to community and between trophic levels. If anything, they are likelier to be slightly more than the 10 percent, although they are rarely more than 25 percent. Yet efficiencies as great as 70 percent have been reported for some marine food chains. [40]

Efficiencies within trophic levels vary a great deal, but tissue-growth efficiences tend to decrease as one goes up the food chain. [Tissue-growth efficiency is the ratio of net productivity at level *n* to assimilation (energy fixed in photosynthesis or food absorbed from the alimentary canal) at the same level.] For entire communities these efficiencies seem to average around 60 percent for plants, about 40 percent for herbivores and carnivores, and perhaps 30 percent for secondary carnivores. [41] Efficiencies for a particular species may be very much lower,

however. (Of course, care must be taken in calculating efficiencies in order to avoid, say, computing the ratio of dry dog food consumed to wet weight of dog produced!)

It is important to keep in mind that basically these efficiencies are a consequence of the second law of thermodynamics -- that in the respiratory process some of the high-grade energy of the chemical bonds is degraded to heat at a temperature so close to ambient that organisms have not been able to evolve a way to make it do work -- in other words, it has become inaccessible to the ecosystem. It is this inexorable action of the second law that produces the pyramidal form of the diagrams in Figure 4-18. The relationships between trophic levels are conventionally illustrated by pyramid diagrams based on numbers of individuals, energy, or biomass.

Figure 4-19 shows pyramids of numbers for a grassland and for a temperate forest in summer. Note that the forest pyramid is partly inverted because of the large sizes of the individual trees. Figure 4-20 shows pyramids of biomass for a tropical forest community in Panama and the marine community of the waters of the English Channel. The numbers pyramids show the numbers of organisms that exist at an instant of time; the biomass pyramids show the dry weight of the crop of organisms at a given instant.

Note that the English Channel pyramid is also inverted -- the biomass of phytoplankton is smaller than that of zooplankton. Does this mean that plankton have

found a way around the second law? Hardly -- the pyramid of productivity for the English Channel community is right side up. The key point is that in that community the phytoplankton have a much more rapid turnover than the zooplankton. As an analogy, suppose you had on your kitchen shelf only one day's food at a time and the shelf was restocked every night. Since a biomass pyramid represents the situation at a given point in time (rather than productivity over time) a biomass pyramid of the shelf-person system would also be inverted.

In general, small organisms use energy at higher rates (the *metabolic rate*) and reproduce more rapidly than large ones. Thus, for a given amount of energy flowing into a trophic level, the standing crop or biomass will vary directly with the size of the organisms. The biomass of elephants that could exist on a given chunk of Africa would be much greater than the biomass of a hypothetical insect population that ate precisely the same plants.

The relationships among size, standing crop (biomass), and energy flow can be seen in Figure 4-21. Note that the standing crop of decomposers (bacteria and fungi) is proportionally tiny -- only 0.58 percent of the biomass of the community. In contrast, they account for 17 percent of the energy flow in the community. In a sense, the energy-flow pyramids give the most accurate assessment of the roles of organisms at various trophic levels. Numbers pyramids tend to exaggerate the importance of small organisms; biomass pyramids, to underrate them. And, as long as the second law holds, energy-flow pyramids will show no inversions!

It is, of course, extremely important to keep the difference between biomass and productivity in mind when considering the exploitation of a population. As one might expect, productivity is the critical variable. Knowledge of the total biomass of blue whales in existence is much less important in determining a

rational harvesting scheme than knowledge of the weight of blue whales produced annually (there are many other important variables, as well -- see Chapter 7).

Succession

Biological communities are not static. They change over relatively long periods of time -- hundreds, thousands, and millions of years -- as the climate of Earth changes and as their component species evolve and coevolve. They also change on a time scale of years, decades, and centuries, in a process known as *succession.* Suppose a piece of land is newly exposed by the retreat of a glacier, the lowering of a lake, or the emergence of land from the ocean by volcanic action. Gradually the exposed rock is fragmented under the action of the wind, running water, and alternate heating and cooling, and soil starts to form. Plants such as lichens invade and speed the soil formation through chemical interactions with the substrate. Grasses and herbs then move in, adding the action of their roots (and their decaying remains) to the process. Herbivores arrive, followed by carnivores that feed upon them; then the process of primary succession is well underway.

Primary succession is the development of a biological community where none existed previously. The terrestrial process begins with bare substrate and, if undisturbed, continues until a relatively stable community characteristic of the climate regime and the soil type develops. Such a community is called a *climax.* The entire sequence of communities from bare ground to the climax is called a *sere,* and intermediate communities are called *seral stages.* Primary succession, beginning with a lake and progressing to a forest, is diagramed in Figure 4-22.

The earliest studies of succession were done around the turn of the century on a sere from bare sand substrate to a beech-maple climax forest on dunes around the shore of Lake Michigan. Pioneering ecologists H. H. C. Cowles and V. E. Shelford studied the plants and animals of this successional series, and the same system was reinvestigated by J. S. Olson a half-century later. [42] In the later study it was determined through carbon dating that the entire successional process took about 1000 years -- a relatively long time. This historic sere was threatened by industrial development when one of us first visited it in 1958, and efforts were being made by

conservationists to preserve the dunes as a recreational area and outdoor teaching facility. At this writing the issue remains unresolved, because although Congress set aside 3360 hectares of Indiana dunes as a national park, a nuclear power plant and adjacent industrial development are threatening it.

Secondary succession occurs when a climax community is destroyed -- say, by a fire or by human activities. It differs from primary succession largely in the early stages -- the time-consuming process of soil-building is partially or wholly unnecessary. Human beings are often responsible for secondary succession, as when a clearing in a tropical forest is abandoned by a milpa farmer or when a dirt road or railway right-of-way is no longer used.

A great deal has been written and many names have been coined by ecologists attempting to define and classify climaxes. The problem is fundamentally one of time -- how long must a community last in a changing world in order to be considered a climax? No precise answer can be given. In periods of relatively little climatic change, a penultimate seral stage (the subclimax) may last a long time before an even more persistent climax stage replaces it. In parts of northern California, a grassland disclimax (a climax maintained by disturbance) is created by overgrazing in areas that otherwise would be live-oak woodland (cattle eat the young oak saplings, leaving the grassland that appears in Figure 4-23).

There generally are significant changes in the ratio of gross production, *P* (or GPP), to total community respiration, *R* (autotrophic and heterotrophic as succession proceeds. [43] At the early stages of normal succession, the *P/R* ratio is greater than 1. Material is being added to the system, and net community production is high. As the climax *P/R* approaches 1, the system is more or less in equilibrium, and NCP is low or 0 (Figure 4-24).

There are other differences, too. At the early stages of

[42] J. S. Olson, "Rates of succession and soil changes on southern Lake Michigan sand dunes", *Botanical Gazette*, vol. 119 (1958), pp. 125-170.

[43] A fine summary of the differences between early and late seral stages was given by E. P. Odum in The strategy of ecosystem development, *Science*, vol. 164 (1969), pp. 262-270.

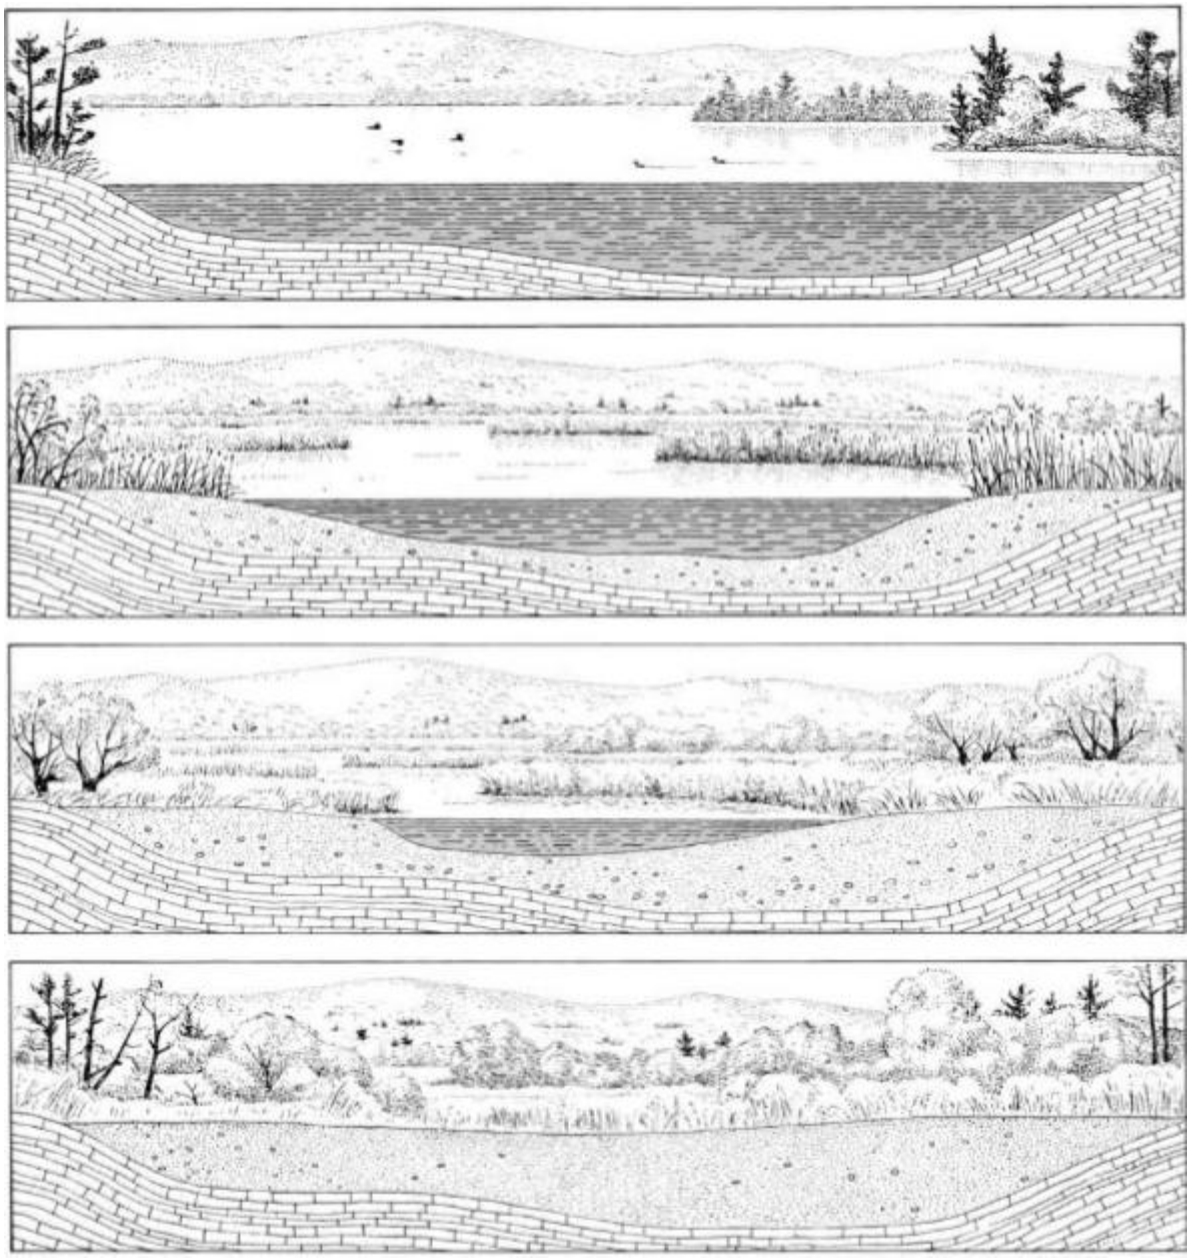

FIGURE 4-22

Primary succession leading to the obliteration of a lake. The process starts at the edge of the water *(top);* where a few bog-adapted conifers rise in a forest of hardwoods. Next the debris of shallow-water plants turns the lake margin into marsh, which is gradually invaded by mosses and bog plants, bog-adapted bushes and trees such as blueberry and willow, and additional conifers. Eventually the lake, however deep, is entirely filled with silt from its tributaries and with plant debris. In the final stage *(bottom)* the last central bog grows up into forest. (Adapted from Powers and Robertson, 1966.)

succession, food chains tend to be rather linear, and the bulk of the energy flows through the herbivores (through the so-called grazing food chain). In the climax the food chains tend to be woven into complex food webs (as discussed below and as much as 90 percent of the NPP bypasses herbivores and goes directly into the *detritus food chain* -- that is, to the decomposers.

It is useful to think of modern people as grazers -animals tied to the eating of grass -- since the vast majority of human food is either grain or animals fed on grains or other grasses. It is not surprising, therefore, that a major human activity is keeping succession from proceeding beyond

the early seral stages: in other words, in farming. Farms are man-made simplified ecosystems in which farmers attempt to maximize the *P/R* ratio. In this endeavor, considerable energy must be expended (weeding and eliminating competing herbivores) to prevent the natural processes of succession and to counteract other forces that tend to destroy what is an inherently unstable ecosystem.

Complexity and Stability

What tends to make early seral stages in general, and farms in particular, less permanent features in the landscape than, say, the oak-hickory forest climax? One explanation frequently cited is that farms are less complex. The climax contains more species of plants, animals, and microorganisms, and their food chains are more intricately interwoven.That there is a causal connection between complexity (or diversity) and stability (which in one sense is thought of as resistance to change in species composition and numbers of individuals) in biological communities is part of the folk wisdom of ecology. Six lines of evidence for this notion were presented by the famed British ecologist Charles Elton in his classic book, *The ecology of invasions by animals and plants*.

> Mathematical models of simple ecological systems indicate little stability; ordinarily there are great fluctuations in numbers of the population of each species.
>
> In simple laboratory systems, such as those containing a single predator species and a single prey species, extinction is the normal outcome for the predator or for both species.
>
> Natural communities on small islands are much more vulnerable to invasion by organisms that did not evolve with the community than are continental communities. This is especially true of oceanic islands with depauperate biotas (relatively few species present).
>
> Cultivated land (communities greatly simplified by human beings) is especially subject to invasions and to population explosions of pest species.
>
> Species-rich tropical rain forests are not as subject to insect outbreaks as are less-complex, temperate-zone forests.
>
> Pesticide treatment of orchards has resulted in pest outbreaks by upsetting the relationships between pests and their predators and parasites.

These observations appear to be confirmed by many others. Recall that *Heliconius ethilla* in tropical forests is extremely stable in numbers, whereas populations of *Euphydryas editha* in temperate areas fluctuate greatly. In addition, the floristically rather uniform northern coniferous forest seems especially vulnerable to outbreaks of insect pests; and heavy use of pesticides has frequently created pest problems -- for example, the famous Cañete Valley disaster in Peru (described in Chapter 11).

To understand one possible mechanism for the diversity-stability relationship, consider a complex food web (the intertwined food chains of a community). The food web of a Long Island estuary was thoroughly investigated by biologists George M. Woodwell, Charles F. Wurster, and Peter A. Isaacson. [44] Some of the relationships they discovered are represented in Figure 4-25. Their study illustrates several important characteristics of most food webs, one being complexity. Although the figure shows only a sample of the kinds of plants and animals in this ecosystem, it is evident that most of the consumers feed on several different organisms and that most prey organisms are attacked by more than one predator. To put it another way, the food chains are

interlinked. This interlinking may be one of the reasons that complexity is associated with stability in ecosystems. Presumably, the more food chains there are in an ecosystem and the more cross-connecting links there are among them, the more chances the ecosystem has to compensate for changes imposed upon it.

For example, suppose the marsh-plant--cricket--redwing-blackbird section of Figure 4-25 represented an isolated entire ecosystem. If that were the case, removing the blackbirds -- say, by shooting -- would lead to a plague of crickets. This in turn might lead to the defoliation of the plants, and then to the starvation of the crickets. In short, a change in one link of such a simple chain would have disastrous consequences for the entire ecosystem. Suppose, however, that the cormorants were removed from the larger system. Populations of flukes and eels would probably increase, which in turn might reduce the population of green algae (*Cladophora*). But there would be more food for mergansers and ospreys, so those populations would probably enlarge, leading to a reduction in the numbers of eels and flukes. In turn, the algae population would recover.

Needless to say, things do not normally happen that

---

[44]George M. Woodwell, "Toxic substances and ecological cycles", *Scientific American*, March 1967.

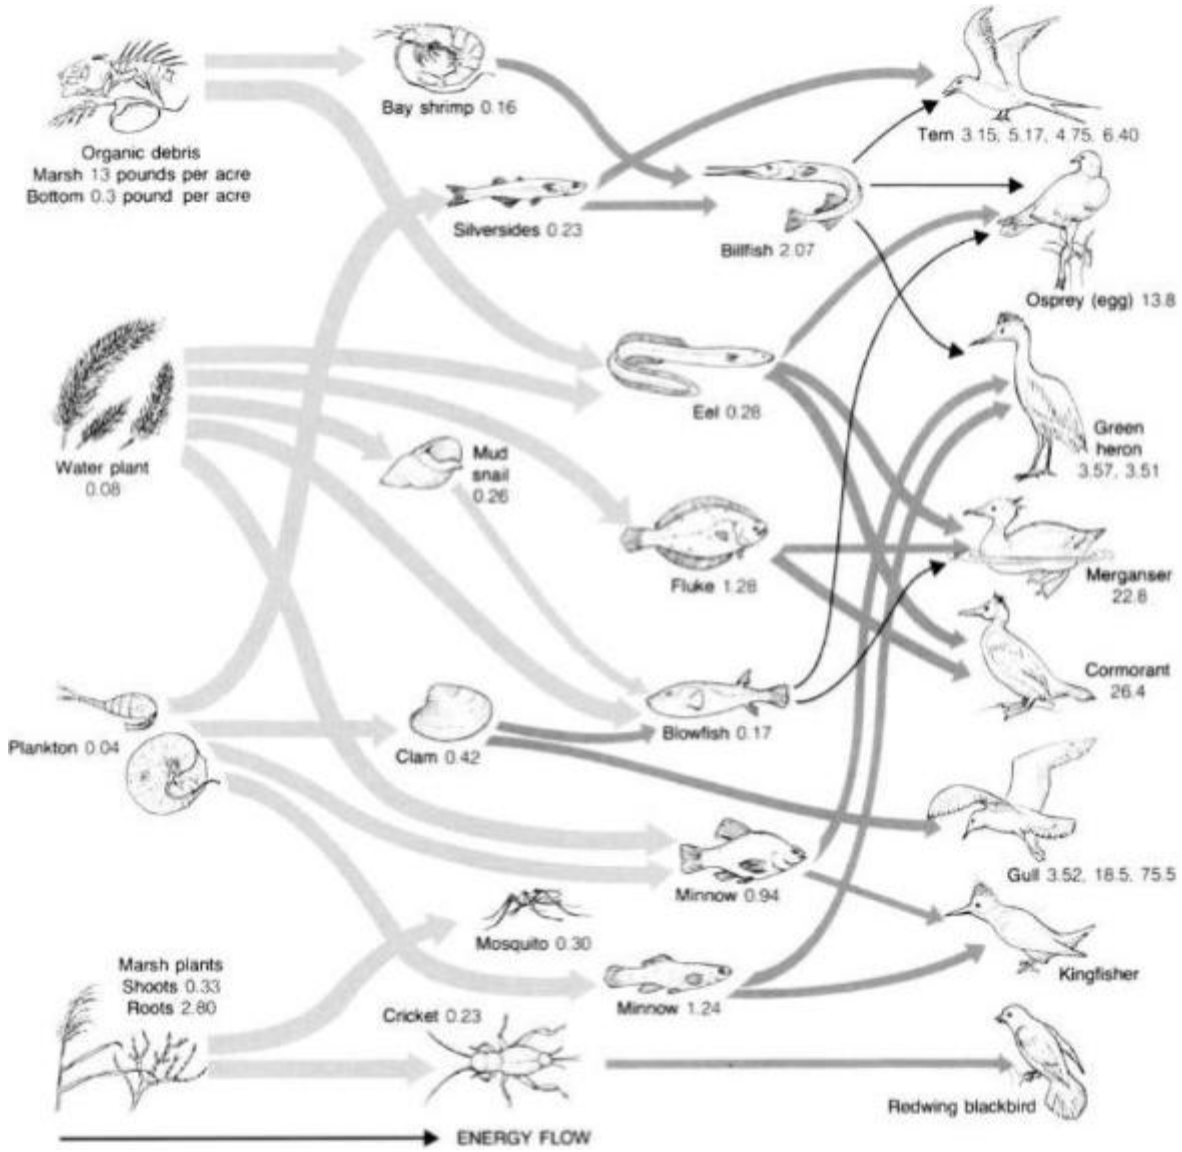

FIGURE 4-25 Portion of a food web in a Long Island estuary. The arrows indicate the flow of energy; the numbers tell how many parts per million of DDT are found in each kind of organism. (Adapted from Woodwell, 1967.)

simply and neatly in nature. But there appear to be, then, both observational and theoretical reasons to believe that a general principle holds: stability is related to complexity. Complex communities such as the deciduous forests that cover much of the eastern United States persist year after year if people do not interfere with them. An oakhickory forest is quite stable in comparison with an ultrasimplified community such as a cornfield, which is a man-made stand of a single kind of grass. A cornfield has little natural stability and is subject to almost instant ruin if it is not constantly managed by the farmer. Similarly, arctic and subarctic ecosystems, which are also characterized by simplicity, tend to be less stable than complex tropical forest ecosystems. In arctic regions the instability is manifested in frequent, violent fluctuations in the sizes of populations of such northern animals as lemmings, hares, and foxes. In contrast,

outbreaks of one species seldom occur in complex tropical forests. The late Robert MacArthur, who played a key role in stimulating the surge of interest in theoretical ecology in the last two decades, suggested in 1955 that the stability of an ecosystem is a function of the number of links in the web of its food chains. He developed a measure of that stability using information theory. [45]

More recent work, however, indicates that the relationship is more complicated and difficult to explain. For example, in some experimental work, an increase in diversity at one trophic level decreased stability at the next higher level; in other work it did not. [46] It turns out that both of the terms *complexity* (diversity) and *stability* have many meanings. Complexity, for instance, may refer merely to the species diversity -- how many kinds of organisms are present and the equitability of their abundance. (A community consisting of 100 individuals of each of three species is more diverse than one having 10 individuals of each of two species and 280 individuals of a third.) Or the term may be used to refer to the spatial diversity or patchiness of the environment (a number of vertical layers in the vegetation; uniform fields or fields interspersed with hedgerows). It also may include the genetic diversity within populations.

Stability, as the term is most generally used, refers to the propensity of an ecosystem (or any system, for that matter) to return to equilibrium following perturbation. Since equilibria are difficult to define and measure in entire ecosystems, however, very often definitions of stability are based on the amplitude of fluctuations in the sizes of sample populations in an ecosystem.

Recently the mathematics of complexity-stability theory has been synthesized by R. M. May, [47] who has shown convincingly that stability does not increase as a simple mathematical consequence of an increase in species diversity. But the mathematical models of ecosystems considered by May involve so many simplifying assumptions -- especially the absence of coevolution -- that they really do not address the key question of whether diversity causes stability.

Two other reviews of the diversity-stability question, by ecologists Daniel Goodman [48] and William W. Murdoch, [49] both conclude that in natural ecosystems there is no reason to believe that diversity produces stability. Both cite numerous examples casting doubt on the classic Eltonian formulation of the relationship and the evidence that has been rallied to support that formulation. Murdoch focuses on the coevolutionary nature of species interactions in natural systems. He suggests, "The marked instability of agroecosystems (and other artificial communities), in contrast with the stability of natural communities, results from the frequent disruption of crops by humans and from the lack in crop systems of co-evolutionary links between the interacting species. This second feature of crops is caused by the haphazardness of the collection of species on any given crop field, the changing selective regime imposed by humans, and the fact that crops [crop ecosystems] have lost many species that were present in the previously existing natural communities." [50]

Subsequently, however, Jonathan Roughgarden in a theoretical study of the role of coevolution in communities has shown that it may be either a stabilizing or a

---

destabilizing force. [51] In some circumstances coevolution can greatly enchance community stability, leading to a structure that will not collapse if a single species is removed. More frequently it leads to a configuration less stable than the original -- to situations where, for example, the loss of a single species population may lead to the decay of the entire system.

The last word on the relationship between diversity and stability is clearly not in. Perhaps the best hypothesis available today is that where one finds an association between diversity and stability it is probably the result of parallel evolutionary trends rather than a direct causal relationship. [52] To put it another way, an increase in the complexity of ecological systems does not necessarily lead to an increase in their stability and, in fact, may destabilize them. But in the course of evolution the most stable complex systems are by definition those that have persisted for long periods. Unstable complex systems, on the other hand, have disappeared.

Some tentative conclusions can be drawn from this. First of all, merely adding more species to agricultural ecosystems will not necessarily stabilize them. Indeed, it may have exactly the opposite effect. Van Emden and Williams [53] cite numerous examples of this before giving a weak endorsement to the desirability of maintaining hedgerows between fields. They may take a somewhat too gloomy view of the benefits of such maintenance of spatial diversity, however, since they do not consider the positive effects of the hedgerows as pollinator refuges. But it is clear that careful evaluations of all the properties of the coevolved complexes of an ecosystem are necessary before attempting to tinker with increasing diversity in order to stabilize such systems.

On the other side of the coin, one can say that removing elements from relatively stable natural ecosystems may well destabilize them, with unfortunate consequences for *Homo sapiens*, which depends on those systems for a variety of indispensable services. For instance, in Africa a reduction in the diversity of the antelope fauna by brush clearing has destabilized the grazing ecosystem, and the game herds are diminishing. The productivity of herbivores in the new system, in which cattle are replacing the antelopes, is much less, as is the potential of that system for supporting human life. [54]

Loss of herbivore productivity is not the only possible consequence of reducing complexity. Ecologist George Woodwell has emphasized the tightness of normally complex, mature

ecosystems. Several studies show that disturbance (for example, cutting down the trees of a forest) leads to a leakage of nutrients from a system. Such leakage, according to Woodwell, "may be large enough under certain circumstances to reduce the potential of the site for repair through succession and to degrade other systems by overloading them with nutrients." [55] The phenomenon of nutrient leakage is worldwide, but it seems especially critical in that most threatened of all ecosystems, the tropical rain forest.

Unhappily, there is no way to predict exactly what the consequences will be of removing even one species from an ecosystem or even of reducing the genetic variability of a species. In some cases a removal may make no discernable difference; in others it may be catastrophic. In one instance, removal of a single species from a fifteen-species intertidal community of marine invertebrates caused it to collapse to an eight-species system in less than two years. [56] Similarly, it is clear from the work in lupines and lycaenid butterflies discussed earlier that genetic diversity may be very important in the trophic relationships of plant populations.

Diversity, stability, and ecological politics. Ecologists have commonly argued for the preservation of diversity because they have believed that the stability of ecological systems may depend upon it. Now, as we have seen, considerable doubt has been thrown on the notion

that diversity causes stability, and even on the idea that the two are associated. It therefore is important that general statements about diversity, complexity, and stability now be eliminated from the political rhetoric of the environmental movement, for that movement must give as accurate an interpretation of the current state of ecological science as possible.

It is important to note that the diversity-causes-stability argument is not necessary in order to demonstrate that extermination of populations or species, destruction of genetic variability, and other actions that simplify ecological systems are threatening not just to those systems but to humanity as well. Lessening the diversity of both simple and complex natural ecosystems may lead to their destabilization, with results that are extremely undesirable from a human viewpoint.

As Goodman succinctly put it, "From a practical standpoint, the diversity-stability hypothesis is not really necessary; even if the hypothesis is completely false it remains logically possible -- and, on the best available evidence, very likely -- that disruption of the patterns of evolved interaction in natural communities will have untoward, and occasionally catastrophic, consequences." [57]

Extinction, Endangered Species, and Invasions

It should be apparent from the preceding that humanity forces populations and species to extinction at its peril. Of course, extinction is a natural phenomenon -organisms have been going extinct for billions of years. There have been episodes of "rapid" extinction in geological history, such as the disappearance of the dinosaurs about 70 million years ago. Those rapid episodes, however, were actually quite slow compared to the extinction "explosion" now occurring. Records of the disappearance of species of birds and mammals have been reasonably accurate since 1600. Since then some 130 species have become extinct -- roughly I percent of the 12,910 species of birds and mammals alive 375 years ago. [58]

Although past rates of extinction are very difficult to estimate, if the average "life span" of a species of higher vertebrate is assumed to be between 200,000 and 2 million years, then extinction of I percent of the species could be expected every 2000 to 20,000 years. If so, in the period from 1600 to 1975 the rate of extinction was five to fifty times as high as in the past. Furthermore, some 300 additional species of birds and mammals are now threatened with extinction. Should one-fifth of those actually become extinct before the year 2000, the rate would be from 40 to 400 times normal. Such rates of extinction are much too rapid for the normal evolutionary processes that generate organic diversity to be able to replace them.

Human beings first became a significant force for extinction when they became hunters. There is little question that the extinction of many large mammal species during the late Pleistocene 10,000 to 12,000 years ago was accelerated by the human search for food. [59] In more recent times, however, this has declined in importance as a cause, and the destruction of the habitats of birds and mammals has become a more important element in extinction. [60.] For other animals and plants, habitat destruction is the primary cause of extinction. When those much more numerous organisms are added to the bird-mammal picture, the rate of extinction then seems to be about 10,000 species per century (from a total of perhaps 10 million). If the Brazilians and others succeed in destroying the flora and fauna of the Amazon basin (as discussed in Chapter 11), perhaps *1 million* kinds of plants and animals could disappear from that region alone. [61]

Furthermore, in many (if not most) situations, saving small patches of habitat is not enough to prevent a decay of species diversity. A preserved area must be large enough to support all of the populations belonging there -- and some mammalian carnivores and raptorial birds require territories of many square kilometers. Even populations of insects may require sizable areas for their maintenance. It seems likely, for example, that because of its trap-lining behavior a population of the butterfly

Heliconius ethilla requires at least one square kilometer. Many euglossine bees also require large areas of forest, and many bee populations and species are being wiped out as the forests of Central America are decimated. [62] Their loss, in turn, is having dire consequences for the orchids and other plants that depend on them for pollination. The future well-being of the ecological systems that support our civilization may be threatened by the extinction of these species. Some of the species now endangered may be key species in systems important to people, but there is no way to tell whether they are, without the most exhaustive investigations of the ecosystems involved. Who, for instance, would have guessed that E. J. Kuenzler would discover in his study of a Georgian salt marsh [63] that a seemingly insignificant mussel was largely responsible for making phosphorus (a limiting resource) available to the community?

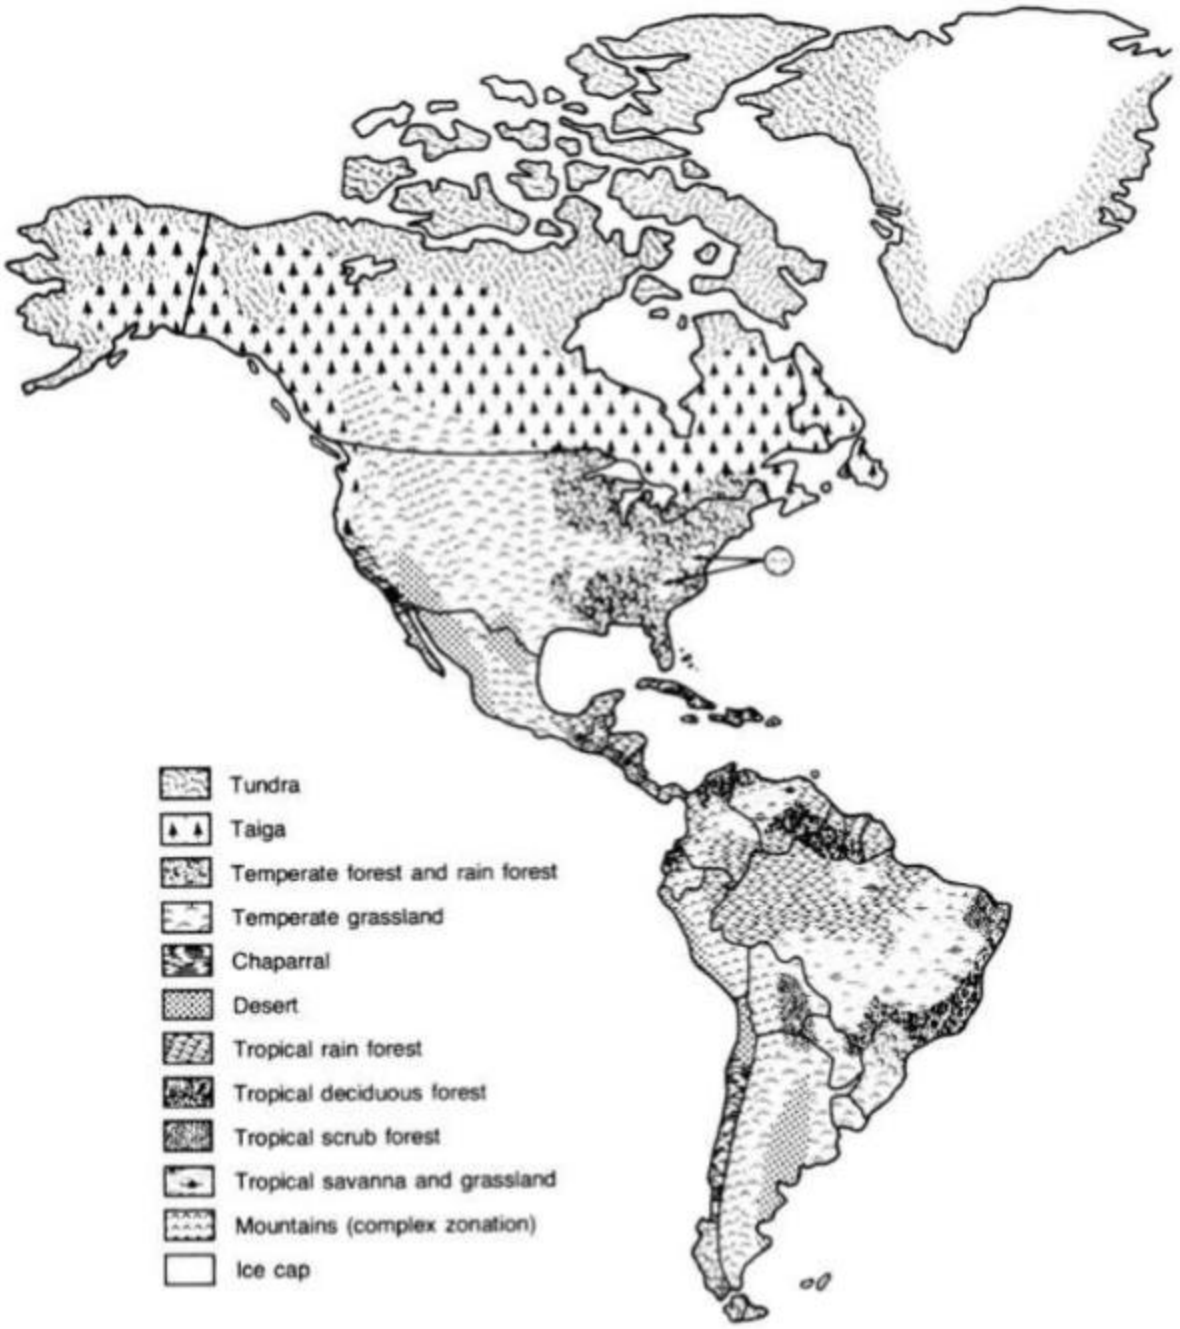
Thus, conservationists have a powerful argument for the protection of endangered species beyond the compassionate-esthetic-recreational arguments usually raised, although those are compelling in themselves. As far as anyone knows at this writing, the other species of organisms on Earth are our only living companions in the universe. Each one that is forced to extinction is one that our descendants will not have the opportunity to see (or exploit), just as we have no possibility of seeing alive dodos, passenger pigeons, or the Xerces butterfly. And, of course, each extinction carries with it the threat of the loss of other values as a pool of genetic information is destroyed forever. These losses range from potential sources of antibiotics and laboratory animals for medical research to genetic material useful for domestication, or, through crossing, for improving plants and animals already domesticated.

Nor is it possible to insure adequately against such loss by maintaining samples of organic diversity in zoos, experiment stations, and botanical gardens. The problems of maintaining many species in captivity are extremely complex -- and, as the numbers that need to be saved grow, the task could become immense. [64] But, even if culture techniques were perfected for most species, the serious problem of the decay of genetic variability would remain.

Finally, it is important to remember that human beings decrease organic diversity, not only by directly assaulting species and by destroying habitats, but also by moving organisms around. Species transplanted are often species removed from the presence of natural enemies that keep their numbers in check, and inserted into the presence of others that have never evolved defenses against the invaders or the capacity to compete with them. In 1975 on the island of Maui in Hawaii, we were surprised to find a dense population of swallowtail butterflies. The only large butterflies on the Hawaiian islands previously had been monarchs. The new butterfly was *Papilio xuthus*, a common Asian species in a group that feeds on plants of the Citrus family Rutaceae. A phone call to the Hawaii Department of Agriculture revealed that *P. xuthus* had been in the

Hawaiian islands for more than a year and on Maui for "about three months." In that time a population much denser than most *Papilio* populations had built up, apparently in the log phase of growth, and considerable damage was visible on the citrus trees, grown largely as ornamental plants.

What impact this import will have on native Hawaiian Rutaceae remains to be seen. The Hawaiian Islands, however, have lost a great deal of their native forests to clearing for agriculture and for urban and resort development. The unique fauna of Hawaiian honeycreepers (finchlike birds of the family Drepanididae) has already suffered severe losses. Eight of twenty-two species discovered before 1900 are now extinct or presumed extinct, and several others have lost distinct races from various islands. Forest clearing, the introduction of mongooses for rat control, and the introduction of foreign birds that both competed with the honeycreepers and carried disease, all played parts in this disaster. (The mongoose, by the way, is one of the most destructive exotic animals. Wherever it has been introduced to control rats or snakes, it has made haste to devour part of the local bird fauna as well.)



Enormous areas may be dramatically changed by introduction of a single species freed of its natural controls. The flora of much of the Mediterranean area

today is impoverished because of the activities of that ultraefficient grazer and browser, the goat. *Opuntia cactus* imported into Australia covered vast areas until its populations were brought under control by a moth, *Cactoblastis cactorum*, taken there for the purpose from the native haunts of the cactus in South America.

The history of human transfers of organisms, purposeful or accidental, is replete with disasters -- the cabbage butterfly, the Hessian fly, the gypsy moth, the starling, and the walking catfish have made trouble in North America; rabbits overran Australia; and the grape pest *Phylloxera* nearly destroyed France's wine industry in the nineteenth century. The great ecologist and conservationist Aldo Leopold once said, "The first rule of intelligent tinkering is to save all the parts." Perhaps we should now add to that, "and don't put them in the wrong place."

BIOMES

Terrestrial communities differ dramatically from place to place. The assemblage of plants and animals observed by a resident of California or Chile, for example, is strikingly different from that familiar to a resident of New Jersey or Great Britain. The major kinds of terrestrial communities are called biomes by ecologists. Since the impact of human activities varies greatly from biome to biome, you should be familiar with the distribution and at least some of the characteristics of these broadest groupings of communities (Figure 4-26A). [65]

Climatic factors exert the primary control over the nature of the biota (a collective term for the organisms) of

[65]Further details on the fauna and flora of biomes can be found in the books by Kendeigh; Odum; Raven, Evert, and Curtis; and Alice et aL., listed at the end of the chapter.

TABLE 4-8 Biological Productivity in Differing Biomes

Biomass	Arctic tundra (USSR)	Northern taiga (USSR)	Beech forest (central Europe)	Subtropical deciduous forest (average)	Tropical rain forest (average)	Dry savanna (India)	Desert (USSR)
Photosynthetic parts (%) (mostly leaves)	30	8	1	3	8	11	13
Perennial parts (%) (stems, etc.)		70	73	77	74	47	25
Roots (%)	70	22	26	20	18	42	62
	---	---	---	---	---	---	---
Total	100	100	100	100	100	100	100
Litter fall (% of plant biomass)	20	4	3	5	8	27	38

broad geographic areas -- they are responsible for the characteristic life forms that permit ecologists to distinguish biomes. The relationship of average annual precipitation, average annual temperature, and biome type is shown in Figure 4-26B. Some of the characteristics of ecosystem productivity in the various biomes are listed in Table 4-6. Table 4-8 presents a picture of the distribution of biomass among roots and above-ground parts of plants and indicates what percentage of the biomass the litter fall is, in seven biomes. There are characteristics of the ecosystem in various biomes that transcend the collection of species functioning in the ecosystems. Thus, two tropical rain forests may have entirely different floras, but they will be much more similar to each other in their productivity and in the apportionment of biomass between roots and above-ground parts than either would be to a temperate forest or a desert ecosystem.

Temperate Forest

In regions where the minimum temperature is below freezing each winter but usually does not drop below -- 12° C (10° F) and the annual rainfall is between about 75 and 200 centimeters (30-80 inches), the dominant plants and animals belong to the *temperate forest biome*. This is the biome familiar to most readers of this book, because it is the biome in which Western (and Chinese) civilization developed. It is typified by the deciduous forest of the eastern United States but is also found in Western Europe and Northeastern China. Where soil conditions permit, mixtures of broad-leafed deciduous trees, such as maples, hickories, and many oaks, grow in dense stands. In the American forests, characteristic mammals such as white-tailed deer,

squirrels, shrews, bears, and raccoons forage; so do birds such as warblers, woodpeckers, a wide variety of thrushes and flycatchers, wild turkeys, and owls and hawks.

The deciduous nature of the dominant trees plays a critical role in determining the nature of the temperate forest biome (Figure 4-27). It permits a rich secondary flora to coexist under the trees, flowering in the early spring before the leafing of the trees shades the flora out. In turn, the members of this secondary flora are producers of major components of the temperate forest food web. Many forest insects, for example, feed on these plants of the understory. Furthermore, the deciduous habit itself can be considered an evolutionary response of basically tropical flowering plants that permits them to survive periods when low temperatures would interfere with their photosynthetic mechanisms and water balances.

Because of the annual leaf drop, temperate forests generate soils rich in nutrients, which in turn support an extravagant microbiota in the soil itself. A gram of forest soil has been found to contain 650,000 algae, and counts of microarthropods may number in the hundreds of thousands and nematodes (roundworms) in the millions per square meter. [66] Hence, soil is not just small particles

[66] L. Steubing, Soil flora: Studies in the number and activity of microorganisms in woodland soils, in *Analysis of temperate ecosystems*, David E. Reichle, ed.

worn from the rock of Earth's crust, but a complex integral part of the ecosystem, containing both plants and animals. Especially important to the fertility of the soil is its content of decomposed organic matter or humus (see Chapters 7 and 11).

When a temperate forest is cleared, the stored energy and nutrients in the trees are removed, as is the protection from wind and torrential rain that a forest canopy provides. Furthermore, an important source of new nutrients is lost, for the forest trees serve as nutrient pumps. Their deep roots bring vital substances up from the lower regions of the soil, and the trees deposit them at the surface when they shed their leaves.

FIGURE 4-27 A deciduous forest. (Photo by George Taylor, courtesy Friends of the Earth.)

When temperate forests are cleared, the richness of the soils can be preserved if great care is taken to see that their supplies of nutrients and decaying organic material are maintained. It is critical to remember that raising crops or grazing animals on land is, in a sense, mining the soil unless nutrients are carefully returned to it. The nutrients depart along with the crops, meat, wool, or whatever is removed. These may be returned in a variety of ways so the crucial nutrient cycles are continued (see Chapter 3). But, all too often, short-term careless exploiters have permitted soils to deteriorate or have ignored opportunities to improve them. Numerous abandoned farms in Virginia and the Carolinas show the cost to humanity of ignoring the fundamentals of soil ecology; the rich farms of, say, Bavaria show the rewards of paying careful attention to them.

Unfortunately, economic considerations often lead individuals who are exploiting an ecological system to use short-term strategies that are disastrous for humanity in the long run. Thus, it might have been uneconomical for nineteenth-century farmers in some parts of the eastern United States to maintain the nutrient supplies in the soil of their farms carefully. Perhaps they could only survive by living on the capital of nutrients in the land they cleared. In more densely crowded Europe, without competition from other farmers continually exploiting an expanding frontier, a Bavarian farmer of the same period could afford the appropriate soil husbandry -- a husbandry that was part and parcel of ancient local tradition.

Deserts

In areas where rainfall is less than 25 centimeters (10 inches) a year are found the world's deserts. They are concentrated in the vicinity of the latitudes 30° north and 30° south, where the global weather system tends to produce descending masses of dry air (although special local conditions may create deserts far from these latitudes). Lack of moisture is the essential factor shaping the *desert biome*. Most deserts are quite hot in the daytime and, because of the sparse vegetation and resultant rapid reradiation of heat, quite cold at night (Figure 4-28). Some, like the fog desert of the Peruvian coast, which

FIGURE 4-28 A desert plant community, central Baja California, Mexico. Notice the variety of spiny, succulent plants and their wide spacing. (Photo courtesy of Robert Ricklefs.)

FIGURE 4-29 A fog desert on the Peruvian coast south of Lima (the shore is in the background). Note the lack of vegetation in this habitat. (Photo by P. R. Ehrlich.)

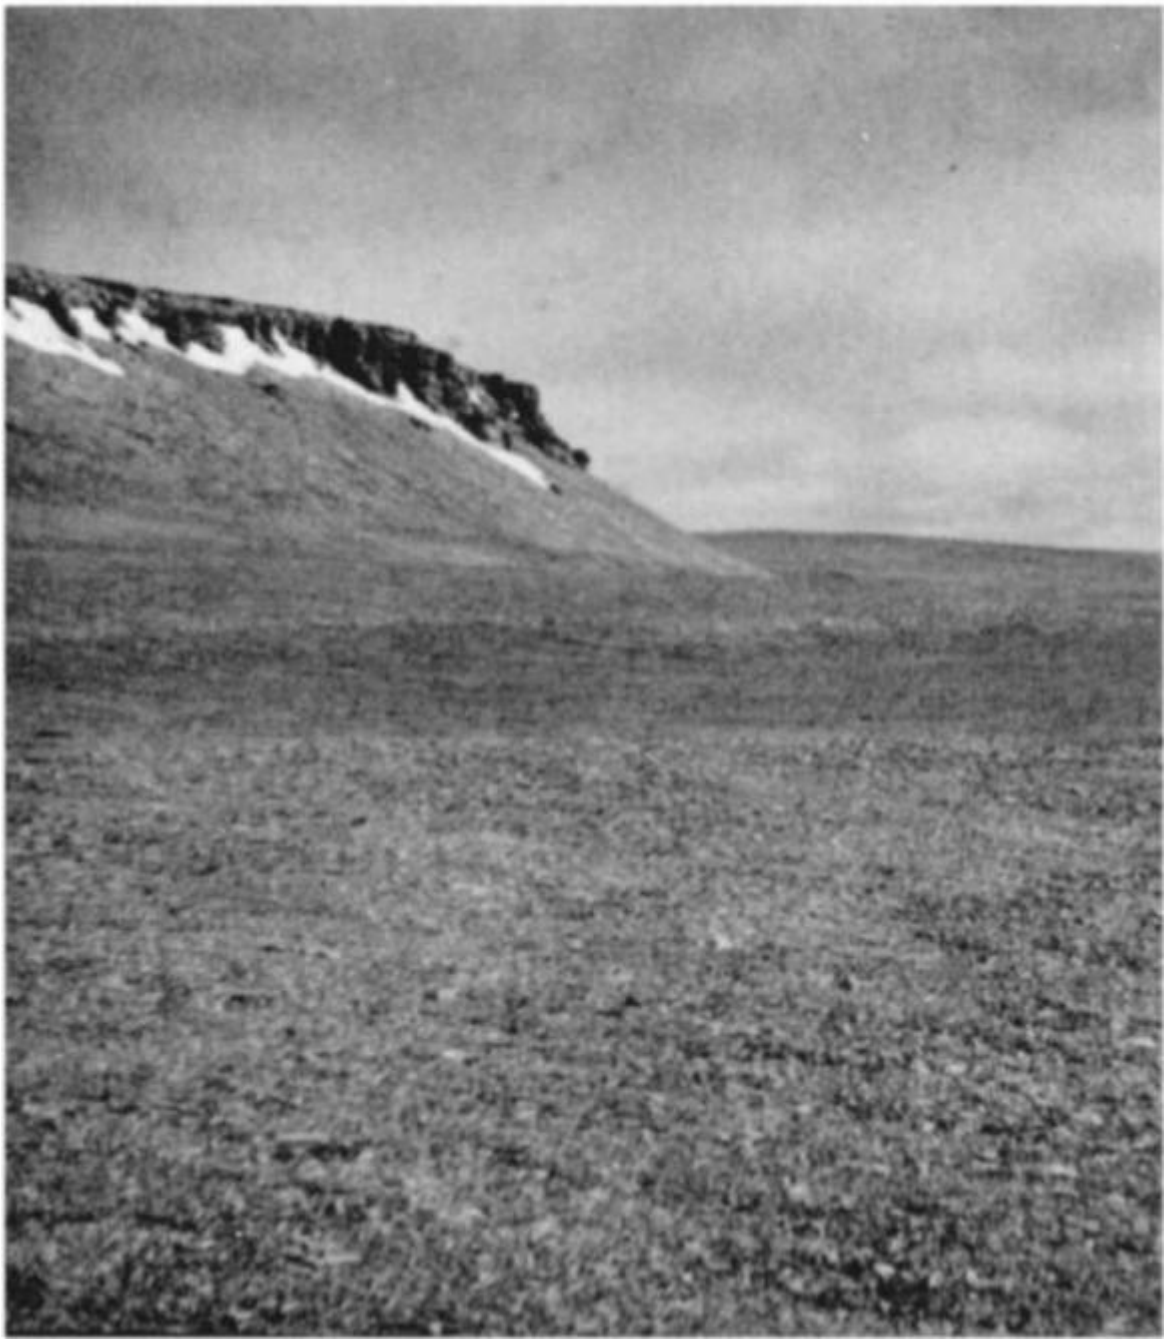

FIGURE 4-30 An Arctic rock desert, Cornwallis Island, Northwest Territories, Canada. Like the fog desert, this habitat is often nearly devoid of plants, which in this area are most abundant on the relatively nutrient-rich sites of the middens of ancient Eskimo camps. (Photo by P. R. Ehrlich.)

gets little sun over much of the year (Figure 4-29) and the arctic rock desert (Figure 4-30) are relatively cool even at midday. Both of these desert habitats can be nearly devoid of plants.

Desert plants and animals have evolved many specializations for conserving water. In plants these include unusually thick, waterproof outer layers or cuticle, modifications of breathing pores (stomata), reductions in leaf area, and specialized hairs or outgrowths that reflect light. Many desert plants also are heavily armed with spines to repel the attacks of moisture-seeking animals. They frequently are aromatic, indicating the presence of biochemical defenses against herbivores.

Plants may appear to be widely spaced in deserts, but if their roots were visible, the ground between the plants would be seen to be laced with shallow root systems that allow maximum absorption of the rain that does fall. In certain soil conditions, desert plants may have extremely long taproots to reach deep underground water supplies.

Germination of the seeds of desert plants is often inhibited by water-soluble chemicals that must be leached out by a threshold amount of rain before sprouting can occur. Other plants that grow in gravelly arroyos have seeds that require abrasion as the first rains wash them along before they will germinate. Thus, deserts appear to turn miraculously green almost overnight following significant rains, and fast-growing annual plants often create spectacular floral displays.

Proportionately more annual plants are found in the desert biome than in any other. If rainfall is relatively abundant, each individual plant may produce numerous flowers. If rainfall is sparse, many individuals produce only a single blossom each. Since the period of bloom is brief and only follows sporadic rainfall, many people who have traveled in desert areas have not seen them in bloom and remain unaware of the wonderful aesthetic resource they represent.

Desert animals also solve the problem of water shortage in diverse ways. Most are active primarily at night, remaining under cover in the heat of the day. Excretory systems are designed to conserve water, and many desert animals are able to use the water they produce in their cellular metabolism. Many desert insects are "annuals," like the plants they feed on -- synchronizing their periods of activity with the evanescent desert bloom.

Desert soils contain little organic matter and must ordinarily be supplied with both water and nitrogen if they are to be cultivated. Much of the uncultivated flat land remaining in the world today is desert, and it seems inevitable that large-scale attempts will be made to expand agriculture into this biome. As we discuss in Chapter 11, irrigation is an expensive and often temporary process -- very often a system cannot be maintained and once-cultivated and lands revert to desert.

Human activities already have produced a great increase in the amount of desert and wasteland. In 1882 land classified as either desert or wasteland amounted to 9.4 percent of the total land on Earth. In 1952 that proportion had risen to 23.3 percent. (Part of this increase doubtless is the result of better information or changes in the definition of wasteland.) During the same period, land classified as carrying inaccessible forest decreased from 43.9 percent to 21.1 percent. [67] The vast Sahara itself is in part man-made, the result of overgrazing, faulty irrigation, and deforestation, combined with natural climatic changes. Today the Sahara seems to be advancing southward into the drought-stricken Sahel, its advance aided by overpopulation of people and domestic animals. The great Thar desert of western India is also partly the result of human

influence. Some 2000 years ago, what is now the center of that desert was a jungle. The spread of the desert has been aggravated by poor cultivation practices, lumbering, and overgrazing. Human activities could lead to repetition of the Sahara and Thar stories in many parts of the globe. [68]

Grasslands

Where broad climatic conditions are intermediate between those favoring temperate forest and those producing desert, microclimatic factors (controlled by slope, exposure, and the like) determine whether forests grow.

---

[67] R. R. Doane, *World balance sheet*, Harper, New York, 1957.

[68] The Sahara and Thar situations are described in M. Kassas, Desertification versus potential for recovery in circum-saharan territories, in *Arid lands in transition*, Harold E. Dregne, ed., American Association for the Advancement of Science, Washington, D.C., 1970, and B. R. Seshachar , Problems of environment in India, in *Proceedings of joint colloquium on international environmental science*. U.S. Government Printing Office, Washington, D.C., 1971, Report 63-562.

Thus, tongues of forest may intrude into areas of desert climate along river valleys. The trees themselves change the microclimate in their vicinity, and if they are removed from an area otherwise suitable for their growth, a *grassland* may develop (Figure 4-23). Many ecologists feel that the great grasslands of the American prairie and Great Plains, the steppes of Russia, the vast savannas of Africa, and so forth are all zones between forest and desert where fire and/or browsing animals have prevented the spread of trees, even though rainfall is more plentiful than that which produces typical desert. Various specializations of grasses lead to their dominance in such situations.

Large animals typical of grasslands include the bison ("buffalo") and pronghorn antelope in North America; wild horses in Eurasia; large kangaroos in Australia; and zebras, giraffes, white rhinoceros, and a vast diversity of antelopes in the African savannas. The latter support the richest fauna of large grazers, and the grazers seem to have coevolved in ways that maximize the utilization of the local plant resources. [69]

Other important grassland animals include lions, cheetahs, hyenas, coyotes, and other predators; a variety of birds, ranging in size from ostriches and vultures to small sparrows; rabbits and other burrowing rodents (including the prairie dog); and grasshoppers (locusts). Some grasshoppers exist in a solitary form when their population density is low but transform under crowded conditions over a generation or so into a gregarious form that differs strikingly in both appearance and behavior. The crowded forms migrate in huge masses, laying waste to the countryside -- a plague of locusts. For a long time the origins of the locust plagues were not understood because the solitary and gregarious forms were so dissimilar they were identified as different species. [70]

The grassland biome has a higher concentration of organic matter in its soil than any other biome. The amount of humus in grassland soil is about a dozen times that in forest soils. The extraordinary richness of grassland soil has led to the establishment of extremely successful agricultural ecosystems in grassland areas -- in the American prairies, for example. These agricultural systems can deteriorate rapidly, however, if careful soil husbandry is not practiced.

The interlaced roots and creeping underground stems of grasses form a turf that prevents the erosion of soil by wind and water. When the turf is broken with a plow, however, the soil is exposed to those erosive influences. In addition, certain kinds of plowing can lead to the formation of a hardpan (a soil horizon nearly impervious to water and roots) below the surface. These two factors have led to rapid deterioration of agroecosystems established in some grasslands -- a deterioration dramatized by the dust bowl of the American Great Plains in the 1930s, described so graphically by John Steinbeck in his classic *The Grapes of Wrath*. Indeed, lack of proper soil conservation has already led to a loss of an estimated one-third of the topsoil of the United States (see Figure 4-31). [71]

The situation elsewhere is even more serious. It is estimated that half the farmland in India is not adequately protected from erosion, and on fully one-third of the farmland, erosion threatens to remove the topsoil completely. As agronomist Georg Borgstrom has pointed out, soil conservation procedures are especially difficult to institute in areas where a population is poorly fed. He cites a study that recommended a one-fifth reduction in the amount of cultivated land and a one-third reduction in the size of livestock herds in Turkey. [72] It was hoped that these reductions would help to diminish the danger of catastrophic erosion caused by overgrazing. Unfortunately, the program was not initiated, presumably because the local people depended upon the land and the herds for food and other necessities. As so often happens, a short-run need took precedence over long-run wisdom.

Agriculture in grassland biomes can only be successful over the long term in areas where considerable effort is put into the maintenance of soil structure and nutrients. As we discuss in Chapters 6 and 11, there is considerable reason on this account for anxiety about the prospects for continued high productivity in the American Midwest.

Taiga

North of the temperate forests in the Northern Hemisphere lies a broad zone of coniferous forest, generally called by its Russian name, *taiga* (Figure 4-32A). Most of the trees do not shed all their leaves in winter. Their leaves are specialized to reduce water loss, especially in the cold season when the area is, in physiological effect, a desert. The leaves in many cases are needlelike and generally last three to five years. Although one thinks of spruce, fir, and other conifers as typical of the taiga, in local regions -- including disturbed areas --such deciduous trees as aspens, alders, and larches may be prominent elements of the flora (Figure 4-32B). In general, the trees are much less diverse than those in temperate forests, and the soils have a different kind of humus and are more acid.

Bears, moose, lynxes, rabbits, squirrels, and a variety of birds live in the taiga, but the diversity and abundance of warm-blooded vertebrates are generally less than those of the temperate

forests. An exception to this rule are the mustelids (weasels, martins, sables, fishers, and wolverines), which are relatively richly represented. The diversity of cold-blooded vertebrates is even more dramatically restricted -- snakes are uncommon, and few amphibia are to be found. Insect diversity is correspondingly low, but the existence of huge stands of one or two species of conifer provides an opportunity for periodic

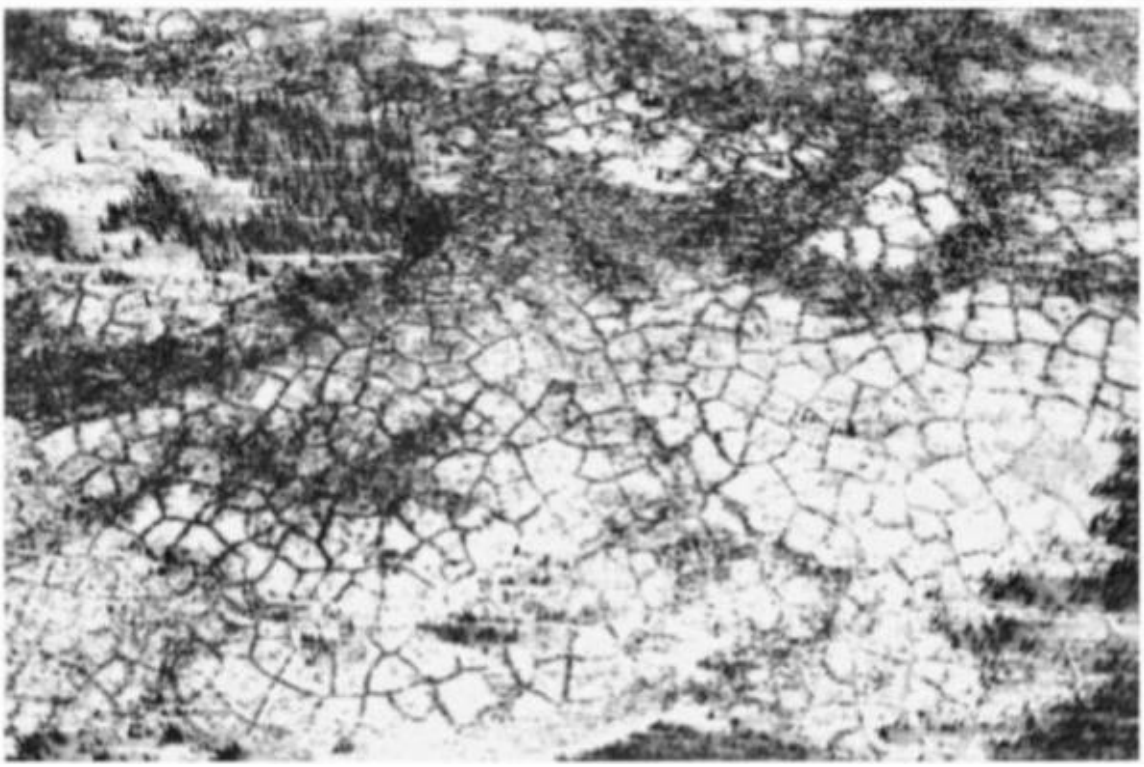

FIGURE 4-32 A. Taiga along the Hay River, Northwest Territories, Canada. A growth of aspens and willows occupies the area subject to flooding along the riverbank. (Photo by P. R. Ehrlich .) B. outbreaks of herbivores like the spruce budworm (the larva of a moth, *Choristoneura fumiferana*), which can defoliate huge areas of forest. In the early 1950s in New Brunswick, Canada, more than 6 million acres were defoliated by the spruce budworm. [73] Mosquitoes and other biting flies reach abundances in the taiga unknown elsewhere in the world and can make human life very difficult in summer (Figure 4-32D). The uniformity of the taiga ecosystem in comparison with the temperate forest and its comparative sensitivity to insect plagues has been one of the underpinnings of the notion that diversity in ecological systems tends to be associated with their stability.

First animal pelts for the fur trade and then wood were the major commodities people extracted from the taiga. Decimation of the fur-bearing animals, changes in clothing styles, and a growing demand for pulp for manufacturing paper have led to an almost total shift to logging in the

exploitation of this system. Huge areas have been denuded of forest, often with little or no attempt to protect the soil, so in many places the existence of the climax coniferous forests of the taiga is threatened by erosion. Furthermore, broadcast use of insecticides against insects has been widespread, adding persistent poisons to the already heavily taxed ecosystems of the planet and normally failing to fulfill the goals of the spray program. [74]

In the Southern Hemisphere, little of the land area extends to high enough latitudes to support an extensive taiga like that of the Northern Hemisphere. A somewhat comparable ecosystem is found in the cool areas of South America and Australia, dominated by evergreen trees of the beech family in the genus *Nothofagus* (Figure 4-33). A characteristic of *Nothofagus* forests, like those of the taiga, is an extensive litter of tree trunks and branches on the forest floor, since in cold climates the action of decomposer organisms is quite slow.

Tundra

North of the taiga lie the treeless plains of the *tundra*. In those areas, where the average annual temperature is below -5° C (23° F), the ground normally thaws in summer only to a depth of less than a meter. Below that it remains permanently frozen (permafrost). Precipitation is usually less than 25 centimeters (10 inches) per year. The permafrost effectively prevents the establishment of

[73]R. F. Morris, (ed.), The dynamics of epidemic spruce budworm populations, *Memoirs: of the Entomological Society of Canada*, vol. 31 (1963) pp. 1-332.

[74]Ibid. Also, see Chapter 11 for a fuller discussion of the use of insecticide.

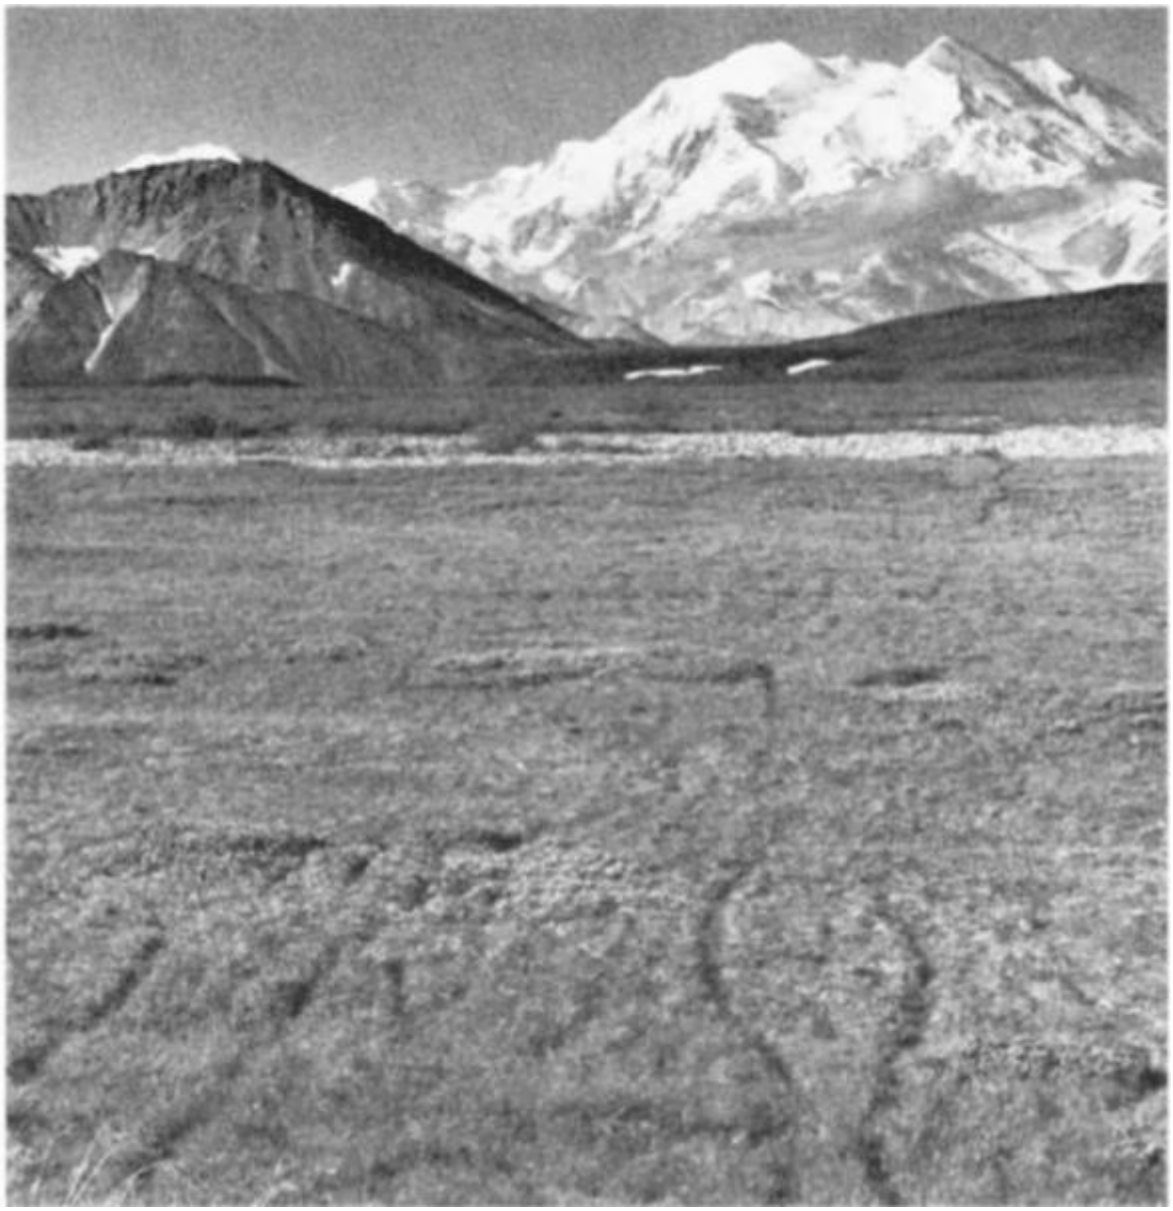

FIGURE 4-34 Tundra biome. A. Grassy tundra at Duke of York Bay, Southampton Island, Northwest Territories, Canada. The bones in the foreground are the vertebrae of a right whale at the site of an old Eskimo encampment. The right whale is now extinct in this area. B. An Eskimo child holding a piece of white whale (beluga) skin on Coral Harbour, Southampton Island, 1953. The skin of this small whale is considered such a delicacy that the Eskimo word for it, *muktuk*, forms the root of the Eskimo word for "delicious," *a nah muktuk*. The tundra biome in most areas is relatively devoid of large food animals, the exception being migratory caribou. Therefore, primitive Eskimo groups were heavily dependent upon sea mammals and fishes for food and other resources. C. Eskimo men butchering walruses on Walrus Island in northern Hudson Bay, Canada. Walrus provide food for sled dogs, skin for making harness, and ivory for carving. D. Low tundra with extensive willow stands around lakes on Southampton Island. (Photos by P. R. Ehrlich.) E. Tundra below Mount McKinley, Alaska, showing caribou trails. (Photo by Charlie Ott, courtesy National Audubon Society.)

trees. Not surprisingly, the soil fauna is poorly developed -- nearly as depauperate as that of deserts. [75] Lichens, sedges, grasses, willows (which normally reach a height of less than a meter), and members of the cranberry family are among the dominant plants (Figure 4-34A). In some areas of the central Canadian Arctic, however, rainfall is so low that a rock desert nearly devoid of vegetation occurs (Figure 4-30).

Caribou, wolves, musk-oxen, arctic foxes, rabbits, and (occasionally in summer) polar bears are among the mammals found in the tundra. In the brief arctic summer, an astounding diversity of birds (especially waterfowl), migrate to the tundra to breed, feeding on an ephemeral bloom of insects and freshwater invertebrates. Mosquitoes can make one's life nearly as miserable in the tundra as in the taiga. Reptiles and amphibians are absent. As in the taiga, animal populations in the tundra may be subject to dramatic oscillations in size. Best known are the lemming cycles, which induce cycles in the owls, jaegers (predatory gulls), and other predators that feed on them.

Because of the slow rates at which plants grow and decompose, with the low temperatures and the characteristics of permafrost, the thick, spongy matting of lichens, grasses, and sedges that characterizes the "low tundra" (that found in depressions and on plains rather than ridges and slopes) is especially slow to recover from disturbance. [76] Tracks of vehicles or animals can remain visible for decades (Figure 4-34E). Great care must be taken in building on tundra because heat from structures will melt the permafrost and cause uneven settling, which often badly distorts the structures. The tundra has been one of the least exploited biomes, but that era is also ending.

Tropical Rain Forests

Near the equator, in areas where annual rainfall is greater than about 240 centimeters (95 inches) and the mean annual temperature is more than 17° C (64° F), are found the *tropical rain forests* -- the jungles of popular fiction. Tropical rain forests grow in climatic zones where neither temperature nor water is a limiting factor. They once covered much of Central America and South America, central and western Africa, Madagascar, and Southeast Asia. Tropical rain forests are characterized by a great diversity of plant and animal species and by their spacial structure.

The trees of these forests are taller than those of many temperate forests, the tallest reaching 60 meters (200 feet) or so. The tops of most trees are intertwined, to form a dense canopy 30 meters (100+ feet) or more above the ground (Figure 4-35A). The tallest trees stand out above the canopy. Beneath it little light penetrates to the ground. There are in many places more than fifty species of trees per hectare -- many more species than one could find in a day's walk through a temperate forest, where the vast majority of trees represent only a few species. Characteristic of tropical forests, also, are a wide variety of epiphytes (plants that grow high on the trees in the sunlit zone whose roots do not reach down to the soil). Except where a fallen tree has created a hole in the canopy to admit light, the understory in a rain forest is sparse, unlike that of a temperate forest. Since the trees normally do not branch below the canopy, one can often walk almost unobstructed through the dimly lit depths of a mature forest (the forest's edge, in contrast, is usually a tangle of riotous growth). Most trees have shallow roots, and many develop huge buttresses for support (Figure 4-35C).

Animal species in tropical rain forests are also very diverse, with insects, amphibia, reptiles, and birds especially well represented. For example, roughly as many butterfly species can be found in a single rain forest locality as are found in the entire United States (five or six hundred), including whole groups unknown or scarcely represented in the temperate zones. Coevolutionary relationships appear to be more highly developed in this biome than in any other.

To a layman the luxuriant growth of a tropical jungle implies a rich soil. Nothing, however, could be further from the truth. Tropical forest soils are in general exceedingly thin and nutrient-poor. They cannot maintain large reserves of minerals needed for plant growth, such as phosphorus, potassium, and calcium, primarily

(Photos by P. R. Ehrlich.)

because heavy rainfall and a high rate of water flow through the ground to the water table leach them from the soil. The leaching process leaves behind large residues of insoluble iron and aluminum oxides in the upper levels of tropical forest soils.

What nutrients there are in the tropical forest ecosystem are tied up in the lush vegetation itself. Those nutrients that are released by the decay of dropped leaves and fallen trees are quickly taken up by the shallow network of roots that laces the forest floor and are returned to the living vegetation. Since most tropical forest trees are evergreen, the process is continuous. A rich layer of humus does not accumulate as it does in a temperate forest, where, after a general leaf-fall, the trees are dormant each winter.

Tropical rain forests are being destroyed more rapidly than any other biome. In Central America, the forests are "vaporizing," to borrow the term of Daniel Janzen, one of the most distinguished tropical ecologists. [77] In Brazil they are being destroyed as a consequence of direct governmental action, in an effort to develop the Amazon basin. Throughout the tropics, forests are being cut down to make room for farms. The pressure of human population and ignorance are quickly robbing the world of its richest reservoir of terrestrial organic diversity.

Altitudinal Gradients

In areas where there are substantial variations in altitude, the terrestrial communities differ at different elevations. This is primarily because the temperature of the air decreases about 6° C for every 1000-meter increase in altitude, and because, especially in desert areas, rainfall increases with altitude. [78] Thus, in the mountains of Colorado above about 3500 meters, temperature conditions are similar to those of the tundra biome at sea level, and a treeless alpine tundra exists. As one travels northward in the Rocky Mountains, the treeline (the altitude above which tundra occurs) gradually lowers until in northern Alaska and Canada it reaches sea level.

Tundra is virtually continuous in the northern Rocky Mountains; in Colorado "islands" of mountain tundra occur as dense archipelagos. Because of this, the faunas and floras of the arctic and North American alpine tundras have many similar organisms. For instance, among the butterflies of Colorado mountaintops are numerous genera, and even a few species, also found in the sea-level tundras 3800 kilometers to the north. By contrast, the treeless zones of tropical South American and African mountains, where the treeline is around 4000 meters, superficially resemble arctic tundra (Figure 4-36) [79] but show few faunal affinities with the north. For example, satyrine butterflies of the genus *Erebia* found in the high mountains of Colorado are representatives of a circumpolar genus characteristic of cool climates. Satyrine butterflies of the high Andes that are virtually indistinguishable on the wing from *Erebia*, however, are members of the genus *Punapedaloides*, which has strictly tropical affinities.

Thus, in the mountains it is possible to find compressed into 2000 vertical meters a series of communities that would occupy a sea-level latitudinal gradient 1000 kilometers or more in length (Figure 4-37). Alpine habitats contribute greatly to the floral and faunal diversity of Earth because, although in temperature they closely resemble sea-level habitats closer to the

poles, they differ in other factors, such as daylength regime and atmospheric pressure. Anyone who has been active at an altitude of more than 3500 meters knows that the stresses encountered there are quite different from those at sea level anywhere!

Other Biomes

In this brief survey, we have not touched on some less extensive but nonetheless interesting biomes. *Chaparral*, found in places with mild marine climates and winter rainfall such as the Mediterranean basin and the southwest coasts of North America, South America and

[77]Janzen, *The deflowering*.

[78]For example, see J. Terborgh, Distribution on environmental gradients: Theory and preliminary interpretation of distributional patterns in the avifauna of the Cordillera Vilcamba, Peru, *Ecology*, vol. 52 (1971), pp. 23-40; and P. H. Whittaker and W. A. Niering, Vegetation of the Santa Catalina mountains, Arizona, pt.5: Biomass, production and diversity along the elevation gradient, *Ecology* vol. 56 (1975), pp. 771-790.

[79]S. R. Eyre, *Vegetation and soils: A world picture*.

FIGURE 4-36 Above the tree line near La Oroya, Peru, about 4000 meters. (Photo by P. R. Ehrlich.)

Australia, and the Cape region of South Africa, is characterized by dry, aromatic, evergreen shrubs and shrubby trees (Figure 4-38). Chaparral is subject to periodic fires that maintain the

dominance of the shrub vegetation; the underground parts of the perennial plants found there are fire-resistant, and some of the annuals must undergo fire before germination. In areas such as Southern California, people have built homes extensively in chaparral and suffer the consequences of the inevitable fires.

Tropical savannas are grasslands with scattered clumps of trees, which tend to be thorny. This biome covers a large portion of Africa and is familiar to all who have seen movies or television shows on the magnificent herds of hoofed mammals (and the carnivores that prey on them) that still roam in places like the Serengeti Plain. In many regions the savanna is threatened by overgrazing by cattle, but some efforts are now being made to develop systems of sustained-yield harvesting of native antelopes, which are better adapted to feeding on the savanna plants and more resistant to disease than cattle.

Tropical scrub and *tropical deciduous* (or seasonal) forest biomes are found where rainfall is intermediate between that suitable for savanna and that required for tropical rain forest. The scrub (sometimes called thorn forest) is found where the precipitation is between 50 and 125 centimeters (20 to 50 inches) per year; the deciduous forest, where it is between 125 and 250 centimeters (50 to 100 inches). The former consists of small hardwood trees, frequently thorny, as the name implies. The latter, especially where rainfall is toward the top of the range, is a full-scale forest (the monsoon forests of India and Vietnam). In both of these biomes -- in contrast to tropical rainforests -- there are well-defined wet and dry seasons to which both plants and animals are adapted. (The reproductive activities of many insects, for example, are timed to coincide with the wet season, with its abundance of fresh plant food.)

A key point to understand here is that an extremely wide variety of situations is covered by the term **tropical** -- indeed, even by the term *tropical forest*. The tropics are far more diverse than the temperate zones. Consequently, no single system can possibly be devised to solve the problems of "tropical agriculture" because those problems vary so enormously from place to place.

One further biome, the temperate rain forest, deserves mention. These forests are characteristic of the northwestern coast of North America and the southwestern coast of New Zealand, areas that receive 200 to 380 centimeters (80 to 150 inches) of precipitation annually. They are characterized in North America by very tall coniferous trees such as western hemlock, Douglas fir, and redwoods, and have well-developed understories with abundant mosses (there often are epiphytic mosses -- those that grow on trees and other large plants -- as well). This biome is extensively exploited for timber, the redwoods being especially valued for their decay-resistant wood.

FRESHWATER HABITATS

Biological communities in fresh water are classically divided into two groups -- those found in the running water of rivers and streams and those of the standing water of ponds and lakes. What ties these communities into a logical unit, however, are the physical properties of the medium in which they exist. Water, as you will recall from Chapter 2, has extraordinary properties that in many ways govern the climate of Earth and the way in which organisms have evolved here. Indeed, life as we know it is inconceivable without water. Our discussion of freshwater habitats focuses on four properties of water -its change of density at 4° C, its content of dissolved oxygen, its transparency, and its content of dissolved chemicals other than oxygen.

It is fair to say that there would be no freshwater life outside the tropics if H_2O did not reach its highest density above its freezing point. If it did not, ice would sink, and temperate and polar bodies of water would freeze solid each winter. In large lakes in the temperate zone, a decrease in water density with increasing temperature (above 4° C) creates a layering of water during the summer. An upper layer of less dense, warm water, the *epilimnion*, is formed. Deeper waters remain cool and thus more dense, to form the *hypolimnion*. Separating these two stable layers is a zone of rapid temperature change, the *thermocline*. (For a more detailed discussion, see Chapter 11.) This layering and the transparency of the water are intimately related to one of its most critical properties, its oxygen content.

The amount of light that penetrates the water decreases rapidly with depth, the longer (red) wavelengths dropping out first. By measuring oxygen production and consumption by plankton in water samples, it is possible to determine the point in the gradient of light at which photosynthesis is balanced by respiration. [80] This *compensation level* by convention is considered the dividing line between an upper *euphotic* (autotrophic) zone and a lower *profundal* (heterotrophic) zone. In summer the compensation level is usually above the thermocline; because the algae that contribute oxygen as a product of photosynthesis cannot live below that point, the amount of dissolved oxygen in the hypolimnion may drop almost to zero.

The degree of oxygen depletion (summer stagnation) in the hypolimnion is partially a function of the productivity of the lake. Lakes with low nutrient content (because of the characteristics of their drainage basins, or their ages) tend to have a low density of phytoplankton and few plants in their *littoral* zones (shallow regions where sunlight penetrates to the bottom). In such *oligotrophic* (few foods) lakes, the "rain" of dead organisms and other organic debris into the hypolimnion is relatively sparse. Since the degradation of those wastes by decomposers requires oxygen, oxygen supplies are less likely to be depleted there than where there is a heavy input of wastes. Furthermore, in some young lakes the water is so transparent that the compensation level is below the thermocline, and excess oxygen is produced in the hypolimnion by photosynthesis. Oligotrophic lakes can thus support populations of such fish as lake trout, which require both cool water and considerable oxygen.

Most oligotrophic lakes are geologically young. As they grow older, a successional process may occur as nutrients and sediments wash in and the lakes grow shallower and support more littoral

vegetation. Productivity increases, and the lakes may have massive blooms of phytoplankton. The rain of organic debris into the hypolimnion is heavy, and oxygen depletion there becomes severe -- especially after the die-off of a plankton bloom. Such *eutrophic* (well fed) lakes will not support some commercially valuable fishes like trout, but will support food fishes like bass and bluegills, as well as carp and other "trash fish," all of which are at home in warmer waters and tolerant of lower oxygen concentrations.

Eutrophication is a natural successional process in some lakes, but injections of nutrients in the form of pollutants can hasten the process, greatly reducing the value of a lake for recreation and fishing (see Chapter 11). Hence, one index of the degree of pollution in a body of fresh water is the *dissolved oxygen concentration* (DO); another is the difference between the production and consumption of oxygen -- *biological* (or *biochemical*) oxygen demand (BOD). The latter may be thought of as the amount of oxygen required for the oxidative decomposition of materials in the water. The BOD is normally

[80]The technique is described by E. P. Odum in *Fundamentals of ecology*, pp. 14-16.

measured in the laboratory as the number of milligrams of O_2, consumed per liter of water over a period of five days at 20° C (see Chapter 10 for further discussion of BOD).

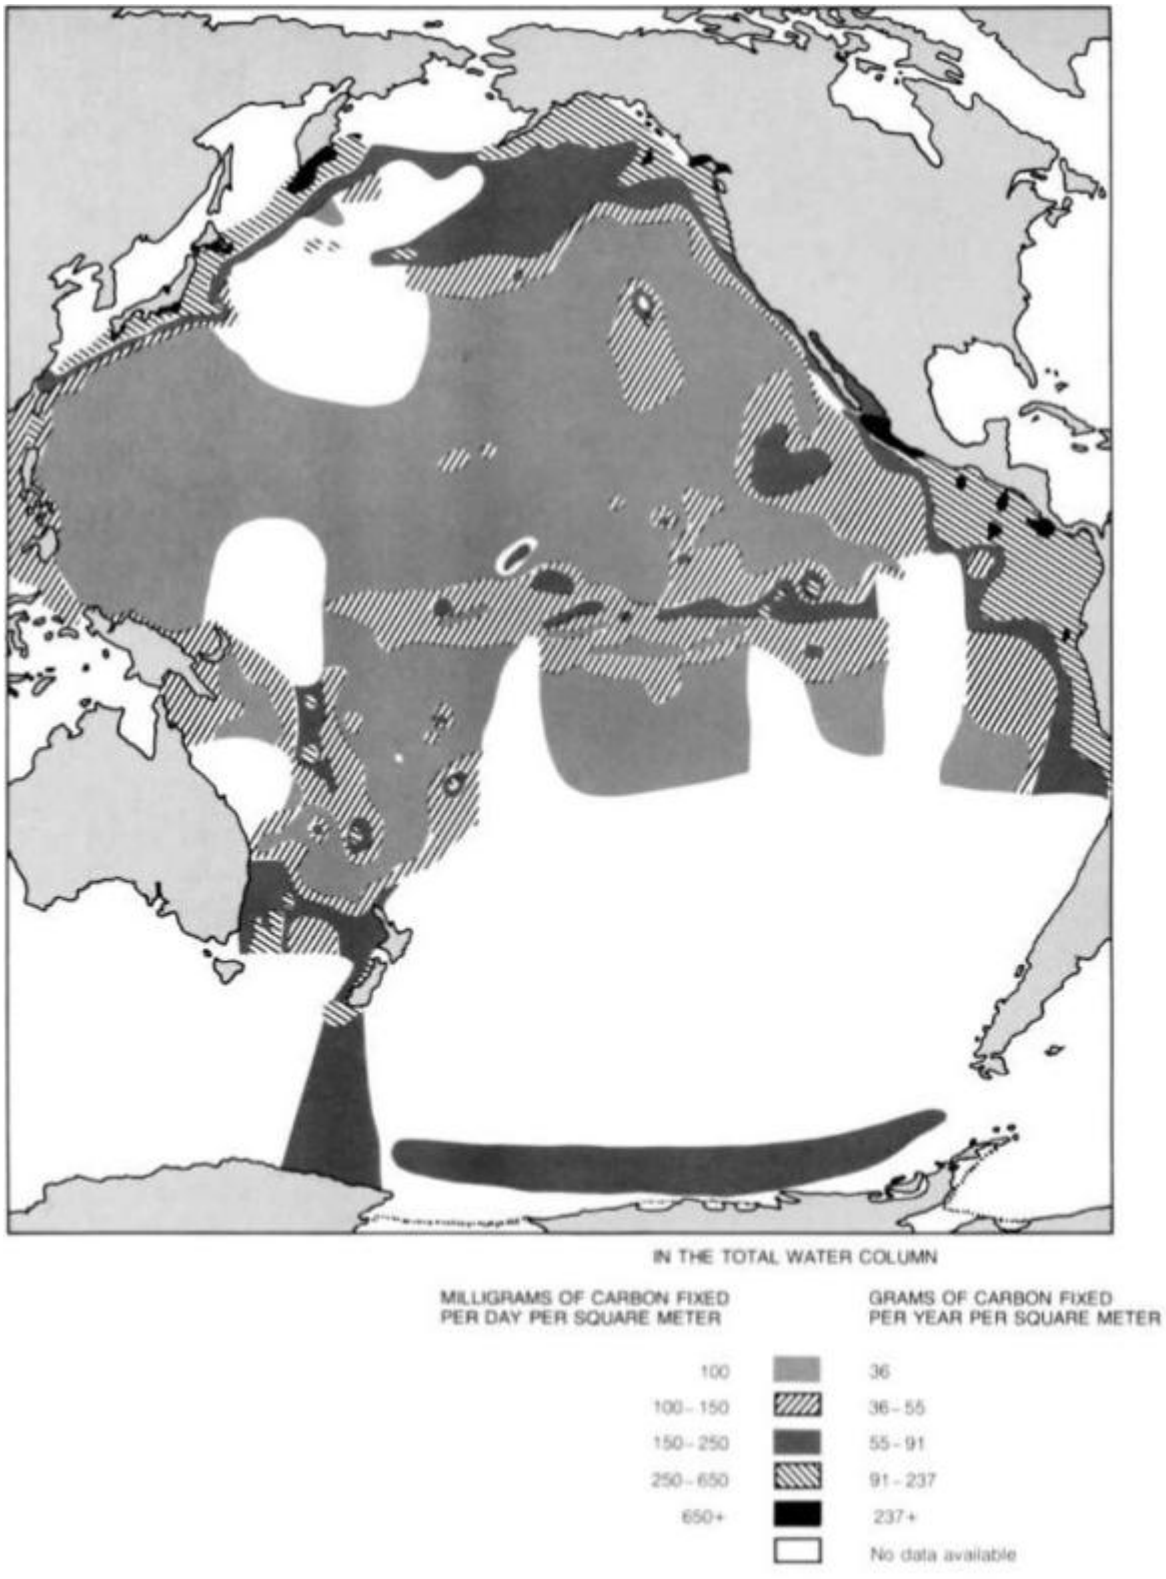
What happens to the stratification of a temperate lake in winter? As the upper layer cools in the autumn, it begins to sink, carrying fresh oxygen with it to the depths. The thermocline disappears, and nutrient-rich waters from the hypolimnion circulate throughout the lake. At one point the lake is *isothermal* (4° C from top to bottom). Then, when the lake freezes, the temperature (and density) gradient is established from the surface ice at 0° C to the rest of the lake at 4° C. In spring after the ice melts, the water at the surface warms to 4° C and sinks through the lighter 2° to 3° C water below, producing a spring overturn and a redistribution of oxygen and nutrients.

Tropical lakes, in which the water has high surface temperatures, have weak temperature gradients and often rather stable layering, created by the resultant slight density differences. Therefore, the ecology of those lakes is substantially different from that of temperate lakes.

The fauna of any body of fresh water, temperate or tropical, will vary somewhat with the chemical characteristics of the water. For instance, the pH of the water must be within a certain range if certain species of fish are to thrive -- as every serious fancier of tropical fish has discovered. Some species, such as neon tetras, come from acid waters and do best in an aquarium if the pH is kept low. Others, such as mollies, do best in more alkaline water (high pH). Aquatic plants are similarly sensitive to pH. The concentration of calcium ions has been shown to be important in restricting the distribution of freshwater sponges and to be related to the distribution of triclad flatworms (planarians), but much still remains to be learned about the relationship between the chemistry of water and its biota. [81] This is becoming especially important as human beings increasingly change the chemistry of fresh waters with pollutants.

Streams and rivers differ from ponds and lakes primarily in their relative lack of stratification in either temperature or oxygen concentration, in their having currents, and in their proportionally greater interface with the land (the length of banks relative to the volume of water). These differences strongly influence the biota. Usually in streams producers are inadequate to supply the consumers, the difference being made up by organic materials washed from the banks. Because of the currents, most of the plants and animals of streams and rivers have evolved ways to keep from being washed downstream -- using holdfasts, burrowing into the substrate, or having superb swimming ability (like brook trout). Plankton is comparatively rare in running water, but in the slower-moving parts of streams and rivers it may be an important part of a community.

The normally high oxygen content of streams and rivers has meant that animals adapted to running water generally have little tolerance for low oxygen concentration. Any addition of oxygen-reducing (high BOD) pollutants to streams or rivers is therefore likely to have a drastic effect on the fauna.



MARINE HABITATS

The oceans cover about 71 percent of Earth's surface, thus making them the most extensive habitat. As we described in Chapter 2, the oceans play major roles in the hydrologic cycle and in the global weather machine; therefore, their influence on life extends to all organisms. Considering their size, the oceans are an extraordinarily uniform environment -- especially the 98 percent or so of their volume that is below the depth to which enough light penetrates for photosynthesis to occur.

Because the oceans are rather thoroughly stirred by currents, there is sufficient oxygen for heterotrophs in most areas, as well as abundant CO_2 for autotrophs. But nutrients are often in short supply, especially nitrogen and phosphorus. Productivity is highest in the oceans in areas of upwelling, as along the western coast of South America, where nutrients are brought to the surface in abundance. In those areas phytoplankton reproduce without the nutrient shortage that restricts much of the open ocean to low productivity.

Many bizarre and wonderful creatures have evolved in the sunless depths of the oceans, feeding on the organic matter that drifts down from above and often signaling one another with luminescent organs. Most of the

production would be about 60 percent of the figures shown. (Data from NAS/NRC, *Resources and man*.)

biological activity of interest to humanity in the oceans, however, occurs near the surface in the euphotic zone (where photosynthesis exceeds plant respiration) and especially near the continents, where the availability of nutrients maximizes productivity. That is where the great fisheries are, and that is also where human inputs to the oceans are greatest (Figure 4-39).

Near the shore the marine environment becomes more complex, and intricate zonations have developed under the influence of light gradients, wave action, and tides (Figure 4-40). The most complex, and perhaps the most interesting, marine habitats are the coral reefs that fringe the shores of tropical landmasses. The reefs are made of the skeletons of coral animals that live in a mutualistic relationship with algae. In some ways the complexity of the reef habitat rivals that of a tropical rain forest, with vertical stratification and great diversity of species. [82] Roughly one-third of all fish species (both freshwater and saltwater) live on coral reefs (Figure 4-41).

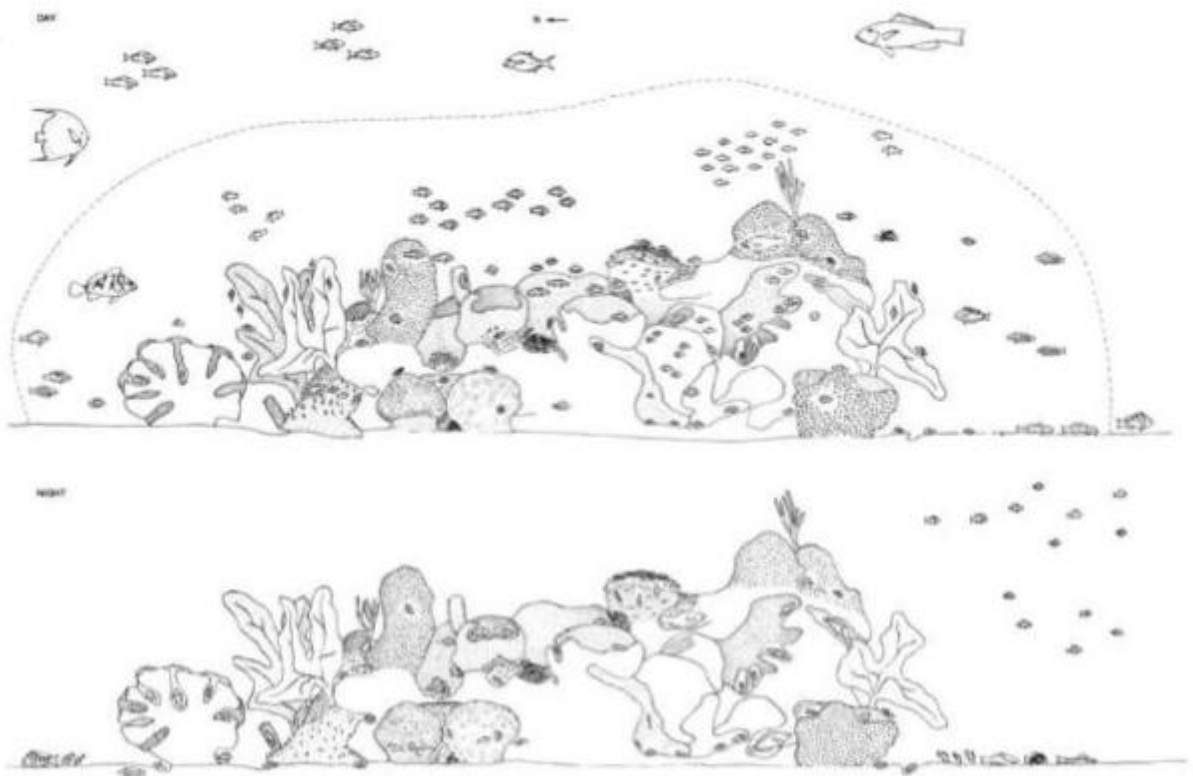
Stephenson, Life between tidemarks on rocky shores, W. H. Freeman and Company. Copyright © 1972.)

[82]Paul R. Ehrlich, "Population biology of coral reef fishes", Annual Review of Ecology and Systematics, September 1975, pp. 211-247.



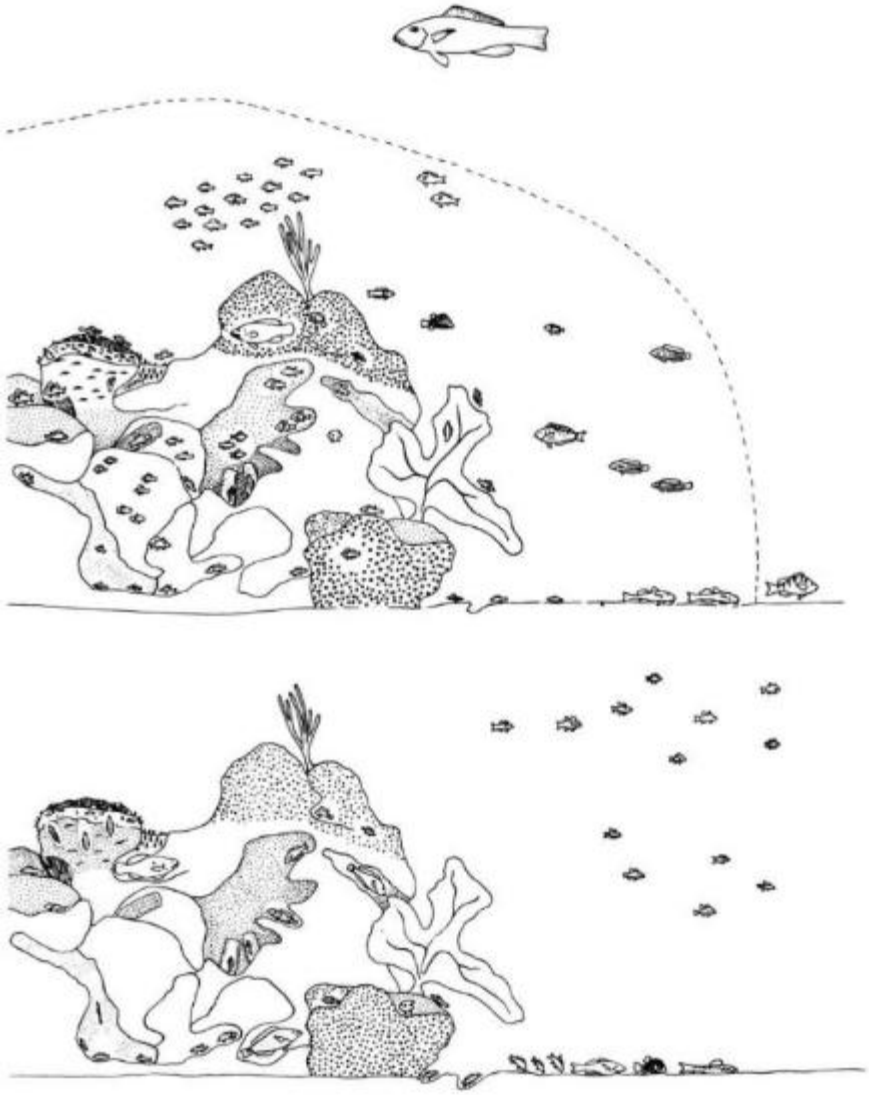


FIGURE 4-41
Complexity and diversity of a coral reef habitat is indicated by this diagrammatic cross-section of reefs off St. John, U.S. Virgin Islands, showing general distribution of 73 fish species, day and night. Reefs in the northern part of the Australian Great Barrier Reef can support up to 1000 fish species. On coral

reefs, of course, them are a great many kinds of invertebrates and algae not indicated here. (Adapted from "Results of the tektite program: ecology of coral reef fishes", Natural History Museum, Los Angeles County, *Science bulletin*, 14, 1972.)

But even the diverse coral reef fauna shows great similarities in such far-apart places as the Society Islands of the central Pacific and the reefs fringing the East African coast -- and genera of fishes found in both of those places also occur in the Caribbean. In contrast to both terrestrial and freshwater habitats, which are often isolated from each other, the oceans have a great unity.

Estuaries

Where rivers and streams flow into the oceans, and fresh and salt water intermingle in tidal ponds, rivers, and embayments are found the habitats known as estuaries. Organisms that live in estuaries must be tolerant of a wide range of salinities and usually of a wide range of temperatures also. The daily rhythm of the tides gives them an ever-changing environment.

Many organisms have evolved to live in these conditions, and the productivity of estuaries (which tend to be nutrient traps) is very high (Table 4-6). Some of this productivity is harvested at the estuary by human beings -- most of the oysters and crabs people eat, for example, are estuarine. More important to *Homo sapiens*, however, is the role estuaries play as "nurseries" for commercially important marine species. Many of the shrimps and fishes that are harvested at sea have estuarine young. Indeed, it has been estimated that about twothirds of the rich commercial fishing on the continental shelf of the eastern United States consists of species that spend part of their life cycles in estuaries. [83]

Another estimate [84] credits each hectare of estuary with contributing more than 550 kilograms of fishes per year to coastal fisheries. Using a conservative estimate of 1.4 X 10_6 kM_2 (1.4 X 108 hectares) of estuaries worldwide, their total annual contribution to fisheries would be 550 X 1.4 X 10_8 = 77 X 109 kg = 77 million MT. That is somewhat more than the present global fisheries harvest and about one-third of the total estimated potential production of fishes in the sea (see Chapter 7). That estuaries are among the most threatened of all habitats today is therefore cause for considerable concern.

Antarctica

One further habitat deserves attention -- one that contains only a small amount of land that isn't perpetually ice-covered and that supports a "terrestrial" community almost entirely dependent on marine producers. That habitat is Antarctica. There are two flowering plants (a grass and a plant of the carnation family) and a variety of mosses and lichens scattered around the fringes of the Antarctic continent. These producers support small communities of invertebrate consumers and decomposers, but all of the vertebrates found on land in the Antarctic feed on food chains based on massive summer blooms of marine phytoplankton, supported by extremely nutrient-rich upwellings in the sea. The phytoplankton support large populations of shrimplike krill, which in turn form the feeding base for animals as diverse as baleen whales and penguins (Figure 4-42).

Penguins and other seabirds breed on land in the summer [85] in enormous colonies that in their turn support populations of skuas (predatory relatives of seagulls), which feed on penguin eggs and young penguins. One antarctic seal, the leopard seal, feeds on penguins. Another, the Weddell seal, feeds on fishes and squid, and a third, the crabeater seal, belies its name by feeding mostly on krill. In turn, those seals are preyed upon by killer whales (Figure 4-43).

Of all the major habitats on Earth, Antarctica, in a physical sense, is the least disturbed by human activities. Antarctica is protected by a barrier of sea ice, so only a handful of people had ever set foot on the continent before the middle of the twentieth century. And, except for the small huts

of explorers like Scott and Shackleton, the bits of land not permanently ice-covered showed no signs of human disturbance before that time.

Rich, and G. A. S. Hall, Carbon in estuaries, in *Carbon and the biosphere*, Woodwell and Pecan, eds., p. 234.

[84]R. H. Stroud, in *Symposium on the biological significance of estuaries*, P. A. Douglas and R. H. Stroud, eds., Sport Fishing Institute, Washington, D.C., 1971, p. 4.

[85]The exception to this is the emperor penguin, which breeds in winter on the ice.

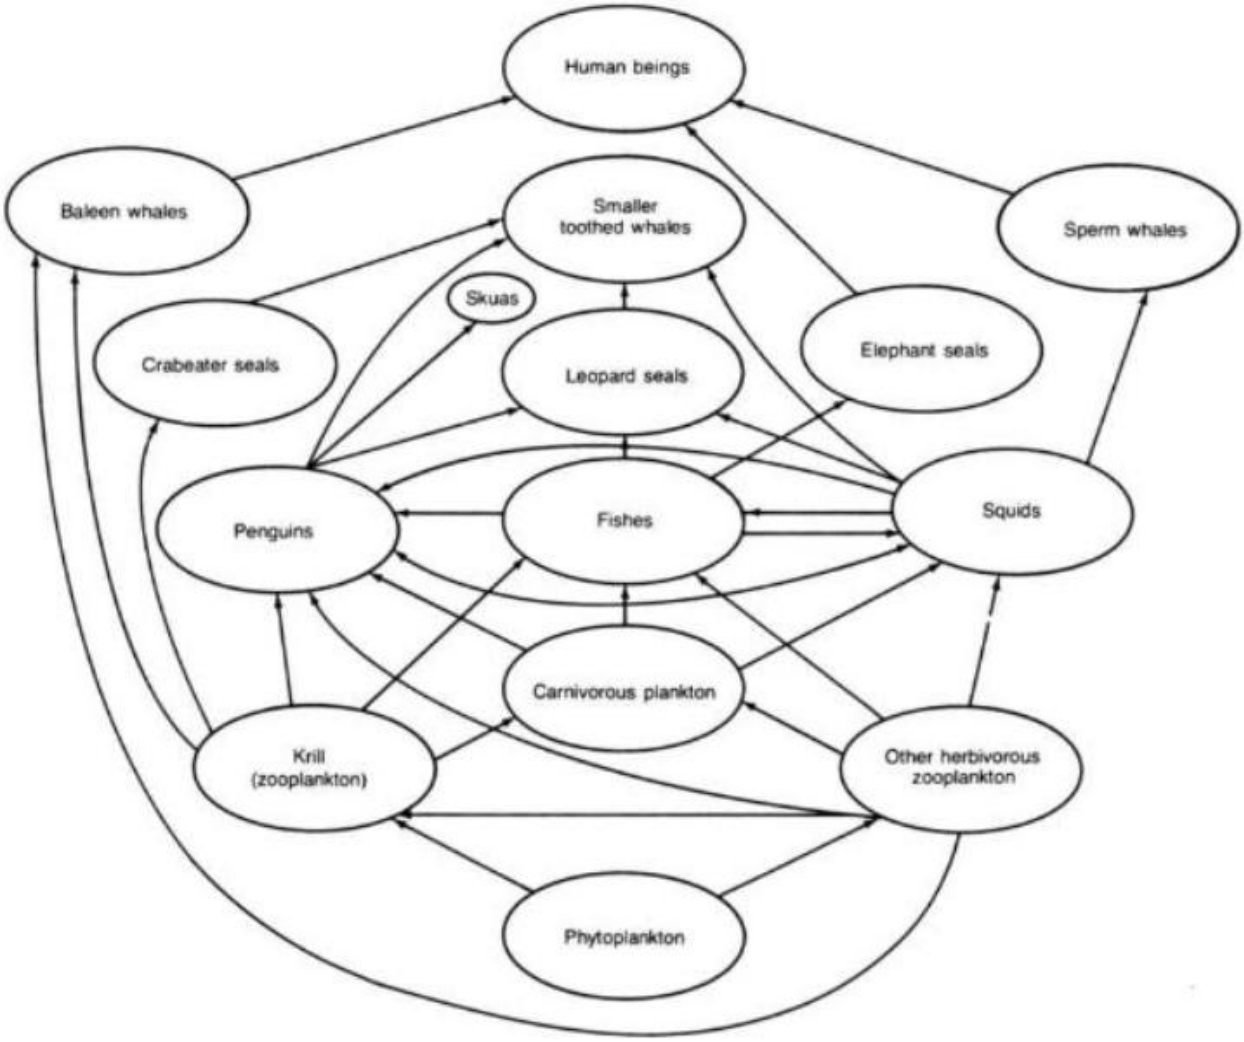

FIGURE 4-42
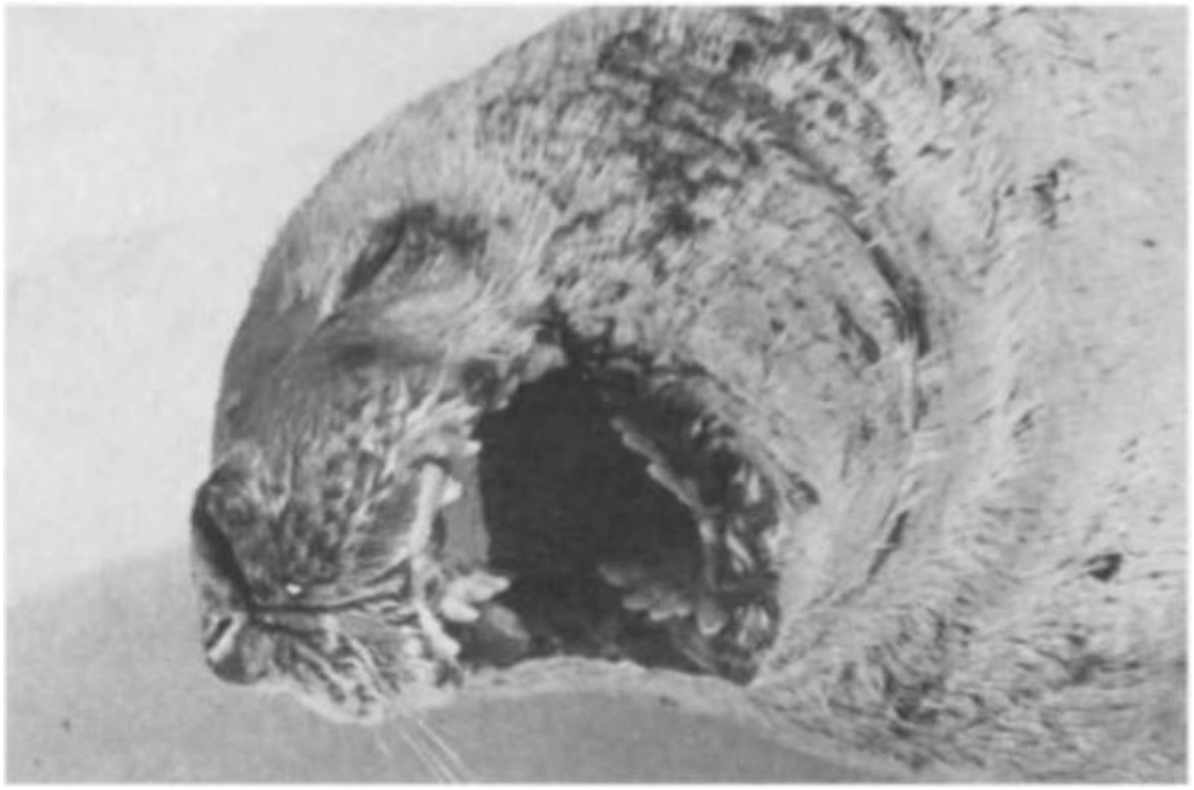
Antarctic food chains. Notice that even the "terrestrial" vertebrates are dependent upon marine productivity.



But long before World War II, humanity was exploiting the antarctic oceanic ecosystem that is the feeding base of all large animal life on that continent. Early in the twentieth century, whaling in antarctic waters was so intense that by 1920 the right whale, so-called because it was easy to catch and floated after harpooning (the "right" whale from a whaler's point of view!) was virtually extinct, and concern was expressed in the international community about the future of all exploited whales. After World War II, overexploitation continued (see Chapter 7 for more detail); today whales are scarce in antarctic waters. In a two-week voyage in antarctic waters in 1974/ 1975, the authors saw no whales of the species that have constituted the backbone of the whaling industry. In the very same waters in 1912, Robert Cushman Murphy reported seeing "whales in all directions," even though the slaughter of those great mammals was far enough advanced by then that the shoreline near the whaling station at South Georgia Island was "lined for miles with the bones of whales." [86]

What effect the removal of the baleen whales from the Antarctic Ocean will have on the structure of the

A

B FIGURE 4-45 A. A small portion of an Adelie penguin colony in Hope Bay, Antarctica. Like many human societies (such as the Netherlands), breeding penguin colonies are utterly dependent upon imported resources for their survival. B. An Adelie parent, having returned from the sea, regurgitates krill for its chick. Notice the spined tongue, which helps the bird to grasp the krill, and compare with Figure 4-43B. (Photos by P. R. Ehrlich.)

ecosystem there remains to be investigated, but it must be considerable. At one time an estimated 100,000 individuals of the now virtually extinct blue whale roamed antarctic waters for four months of every year. Each individual consumed four tons of plankton, mostly krill (*Euphausia superba*), per day; hence, the blue whale alone processed some 50 million tons of plankton annually. The dramatic reduction in the number of whales has in theory made an enormous surplus of plankton available to the seals, penguins, and fishes that also feed on it, but no studies have been made of possible changes in their population sizes. Hence, humanity, through whaling alone, has clearly had a dramatic impact on the biology of Antarctica.

In the years following World War II, land stations have been established on the antarctic continent by various nations. Some were attempts to claim sovereignty; many in the mid-1950s were cooperating in scientific research projects of the United Nations International Geophysical Year. These stations have produced local versions of the kind of environmental deterioration so commonplace in the rest of the world. The United States has produced an ugly town at McMurdo Sound, symbolically complete with a nuclear power plant, and at the Palmer Station on the Antarctic Peninsula, a typical American garbage dump (Figure 4-44), the largest on the continent. More serious than such local blights is the exploration for minerals that someday may open the Antarctic to the kind of destruction now being visited on the Arctic. Recent U.S. Navy reports of 45 billion barrels of oil in Antarctica hardly is a hopeful sign. [87]

Another hazard to the antarctic environment is the possible escape of dogs from stations. Antarctica is devoid of large terrestrial predators, and penguins in particular could easily be decimated. We have seen dogs killing them at the Argentine station at Hope Bay. The penguins nest in vast rookeries on the ground (Figure 44-5); they would be sadly vulnerable to even one or two feral dogs, which could do enormous damage before perishing in the antarctic winter.

Finally, of course, antarctic ecosystems have been polluted with chlorinated hydrocarbons, lead, and other

[87] *"Today" Show*, NBC, February 25, 1975.

products of civilization. Thus, although to the untrained eye the continent still seems remote and untouched, its biology has already been profoundly modified by human action, and further destructive change is threatened.

ECOLOGICAL MODELS

Because ecology often deals with exceedingly complex systems, it is a standard technique in the science to attempt to gain understanding by creating models of them. A model can be thought of as a simplified representation of reality. Ideally, it should be an aid to thinking about reality and should lead to an ability to make predictions about future states of reality and suggest experiments or measurements that could help define reality more precisely. For example, the logistic curve is a model of the growth processes of real populations in certain circumstances. You will recall that in our earlier discussion it was simplified in several ways -- for instance, it assumed that all individuals were ecologically identical, which is never true. Models can be verbal or graphic (or hydraulic or electric), but many of the most useful are mathematical.

Mathematical models fall into two general classes -they either include the random changes that seem to characterize nature or they ignore them. The former are statistical or *stochastic* models; the latter, *deterministic*. The logistic curve is a deterministic model.

In constructing a model, one can strive to build into it one or more of the following properties: precision, realism, generality, and manageability. *Precision* is the ability of a model to predict future states of the system accurately. *Realism* is the extent to which the mathematical formulation of the model reflects the underlying biological processes of the system modeled. *Generality* is the degree to which the model applies to diverse systems. *Manageability* is the ease with which the model can be manipulated -- for example, are the differential equations easy to solve, or are their solutions easy to approximate? The logistic curve model is high in manageability and generality, medium in realism, and low in precision.

Two general schools of model-building have developed in ecology: one dealing with complex computer models (systems ecology) and one dealing with simple analytic models. Systems ecology has concentrated on constructing computer models of ecosystems. The system is broken down into a series of compartments, such as herbivores, top carnivores, cities, and farms; and numbers (system variables) are used to describe the state of each compartment at a given time (say, the biomass present). Functions (transfer functions) are then produced to describe the interactions of the compartments, such as the flows of energy among them. Inputs from outside of the system that are not influenced by the system, such as arriving solar energy or fossil fuels, are described by other functions (forcing functions).

The model is then manipulated in attempts to make it simulate the past behavior of known systems satisfactorily and to see what elements of the system are especially sensitive or insensitive to changes elsewhere in the system. One simple systems model of the general type is shown in Figure 4-46, in which the system is analogized to an electric circuit. The most famous model of this class was the world model developed by Donella and Dennis Meadows and their colleagues at Massachusetts Institute of Technology and published in The Limits to Growth. [88] That study is discussed in greater detail in Chapter 12.

The computer models of the systems ecologists tend to be high in precision and low in generality and to lose reality as they become more general. Whereas they usually do not supply rewarding holistic insights, they can often provide clues as to how and where an ecological system might most profitably be manipulated and the converse, where a system is so robust that manipulation

is likely to have little effect. One of the major drawbacks of systems ecology is the relative paucity of data available with which to develop and test models.

The modeler of the analytic school has a different approach. He or she would start with a question such as, "What would be the form of a population growth curve if the rate of increase were a linear function of size itself?" Or the question might be, "Under what circumstance of resource availability would an organism that can use two

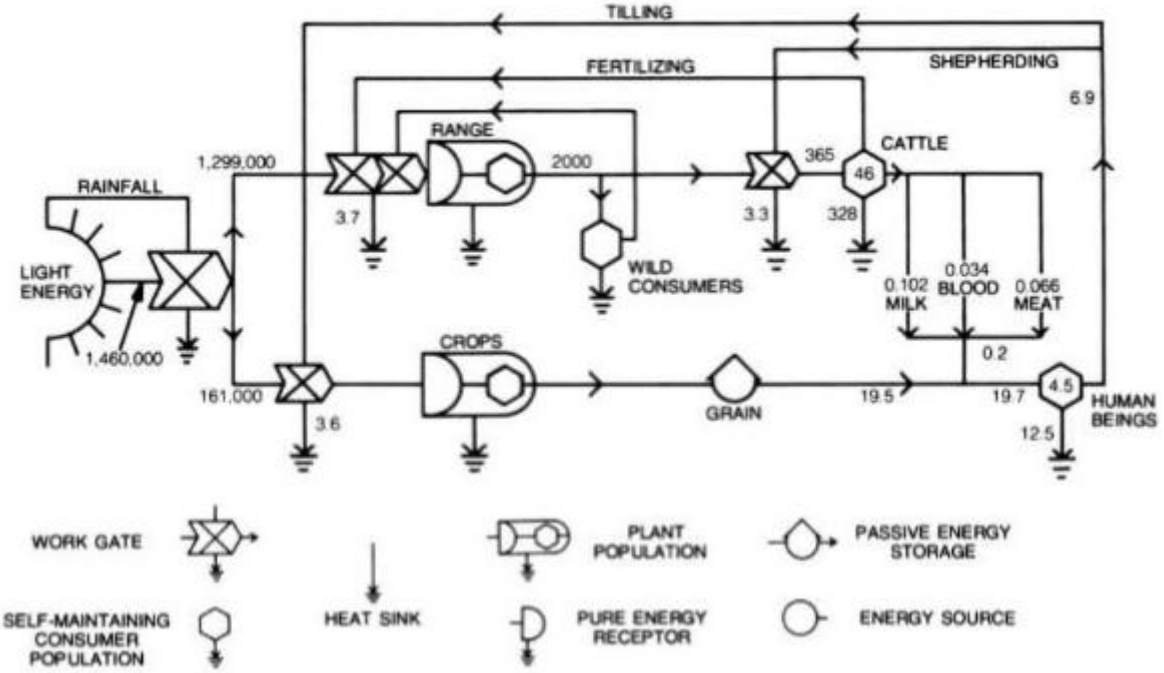

FIGURE 4-46

A simple agricultural system in Uganda. Food is derived from grains, meat, blood, and milk Animals serve as storage units. The numbers represent kilocalories per square meter per year. Dry weights were converted to kilocalories, using 4.5 kcal per gram. There are 70 people per square mile at 150 pounds per person, 25 percent of which is dry matter, which is equivalent to 1 gram per square meter.

The basic net production of plant material for dry regions is a function of rainfall. Using 21 inches of rainfall, one is able to determine that 500 grams of dry plant material are produced per square meter of land each year. Since I acre is cultivated per person and there are 70 persons per square mile, 11 percent of the natural yield area is preempted by crops. At 4.5 cattle per person and 560 pounds per cow, 33 percent of which is dry weight, excluding ash and water, 10.2 grams of animal weight is produced per square meter.

By considering the monthly consumption of milk, blood, and meat, one obtains an annual caloric yield per person from the cattle of 3800 kcal of milk, 2450 kcal of meat, and 1265 kcal of blood, which provides the per-area data in the figure. The caloric requirement per person is given as 2000 kcal per person per day, or 19.7 kcal per square meter per year. The milk, meat, and blood supply only 0.2 of this requirement, so crops must provide the remaining 19.5, a net yield much less than the net yield of vegetation of the natural range. Total insolation in this area just above the equator is about 4000 kcal per square meter per day.

The work of men in tending the crops and cattle can be taken as a percentage of their time spent in this activity (primarily during the daylight hours). As the culture is intimately involved with the cattle, it is assumed that one-sixth of the daily metabolism of each man is devoted to management of the cattle and an equal amount is used for production of crops. The rationale is that the maintenance requirements of a man during his work are necessary to that work, in addition to calories directly expended.

The metabolic activites of a 650-pound steer requires 8000 kcal per day, or 365 kcal per square meter per year. Some fraction of the steer's time and metabolism goes into refertilizing the range on which it grazes, thus reinforcing and maintaining its nutrient loop. Part of a steer's day is spent on the move, and parts of its organ systems are involved in the nutrient regeneration system. One-tenth of its metabolism was taken as its work contribution to vegetation stimulation.

This system does not involve money, and an economic transactor symbol does not appear. (Slightly modified from President's Science Advisory Committee Report on the World Food Problem, 1967.)

classes of resources win out in competition with one that can use three?" Mathematical models of the situation (like the logistic curve in the first instance) are constructed, and then the model and its assumptions are tested against actual systems in nature or in the laboratory.

The models of this school tend to be high in generality and low in precision, although in some simple cases the reverse can be true. Realism, which is generally lower than in systems ecology, also tends to decline with increasing generality.

Although both schools in a sense are in their infancies, it is fair to say that systems ecology is likely to be most productive in providing tools for the solution of practical problems, whereas simple analytic models probably will be most valuable in helping ecologists understand the more general properties of ecological systems. Both schools have provided a welcome infusion of theory into academic ecology. What is badly needed now is a greater concern for applied problems among academic ecologists and a greater appreciation of the potential value of theory among agriculturalists, wildlife managers, city planners, politicians, and others directly concerned with ecological problems.

SECTION II
Population and Renewable Resources

The tide of the earth's population is rising, the reservoir of the earth's living resources is falling.

-- Fairfield Osborn, 1948

Having considered the basic principles of operation of the environment in which human society is embedded, we turn now to the human population itself and certain of the demands it makes on that environment.

Chapter 5 gives a rather detailed introduction to demography -- the study of the size, structure, and distribution of the human population and the ways and reasons these characteristics change. Some knowledge of the history of human population change is essential to an understanding of the present situation, and this is provided. We attempt, as well, to furnish some basis for

estimating what future patterns of population change may be, while recognizing that all forecasts should be heavily qualified and surrounded by disclaimers. (Demographers in the past have been notably more successful at describing what has happened than at predicting what will happen.) Of course, there are some kinds of changes that, barring catastrophe, are extraordinarily unlikely -- for example, a leveling-off of the global population size in less than several decades and at a size much smaller than about twice today's. We explore in detail the reasons for this unfortunate human "commitment" to further growth.

The primary reasons for concern with population are the pressures that population characteristics and population change impose on physical resources, environmental services, economic prosperity, social systems, and human values. The natures of many of those pressures are examined in subsequent chapters, but it is worth setting down some general observations on population pressure here to help place the demographic detail of Chapter 5 in perspective.

It is important to understand, first, that population pressure may arise from large absolute population size or from unsuitable geographical distribution of population

or from high rates of change in size or distribution or from a combination of these factors. Population pressures in Europe, Japan, and the United States, for example, are associated more with the large sizes those populations have already attained than with their rates of population growth, which are relatively low. Of course, even a low rate of growth in such a country is made more significant precisely because the absolute impact of population size and the impact per person are already so high there; but saying the pressures are primarily related to size is to recognize that those regions would be experiencing essentially similar difficulties even if their rates of population growth were zero at this time.

In certain of the less developed countries, by contrast, population pressures are associated more with an inability of social and economic services to keep up with rapid population growth than with the absolute sizes of the populations. This is the situation in many countries in Latin America and Africa. The pressures are often exacerbated by high rates of change in population distribution -- namely, floods of migrants into the cities from the countrysides.

Many Asian countries illustrate a third situation, in which awesome pressures arise both from the great size the populations have already reached and from continuing high rates of growth. India, Pakistan, Bangladesh, and the People's Republic of China are examples of this general situation, although they differ from each other in important respects.

A theme that emerges from these considerations and runs through Chapter 5 is that few generalizations about population and population pressure can be expected to hold worldwide. The variety of conditions and pressures in different countries is enormous. Understanding the overall demographic situation is possible only when these differences are examined in detail, and this we have undertaken to do.

Chapter 6 and Chapter 7 deal with some of the resources necessary for the support of the human population -- more specifically, those resources it has become customary to call renewable. They are land, soil, water, forests, and food. Whether *renewable* is really a useful generic label for these commodities is questionable. The planet's stores of land and water are essentially fixed, and they can be used over and over again; but the same can be said of metals, usually thought of as nonrenewable. The difference is only that, when metals are dispersed in use, society must write them off or pay a heavy price in energy to reconcentrate them, whereas when water is dispersed in use, solar energy reconcentrates it "free" through the hydrologic cycle. At the same time, it is easy to think of circumstances in which soil is a highly nonrenewable resource -- for example, when it is eroded by wind or water much faster than natural processes can replenish it. If soil is lost, the capacity to grow food and forests in that region is lost, too, so those become, at least locally, nonrenewable.

The resources of land, soil, water, and forests are so intimately related that we have put them together in Chapter 6. We devote more space in that chapter to the complex chemical and physical characteristics of soil than is customary in environmental science texts because we believe that soil's central role in support of human society has been widely underestimated. The complexity and subtlety of the

functions performed by soil are a major reason that food production cannot be greatly expanded merely by planting crops on any reasonably flat space not otherwise occupied. That the soil is an ecosystem in itself, moreover, should serve as a warning that it may be vulnerable not only to the traditional threats of erosion, waterlogging, and salination but also to systematic disruption by the chemical assaults of industrial society. (These threats are considered in Chapter 11.)

Food, the subject of Chapter 7, is simultaneously a biological, technological, economic, social, and political problem. Eventual limits to food production by conventional methods will be imposed by limitations on the resources of soil and water, discussed in Chapter 6, and of course by the availability of sunlight. Short of these resource limits, however, society may already be pushing up against limits of another kind -- limits in its ability to make available the expensive technology of high-yield agriculture, to supply and pay for the industrial energy this technology requires on a continuing basis, and to absorb the environmental burdens that expanding agriculture by any means produces. The difficulties of growing enough food are compounded by the problems of distributing the food to those who are hungry. (We are regularly discouraged to hear discussions of food "surpluses" -meaning a supply that exceeds economic demand -- when so much of the problem is that the people who are hungry are also broke.) Like so many of the problems treated in this book, the nature of the food problem varies enormously from region to region, which makes generalizations difficult. Nevertheless, we believe that at least one generalization emerges clearly from the detailed analysis in Chapter 7: concerning the future of food supply, none dare be complacent.

CHAPTER 5
The History and Future of the Human Population

Prudent men should judge of future events by what has taken place in the past, and what is taking place in the present.

--Miguel de Cervantes (1547-1616), *Persiles and Sigismunda*

We shall see finally appear the miracle of an animal society, a complete and definitive ant-heap.

-- Paul Valéry (1871-1945)

The first small population of human beings probably appeared on Earth more than 2 million years ago on the continent of Africa. Since then, the human population has spread out to occupy virtually the entire land surface of the planet. And in the past century or two it has exploded in numbers. Today roughly between 4 and 5 percent of all the people who have ever lived inhabit Earth -- some 4 billion. [1]

This chapter recounts the history of population growth and explores its projected course in the future, especially the next century or so. Principles of human population dynamics (demography) are also presented here, with a view to explaining the present predicament of humanity and how the current demographic situation shapes the future and limits social options. Population size and growth have profound, if seldom noticed, effects on the course of events, and this is likely to be even more true in the future than it has been in the past.

POPULATION GROWTH

Since there are no substantial historical data on which to base estimates of population size and changes before 1650, estimates must be based on circumstantial evi-

[1] N. Keyfitz, How many people have ever lived on Earth? *Demography*, vol. 3 (1966), pp. 581-582. Unless otherwise noted, current population statistics are based on the United Nations *Concise report on the world population situation in 1970-1975 and its king-range implications*, 1974; The Environmental Fund, Inc., 1975 *World population estimates*, Poputation Reference Bureau, 1975 *Population data sheet*; various annual volumes of the *United Nations Demographic yearbook* (United Nations, New York) and *Statistical abstract of the United States* (United States Department of Commerce; Washington, D.C.); and United States National Center for Health Statistics (USNCHS), *Monthly vital statistics report of the United States*.

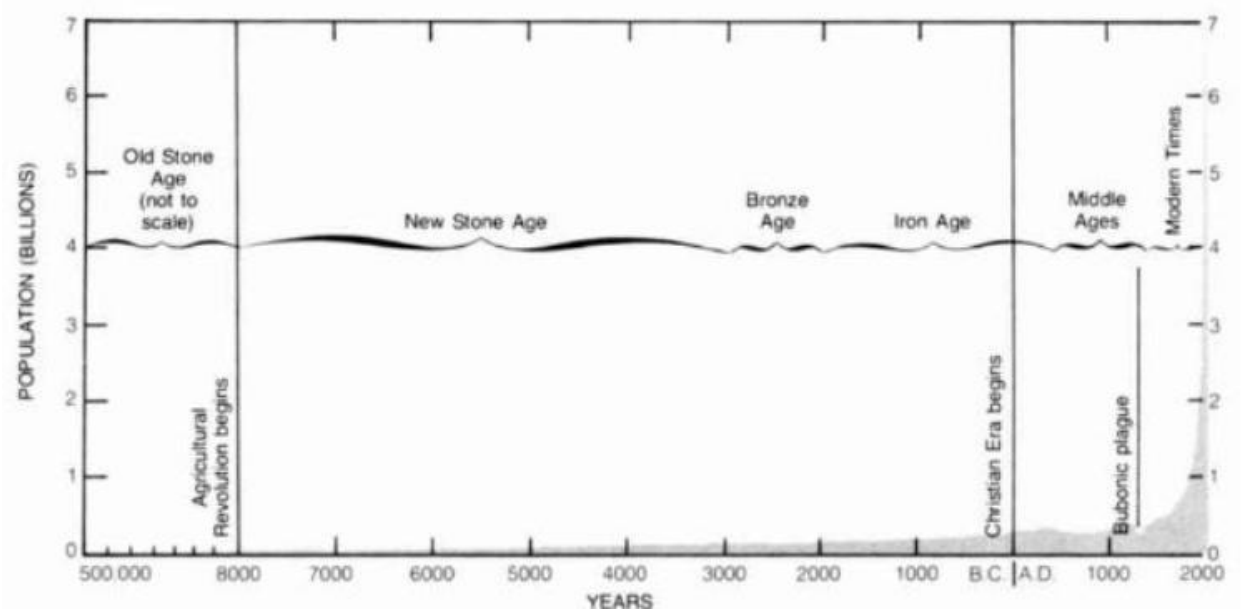

FIGURE 5-1 The growth of human numbers for the past half-million years. If the Old Stone Age were in scale, its baseline would extend about 18 feet to the left. (Adapted from *Population bulletin*, vol. 18, no. 1. Courtesy of the Population Reference Bureau, Inc., Washington, D.C.)

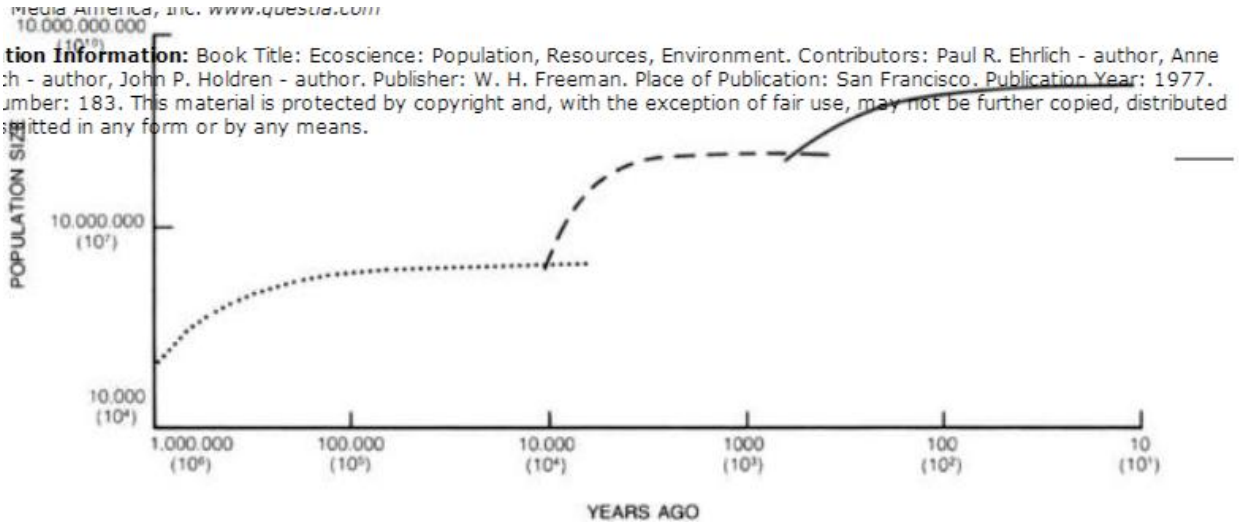
dence. For instance, agriculture was unknown before about 8000 B.C.; prior to that all human groups made their living by hunting and gathering. No more than 52 million square kilometers (20 million square miles) of Earth's total land area of some 150 million square kilometers (58 million square miles) could have been successfully utilized in this way by our early ancestors. From this and the population densities of hunting and gathering tribes of today, it has been estimated that the total human population of 8000 B.C. was about 5 million people.



The sizes of population at various times from the onset of the Agricultural Revolution until the first scanty census data were recorded in the seventeenth century have also been estimated. This was done by extrapolation from census figures that exist for present-day agricultural societies and by examination of archaeological remains. Such data as the numbers of rooms in excavated ancient villages have proven especially useful for calculating village populations. It is thought that the total human population at the time of Christ was around 200 million to 300 million people, and that it had increased to about 500 million (half a billion) by 1650. It then doubled to 1000 million (1 billion) around 1850, and doubled again to 2 billion by 1930. The course of human population growth is traced in Figure 5-1. Note that the size of the population has (with a few setbacks) increased continuously and that the rate of increase has also risen.

Perhaps the simplest way to describe the growth rate is in terms of doubling time -- the time required for a population to double in size. In growing from 5 million in 8000 B.C. to 500 million in 1650, the population increased a hundredfold. This required between six and seven doublings within 9000 or 10,000 years:

Population (millions):

$$5 \rightarrow 10 \rightarrow 20 \rightarrow 40 \rightarrow$$
$$1 \quad 2 \quad 3 \quad 4$$
$$80 \rightarrow 160 \rightarrow 320 \rightarrow 640$$
$$5 \quad 6 \quad 7$$

Thus, on the average, the population doubled about once every 1500 years during that period. The next doubling, from 500 million to I billion, took 200 years; and the

FIGURE 5-2 Human population growth plotted on a log-log scale. Plotted in this way, population growth is seen as occurring in three surges, associated with the cultural, agricultural, and industrial-medical revolutions (discussed later in this chapter). (Adapted from Deevey, 1960.)

doubling from 1 billion to 2 billion took only 80 years. The population reached 4 billion around 1975, having doubled again in only 45 years. The rate of growth in the early 1970s would, if continued, double the population in about 36 years. Table 5-1 summarizes human population history in these terms.

To take a slightly different perspective, it took 1 million or 2 million years to achieve a population size of 1 billion around 1850. The next billion was added in 80 years (1850-1930). The third billion came along in only 30 years (1931-1960), and the fourth took only about 15 years (1961-1975). If this rate of growth continued, the fifth billion would be added in just slightly more than a decade (by 1987).

The sort of graph shown in Figure 5-1 does not reveal details of trends in the long, slow growth of the human population before the current millennium. But if population size and time are plotted against one another on logarithmic scales (a log-log graph, as in Figure 5-2), a greater range of time can be shown, and more detail in the lower range of population sizes is revealed. Notice that the log-log graph shows three surges of population growth, one about 600,000 years ago, one about 8000 years ago, and one about 200 years ago.

The reasons for the patterns that appear on both graphs are reasonably well understood, but before examining them, we must consider some aspects of human population dynamics.

TABLE 5-1
Doubling Times of the Human Population

Date	Estimated world population	Time in which population doubles (years)
8000 B.C.	5 million	1500
1650 A.D.	500 million	200
1850 A.D.	1000 million (1 billion)	80
1930 A.D.	2000 million (2 billion)	45
1975 A.D.	4000 million (4 billion)	
	Computed doubling time around 1975	36

Birth and Death Rates

A human birth rate (b) is usually expressed as the number of births per 1000 persons per year, rather than per individual as in Chapter 4. The total number of births during the year is divided by the estimated population at the midpoint of the period. For example, in the United States there were 3,159,000 live births during the twelve months ending November 30, 1975. The population on May 30, 1975 (the midpoint of that period), was estimated to be 213,000,000. The birth rate

TABLE 5-2
Doubling Times at Various Rates of Increase

Annual increase (%)	Doubling time (years)
0.5	139
0.8	87
1.0	70
2.0	35
3.0	23
4.0	18

(b) for that period was therefore 3,159,000/213,000,000 = 0.0148. There were 0.0148 births per person, or 0.0148 × 1000 = 14.8 births per 1000 people. Similarly, there were 1,912,000 deaths during the period, giving a death rate *(d)* of 1,912,000/213,000,000 = 0.0090 × 1000 = 9.0 deaths per 1000 people in the year from December 1, 1974 to November 30, 1975. [2]

Growth Rate

Ignoring migration, the growth rate *(r)* is calculated by subtracting the death rate from the birth rate (b - d). During the year ending November 30, 1975, the United States growth rate was 14.8 - 9.0, or 5.8 per 1000. That is, in the period from December 1, 1974, to November 30, 1975, 5.8 persons were added to each 1000 in the United States population. Technically, this is the rate of natural increase, since migration is ignored. To add to the confusion, demographers express this growth rate as a percent annual increase -- that is, not as a rate per 1000 or per person, but as a rate per 100. In the example cited above, the annual increase would be 0.58 percent, a typical rate for an industrialized nation today.

Population growth for the entire world presents a different picture. In the early 1970s the estimated world birth rate was around 32 per 1000 per year and the death rate about 13 per 1000. The growth rate was thus 32 - 13 = 19 per 1000, or approximately 1.9 percent. [3] This gives a finite rate of increase (λ) of about 1.02 per year and a reasonably accurate estimate of $r = 0.019$ (doubling time, 36 yr) as discussed in Chapter 4. The age composition of the entire human population is not stable, and the growth of that population therefore is only roughly exponential. If the vital rates of the early 1970s persisted, however, the population would grow to 8 billion people around the year 2010. Table 5-2 shows the doubling times that would be associated with various annual percentage increases.

History of Population Growth

The populations of our ancestors a few million years ago (*Australopithecus* and relatives) were confined to Africa and numbered perhaps 125,000 individuals. By that time, these ancestors of ours had already "invented" culture, the body of nongenetic information passed from generation to generation. The volume of culture is, of course, vastly greater today than in the days of *Australopithecus*. In those days human culture was transmitted orally and by demonstration from the older to the younger members of the group. It doubtless consisted of information about methods of hunting, gathering, and preparing food; rules of social conduct; identification of dangerous enemies; and the like. Today, of course, human culture includes information transmitted and stored in such diverse places as books, phonograph records, photographs, videotapes, and computer tapes.

The possession of a substantial body of culture is what differentiates human beings from the other animals. During human evolutionary history the possession of culture has been responsible for a great increase in human brain size (the australopithecines had small brains, with an average volume of only about 500 cubic centimeters). Early human beings added to the store of cultural information, developing and learning techniques of social organization and group and individual survival. This gave a selective advantage to individuals with the large brain capacity necessary to take full advantage of the culture. Larger brains in turn increased the potential store of cultural

information, and a selfreinforcing coupling of the growth of culture and brain size resulted. This trend continued until perhaps 200,000

[2]USWCHS, *Vital statistics*, vol. 24, no. 11 (February 2, 1976).

[3]The Population Reference Bureau estimate for that period was $b = 31.5$ per 1000, $d = 12.8$ per 1000, $r = 18.7$ per 1000, or an increase of slightly less than 1.9 percent. Other sources (Lester R. Brown, *World population trends: Signs of hope, signs of stress*) have postulated lower rates for 1975: $b = 28.3$, $d = 11.9$, $r = 16.4$ per 1000, or 1.64 percent per year -- a substantial decline since 1970.

years ago, when growth of brain size leveled off at an average of some 1350 cubic centimeters, and human beings considered to belong to the same species as modern humanity, *Homo sapiens*, appeared.

The evolution of culture had some important side effects. Although the prehistoric human birth rate probably remained around 40 or 50 per 1000, cultural advances probably caused a slight decline in the average death rate. But the average death rate could not have been more than 0.004 per 1000 below the birth rate (the corresponding growth rate being 0.0004 percent or less), and there unquestionably were sizable fluctuations in birth rates and, especially, in death rates, particularly during the difficult times associated with glacial advance. Long before the Agricultural Revolution, humanity had spread out from Africa to occupy virtually the entire planet. It is known that human beings reached the Western Hemisphere some time before 45,000 B.C. As they became ubiquitous, increased hunting and gathering efficiency may have led, among other things, to the extinction of many large mammals, such as the great ground sloths, saber-toothed tigers, and woolly mammoths. [4]

The Agricultural Revolution. The consequences of cultural evolution for human population size and for the environment were minor compared with those that were to follow the Agricultural Revolution. It is not certain when the first group of *Homo sapiens* started to supplement its hunting and food-gathering with primitive farming. Archeological studies have produced firm evidence that village-farming communities functioned in the Middle East between 7000 and 5500 B.C. [5] Around that time certain groups of people in the hills flanking the Fertile Crescent, in what is now the border area of Iraq and Iran, gradually began to take up a new mode of life, cultivating a variety of crops and domesticating edible animals. Those people had previously practiced intensive food collection, as do Eskimos today, and presumably they were intimately familiar with the local flora and fauna. It would have been a natural step from gathering food to producing it.

With the beginnings of agriculture, growth of the human population started to accelerate. Two general explanations have been offered. The conventional explanation of this agriculture-related increase until recently was that the sizes of earlier populations had been kept in check by high natural mortality and that the development of agriculture tended to reduce the death rate. Agriculture not only allowed production of food to replace the constant search for it, it also permitted people to settle in one place. This in turn generated possibilities for storing vegetable

foods in granaries and bins, and meat on the hoof. Farmers were able to feed more than their own families, and as a result some members of early agricultural communities were able to turn entirely to other activities. All of these changes helped to raise the general standard of life. Wheeled vehicles appeared; copper, tin, and then iron were utilized; and dramatic sociopolitical changes occurred, along with urbanization. Human existence thus began to lose some of its hazards, and the average life expectancy began to creep upward from its primitive level of perhaps twenty to twenty-five years. [6]

Recently, a rather different view of population growth just after the Agricultural Revolution has developed. It does not dispute the historical trends already described, but it does dispute that their primary cause was a lowered death rate. [7] Instead, the observed changes are attributed primarily to changes in the birth rate.

Using evidence from living populations of hunters and gatherers such as the !Kung [8] bushmen of southern Africa, from the demography of extinct human populations inferred from fossil samples, and from the behavior of nonhuman primates, supporters of this view have concluded that our ancestral hunters and gatherers consciously tried to space the births of their children. If this is true, one of the most "human" of all behavioral traits -- the conscious control of reproduction -- at least with respect to spacing, if not of total family size -- may

[8]The exclamation point denotes a click made with the tongue against the roof of the mouth, a sound with no counterpart in English.

be many thousands of years older than was previously thought. Child-spacing (with gaps of at least three to five years) among nomadic hunters and gatherers was presumably necessitated partly by the inability of the mother to carry more than one child. Another likely reason would have been the need to nurse each child for at least three years because the environment lacked the soft food required for earlier weaning. [9] Moreover, it appears likely that prolonged breast-feeding itself may help in suppressing fertility. Infanticide may also have been practiced widely among hunter-gatherers, when children were born too soon and in times of scarcity. [10]

Anthropological research on various contemporary and recent hunter-gatherer groups (such as the !Kung bushmen) and on migratory agriculturalists such as the Polynesians indicates that those people have been quite conscious of population pressures and aware of the reasons behind many of their customs relating to marriage and child-bearing. The Polynesians are renowned for their long-distance migrations, an obvious response to population pressure. But they also practiced infanticide, polyandry, nonmarriage of landless younger sons, abstention from sexual

activity for a period of time after birth of a child, coitus interruptus, and abortion. [11] Their awareness of the need to limit their numbers probably was sharpened by their confinement to small islands. Whether most hunter-gatherers have been conscious of a need to limit their final family sizes is problematical; but attention appears mainly to have focused on child-spacing.

The imperatives for child-spacing experienced by hunter-gatherers apparently disappeared when agriculture began. Although some changes at that juncture worked toward slowing population growth (for example, unlike hunters and gatherers, a significant proportion of the people in many agrarian societies remains unmarried it is generally agreed that agriculture and high natality go hand in hand. The prime reason for this, many demographers believe, is the perceived economic value of children to farming families. (This pronatalist attitude may still be a major factor in keeping birth rates high in peasant communities today.) The increased natality in agrarian societies, not a decline in death rates, is considered in this school of thought to have been the main reason for the acceleration of population growth following the Agricultural Revolution. They claim that mortality from disease probably increased with the greater population densities of agrarian societies, especially in preindustrial cities, and that there is no persuasive evidence that death rates declined with the start of farming.

Because of the uncertainty of early demographic records and especially the problems of reconstructing prehistoric vital rates, it is difficult to evaluate the two explanations of the population explosion that followed the Agricultural Revolution. It seems clear, however, that the earlier "lowered-death-rate" explanation was at best oversimplified.

Population growth after the Agricultural Revolution. The growth of human populations was not continuous after the Agricultural Revolution. Civilizations rose, flourished, and disintegrated; periods of good and bad weather occurred; and those apocalyptic horsemen -- pestilence, famine, and war -- took their toll. Of course, there has been no accurate record of human population sizes until quite recently, and even today demographic statistics for many areas are unreliable. A general picture that is quite adequate for the purposes of our discussion can be reconstructed, however. Although the global trend (indicated in Figure 5-1) has been one of accelerating increase, a great many local population explosions and crashes are concealed in that trend. For example, bubonic plague (black death) killed an estimated 25 percent of the inhabitants of Europe between 1348 and 1350. From 1348 to 1379 England's total population was reduced almost by half, from an estimated 3.8 million to 2.1 million. Many cities lost half or more of their inhabitants in the second half of the fourteenth century. [12] The demographic effect of repeated visitations of plague on the European population

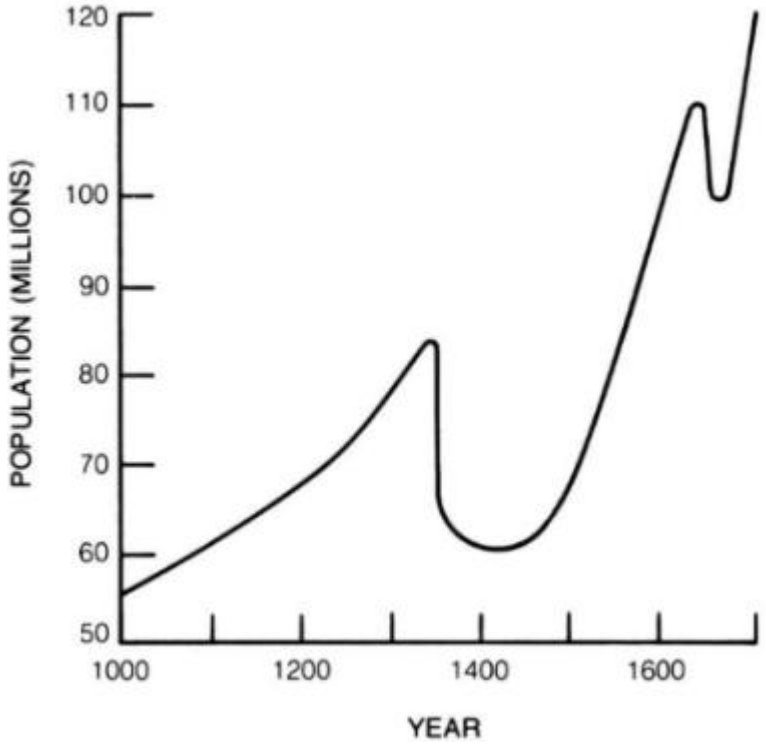

FIGURE 5-3 The effects of the bubonic plague on the size of the European population in the fourteenth and seventeenth centuries. The curve is an estimate based on historical accounts; actual data are scarce. (Adapted from Langer, 1964.)

is represented in Figure 5-3. The plague also triggered great social unrest, a typical concomitant of both dramatic increases and reductions in population size. The social and psychological effects lingered for centuries. [13] These plagues were only the most dramatic and wellknown epidemic in history. Numerous other plagues have taken their tolls over the centuries. For example, the influenza epidemic of 1917/ 1918, a much milder disease, killed some 20 million people in one year.

Famine has also been an important recurring contributor to high death rates. Floods, drought, insect plagues, warfare, and other disasters often have pushed populations over the thin line between subsistence and famine. One study by Cornelius Walford [14] lists more than 200 famines in Great Britain between 10 A.D. and 1846 A.D. (Box 5-1). Many, of course, were local affairs, which nevertheless could be very serious in the absence of efficient transport systems for transferring surplus food from other areas. Another study counts 1828 Chinese famines in the 2019 years preceding 1911, a rate of almost one per year. Some of those famines and some in India have been known to result in millions of deaths. Even in this century famine has killed many millions. For example, perhaps from 5 million to 10 million deaths have been attributed to starvation in Russia in the first third of the century (1918-1922, 1932-1934). Perhaps as many as 4 million deaths were caused by famine in China (1920/ 1921) before the revolution in 1949, and unknown millions in the first decade afterward. And between 2 and 4 million deaths were caused by famine in West Bengal, India, in 1943.

Warfare has often created conditions in which both pestilence and famine thrived, but it is difficult to estimate the direct consequences of war for population size. In many areas of the world, wars must have made a major contribution to the death rate, even when the conflict was between preagricultural groups. The effect of warfare on the sizes and distribution of populations in New Guinea, for example, was rather dramatic until quite recently. For security, villages in many areas were situated exclusively on hilltops, some of them thousands of feet above the nearest available water. A likely fate for a New Guinean man, woman, or child was death at the hands of a hostile group.

Throughout the history of Western civilization, war has been essentially continuous. This doubtless helped to maintain high death rates, particularly by creating food shortages and the preconditions of plagues. Barbarian invasions of the Roman Empire (375-568 A.D.), the Hundred Years' War (1337-1453), and especially the Thirty Years' War (1618-1648) caused substantial increases in the death rate in Europe. To give a single instance from the last of those conflicts, the storming and pillaging of Magdeburg by Catholic forces in 1631 caused an estimated 20,000 deaths. Indeed, some historians feel that as many as a third of the inhabitants of Germany and Bohemia died as a direct result of the Thirty Years' War.

The Peace of Westphalia ended the Thirty Years' War in 1648, introducing a period of relative tranquility and stability. At that time the Commercial Revolution was in full swing. Power was concentrated in monarchies, after having been decentralized in a loose feudal structure, and mercantilism was the economic order of the day. Perhaps

[14]*The famines of the world: Past and present*.

BOX 5-1 Famines

A small sampling of quotes from Cornelius Walford 's 1878 chronology of 350 famines will give some feel for the ubiquity in time and space of this kind of catastrophe. (Quotation marks indicate where Walford was quoting directly from his sources.) Those who have seen films of recent famines in India and Africa are unlikely to consider scenes like those described below as things of the past.

B.C. 436 *Rome*. Famine. Thousands threw themselves into the Tiber.

A.D. 160 *England*. Multitudes starved.

192 *Ireland*. General scarcity; bad harvest; mortality and emigration, "so the lands and houses, territories and tribes, were emptied."

331*Antioch*. This city was afflicted by so terrible a famine that a bushel of wheat was sold for 400 pieces of silver. During this grievous disaster Constantine sent to the Bishop 30,000 bushels

of corn, besides an immense quantity of all kinds of provisions, to be distributed among the ecclesiastics, widows, orphans, etc.

695-700 *England and Ireland* Famine and pestilence during three years "so that men ate each other."

1193-1196 *England, France*. "Famine occasioned by incessant rains. The common people perished everywhere for lack of food."

1299 *Russia*. Ravaged by famine and pestilence.

1412-1413 *India*. Great drought, followed by famine, occurred in the GangesJumna delta.

1600 *Russia*. Famine and plague of which 500,000 died.

1769-1770 *India*. (Hindustan) First great Indian famine of which we have a record. It was estimated that 3,000,000 people perished. The air was so infected by the noxious effluvia of dead bodies that it was scarcely possible to stir abroad without perceiving it; and without hearing also the frantic cries of victims of famine who were seen at every stage of suffering and death.

1770 *Bohemia*. Famine and pestilence said to carry off 168,000 persons.

1789 *France*. Grievous famine; province of Rouen.

1790 *India*. Famine in district of Barda . . . so great was the distress that many people fled to other districts in search of food; while others destroyed themselves, and some killed their children and lived on their flesh.

1877-1878 *North China*. "Appalling famine raging throughout four provinces (of) North China. Nine million people reported destitute, children daily sold in markets for (raising means to procure) food. . . . Total population of districts affected, 70 millions. . . ." The people's faces are black with hunger; they are dying by thousands upon thousands. Women and girls and boys are openly offered for sale to any chance wayfarer. When I left the country, a respectable married woman could be easily bought for six dollars, and a little girl for two. In cases, however, where it was found impossible to dispose of their children, parents have been known to kill them sooner than witness their prolonged suffering, in many instances throwing themselves afterwards down wells, or committing suicide by arsenic.

1878 *Morocco*. ". . . If you could see the terrible scenes of misery--poor starving mothers breaking and pounding up bones they find in the streets, and giving them to their famished children -- it would make your heart ache."

the most basic new idea of mercantilism was that of government intervention to increase the power of the state and (more important, from our point of view) the prosperity of the nation. Planning by government was extended to provide economic necessities for the population.

The preindustrial rise of population, 1650-1850. In the middle of the seventeenth century, a period of relative peace started in a postfeudal economic environment. Simultaneously, a revolution in European agriculture--a revolution that was largely a result of the Commercial Revolution--began to gather momentum. It accelerated rapidly in the eighteenth century. Rising prices and increasing demand from the growing cities added to the commercial attractiveness of farming. The breakdown of the feudal system gradually destroyed the manorial estates. On those estates each male serf had assigned to him several scattered strips of land, which were farmed communally. The serfs grew increasingly unhappy with the communal farming, so the strips were rearranged into single compacted holdings leased by individual peasants from the landholder.

As landowners wished to put more land to the plow, they began to enclose old communal woodland and grazing lands with hedges and walls, barring the peasants from resources essential to their subsistence. This movement was especially pronounced in Great Britain, where it was promoted by a series of special acts of Parliament. Furthermore, much of the peasantry was dispossessed or forced out of agriculture by competition from the more efficient large farming operations. Agriculture was transformed into big business.

Accompanying these changes were fundamental improvements in crops and farming techniques. For instance, the role of clover in renewing soil (by replacing lost nitrogen) was discovered in England by Lord Charles Townshend. This made the practice of letting fields lie fallow every third year unnecessary. Other improvements were made in methods of cultivation and in animal breeding. Agricultural output increased and so, consequently, did the margin over famine. It seems plausible that a combination of commercial and agricultural revolutions, a period of relative peace, and the disappearance of the black death all combined to reduce the death rate and produce the European population surge that started in the mid-seventeenth century. [15] Between 1650 and 1750 it is estimated that the populations of Europe and Russia increased from 103 million to 144 million.

An additional factor that may have contributed to this acceleration in growth was the opening of the Western Hemisphere to European exploitation. In 1500 the ratio of people to available land in Europe was about 10 per square kilometer. The addition of the vast, virtually unpopulated frontiers of the New World reduced the ratio for Europe plus the Western Hemisphere to less than 2 per square kilometer. As historian Walter Prescott Webb wrote, this frontier was, in essence "a vast body of wealth without proprietors." [16] Thus, not only was land shortage in Europe in part alleviated, but several major European nations were enriched. Both factors encouraged population growth.

Furthermore, the introduction of two new foods from the New World, maize (corn) and the potato, either of which could provide sustenance for a large family from a very small plot of land, may have fueled a population increase by expanding the feeding base. [17] Maize was

widespread in southern Europe by the eighteenth century, during which the populations of both Spain and Italy nearly doubled.

Although we can speculate with ease about the causes of Europe's population boom between 1650 and 1750, it is somewhat more difficult to explain a similar boom in Asia. The population there increased by some 50 to 75 percent in that period. In China, after the collapse of the Ming dynasty in 1644, political stability and the agricultural policies of the Manchu emperors doubtless led to a depression of death rates. The introduction of maize and peanuts to China in the eighteenth century may also have stimulated growth there, as the potato and maize seem to have done in Europe.

---

[15]The disappearance of black death was possibly due to the displacemeat of the black rat, which lived in houses by the sewer-loving brown rat. This lessened contact between people and rats, and thus reduced the chances of plague-carrying fleas reaching human beings. In London the great fire of 1666 destroyed much of the city, which consisted largely of rundown wooden buildings that provided excellent shelter for the rats. By orders of the king, the city was rebuilt with brick and stone, thus making it much more secure from plague.

[16]*The great frontier*.

[17]W. L. Langer, *American foods and Europe's population growth, 1750-1850*.

Much of the Asian population growth during that period probably took place in China, since India was in a period of economic and political instability caused by the disintegration of the Mogul Empire. When the last of the Mogul emperors, Aurangzeb, died in 1707, India was racked by war and famine. British soldier and statesman Robert Clive and the East India Company established British hegemony in India during the period between 1751 and 1761. At a time when China may have had the world's most advanced agricultural system under the efficient Manchu government, India was a battleground for the British and French. And the rapid increase in power of the British East India Company following the Peace of Paris in 1763 did not bring rapid relief. Indeed, in a famous famine in 1770, about one-third of the population of Bengal is reputed to have perished--a circumstance that did not prevent industrious agents from maintaining the East India Company's revenue from Bengal during that year!

World population seems to have grown at a rate of about 0.3 percent per year between 1650 and 1750. The rate increased to approximately 0.5 percent between 1750 and 1850, during which time the population of Europe doubled. Because what demographic records exist are scanty, fragmentary, and often anecdotal, the causes of this acceleration are not known and have become a subject of some debate. The prevailing view has been that, in Europe at least, the surge occurred in response to a number of favorable changes that acted chiefly to reduce mortality. [18]

The most important cause of lowered death rates in preindustrial Europe seems to have been a decline in mortality from infectious diseases, especially tuberculosis (at least in England) and smallpox (resulting from the introduction of smallpox inoculation). Demographic historians T. McKeown, R. G. Brown, and R. G. Record attribute this change to "environmental improvements"--primarily, increased food production resulting from continued advances in

agricultural techniques. [19] P. E. Razzell has suggested that the adoption of habits of personal hygiene following the popular introduction of soap and cheap utensils and cotton clothing had more to do with the reduction of infectious diseases than did nutritional improvement. [20] He also cites drainage and reclamation of land as possibly helping to reduce the incidence of malaria and various respiratory diseases.

Another group of historians puts an emphasis on rising birth rates as an explanation of the burst of growth in Europe's population that began in the seventeenth century. Even though agricultural socioeconomic systems (such as that of eighteenth-century Europe) generally promote high birth rates, there is evidence that through most of history, farming populations have kept their natality below the maximum. Not the least of this evidence is the relatively low growth rate during the first 10,000 years of agriculture (less than 0.1 percent.) [21] This suggests that there was a "reserve" of natality that could permit an increase when needed. Some historians think such a reserve may have helped fuel Europe's seventeenth-century growth spurt. [22] The claim is that rising birth rates played an important role in accelerating this population growth and that the decline in death rates may not have been significant or consistent until around 1900. [23] The latter suggestion is not supported, however, by evidence from several northwestern European countries for which data exist (see Figure 5-4).

Historian William Langer believes an overriding factor was the widespread acceptance of the potato as a staple food in northern Europe during the eighteenth century, particularly among peasants trying to subsist on very small pieces of land. [24] His view is that, by providing relatively abundant, nutritious food for the poor, potato cultivation encouraged couples to marry younger and raise larger families. Hence, it stimulated higher birth rates as well as contributing to the improved nutrition that led to lower death rates from disease. The potato's role in generating the population explosion in Ireland during this period (the Irish increased from 3 million to 8 million), followed by a crash when potato blight destroyed the crop in 1846 and 1847 (1 million died, and 2

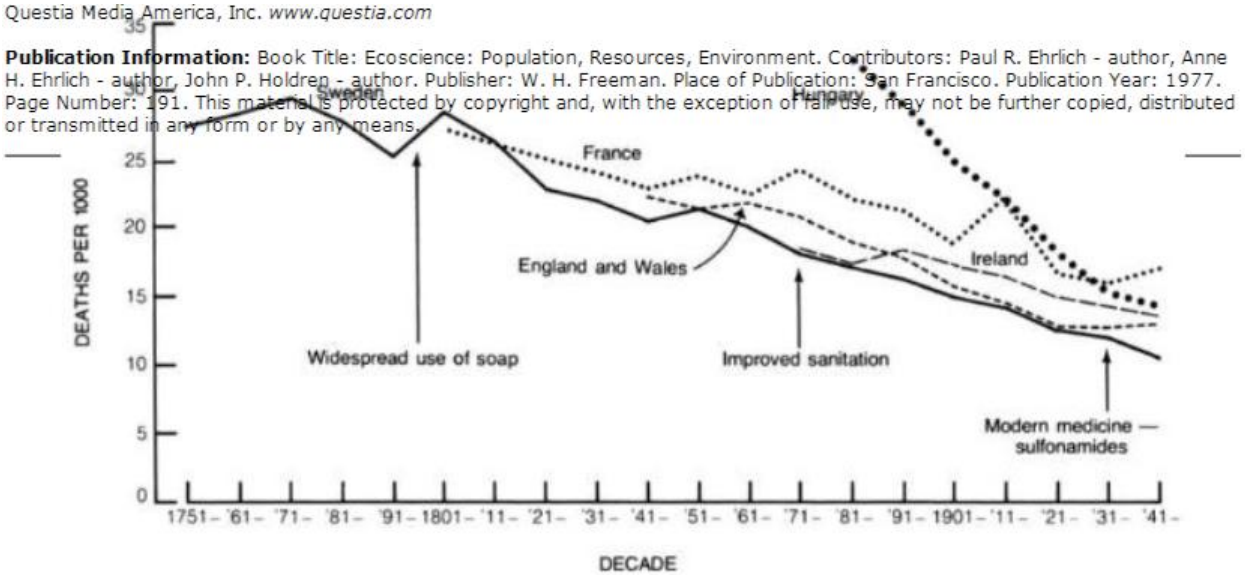

FIGURE 5-4 Mean annual death rates in England and Wales, Sweden, France, Ireland, and Hungary from the time of their initial registration. The times when some factors thought to play important roles in reducing mortality were introduced are indicated, too. Note that modern medicine--as distinct from personal and public hygiene--became an important influence only quite recently. (Adapted from McKeown, Brown, and Record, 1972.)

million emigrated), is common knowledge. Many other areas in Europe were also threatened by the blight, but because the people were less completely dependent on a potato monoculture, more survived.

Quite probably all these factors--prosperity, increased food supplies, diminished mortality from disease, improved sanitation--contributed in some measure to the acceleration in Europe's population growth between 1750 and 1850. There is little evidence to support the hypothesis that birth rates rose significantly. Indeed, in some countries they were declining well before 1800. The argument that the acceleration of growth that accompanied the beginning of agriculture was primarily caused by increased natality seems to us persuasive; the claim that a significant trend in declining death rates did not develop until the end of the nineteenth century is less so, especially since considerable evidence exists to the contrary.

Regardless of whether the growth in Europe's population between 1750 and 1850 was caused mainly by declining death rates, rising birth rates, or some combination of the two, twice as many people were living there at the end of the century as had been at the beginning. Moreover, this increase occurred despite several factors operating against it, notably a high rate of celibacy (nonmarriage) and the apparently widespread practice of infanticide. [25] Reports of infanticide in Europe extend back into the Middle Ages, [26] but by 1800 in England, France, and Germany it seems to have reached almost epidemic proportions. The vast majority of the unwanted children were born to the poor--often to unmarried domestic servants and others unable to care for them. In this connection, there seems to have been considerable social and economic pressure against marriage for the landless poor, and even for younger sons of the wealthier classes. In London and Paris--and perhaps other cities, as well--foundling hospitals were established to care for the growing numbers of abandoned babies. But the level of care provided was so poor that the main

result was the disappearance of infant bodies from streets, roadsides, and streams (evidently they were a very common sight before 1800). [27] The horrors of widespread infanticide-largely suppressed and forgotten today--apparently per-

sisted as late as 1870--perhaps not coincidentally, about the time the birth-control movement was beginning (see Chapter 13). One might speculate that both the birthcontrol movement and Victorian prudery (especially the powerful disapproval of extramarital sexual activity and illegitimacy) were both reactions to infanticide. It is ironic, if so, that the same prudery for decades hindered the spread of birth control!

The doubling of Europe's population between 1750 and 1850 also was achieved in the face of substantial emigration to the New World, where the population jumped from 12 million to about 60 million in the same period. The United States grew from about 4 million in 1790, when the first census was taken, to 23 million in 1850. Much of the increase was due to immigration, mainly from England, but birth rates were also high (an estimated 55 per 1000 in 1800, declining to 43.3 per 1000 in 1850). [28] Mortality data are lacking, but it is probable that the death rate in the United States was declining as it was in Europe, and for similar reasons. As just one example, mass inoculation against smallpox was first introduced and shown to be effective during the Revolutionary War.

Growth in Asia between 1750 and 1850 was slower than in Europe, amounting to an increase of about 50 percent. Most of the developments that favored a rapid increase in Europe's population were to appear in Asia only much later, if at all. Little is known about the sizes of past populations in Africa, a continent that remained virtually unknown to the outside world until well past the middle of the nineteenth century. It is generally accepted that the population there remained more or less constant at around 100 million, plus or minus 5 or 10 million, between 1650 and 1850. After that, death rates appear to have declined somewhat, perhaps because of improved food supplies and distribution and the introduction of European sanitation and medicine.

The demographic transition, 1850-1930. Death rates in Europe and North America continued to decline during the period between 1850 and 1900, probably as a result of improvements in living conditions that accompanied the Industrial Revolution. Although the horrible conditions that prevailed in mines and factories during the early stages of the rise of industry are well known to all who have read the literature of the period, the overall situation in areas undergoing industrialization actually improved. Life in the rat-infested cities and rural slums of preindustrial Europe had been grim almost beyond description. Advances in agriculture, industry, and transportation by 1850 had substantially bettered the lot of the average person in Europe and

North America. Improved agriculture had reduced the chances of crop failures and famine. Mechanized land and sea transport had made local famines less disastrous by providing access to distant resources. Great improvements in sanitation--notably, the installation of sewage systems and the purification of water supplies--in the last third of the nineteenth century helped to reduce death rates further. So did discovery of the role of bacteria in infection and the introduction of inoculation against disease. (The medical advances, however, appear to have had less impact on mortality than has traditionally been attributed to them.) [29]

European death rates, which in 1850 had been in the vicinity of 22 to 24 per 1000, decreased to around 18 to 20 per 1000 by 1900 and went as low as 16 per 1000 in some countries. Combined rates for Denmark, Norway, and Sweden dropped from about 20 per 1000 in 1850 to 16 per 1000 in 1900. [30] In western and northern Europe in the latter half of the nineteenth century, low death rates (and the resultant high rate of population increase) helped stimulate massive emigration. [31]

By the end of the century, another significant trend appeared: birth rates in several Western countries, including the United States, were also declining. In Denmark, Norway, and Sweden, the combined birth rate was around 32 per 1000 in 1850; by 1900 it had decreased to 28. Similar declines occurred elsewhere. This was the start of the so-called demographic transition--a falling of birth rates that followed declining death rates in Europe

---

[29] McKeown, Brown, and Record (An interpretation) are of the opinion that sanitation was far more important than medicine in reducing death rates before 1935. They point out that no significant drugs effective against infectious disease existed until sulfa drugs were developed in the 1930s and modern antibiotics in the 1940s.

[30] A. J. Coale, The decline of fertility in Europe from the French Revolution to World War II, in *Fertility and family planning: A world view*, S. J. Behrman; L. Corsa, Jr.; and R. Freedman, eds.

[31] K. Davis, *The migrations of human populations*.

and North America, which has generally been associated with industrialization. [32] Figure 5-5 shows the progress of the demographic transition in several European countries.

What caused the decline in birth rates in the industrializing Western countries? No one knows for certain, but some rather good guesses have been made. In general, it has been assumed that the changed conditions of life caused by industrialization led to changed attitudes toward family size. In nineteenth-century western Europe, customs of late marriage (which reduces birth rates by reducing the number of years each woman is reproductively active) and a high proportion of nonmarriage were already established. Hence, declining birth rates presumably were due mainly to conscious and increasing limitation of the number of children born within marriage.

It has been observed that in agrarian societies children are commonly viewed as economic bonuses. They serve as extra hands on the farm and take care of parents in their old age. This

pronatalist point of view was beautifully expressed by Thomas Cooper in 1794. [33] He wrote: "In America, particularly out of the large towns, no man of moderate desires feels anxious about a family. In the country, where dwells the mass of the people, every man feels the increase of his family to be the increase of his riches: and no farmer doubts about the facility of providing for his children as comfortably as they have lived. . . ."

As a society industrializes, the theory goes, these things change. Children are no longer potential producers; they become consumers, requiring expensive feeding and education. This is especially so once child labor is abolished and education becomes compulsory. Large families, which become more likely with lowered death rates, tend to reduce mobility and to make the accumulation of capital more difficult. Other factors affecting family size that have been mentioned are the education and employment of women, increased secularization of society, and the decline of traditional religious influence. [34]

The demographic transition in Europe, however, was not limited to urban areas, although it may have begun there. Rapid population increase created a squeeze in rural areas as well, a squeeze that was compounded by the modernization of farms. A finite amount of land had to supply a livelihood for more people. As time went on, increased mechanization, which made larger farms more efficient and reduced the need for farm labor, made it more and more difficult for a young couple to establish themselves on a farm of their own. This may effectively have outweighed any traditional advantages of large farm families. As a result, rural birth rates also dropped, and many people moved to the cities seeking jobs in commerce and industry.

Yet this traditional explanation of the demographic transition, in which industrialization is considered the prime influence, does not account for numerous exceptions. France, for example, industrialized late compared to some of its neighbors, yet it was the first country to experience declining birth rates, beginning in 1800 or earlier (Figure 5-5). The United States also had a dropping birth rate well before industrialization had progressed very far; nor was land scarcity ever a significant factor here. [35] In England, the birthplace of the Industrial Revolution, on the other hand, the birth rate rose slightly between the 1840s and the 1870s, after which it declined steadily.

Hungary, like most of eastern Europe, industrialized much later. Its demographic transition also began later (and proceeded faster), but the birth rate was dropping precipitously well before industrialization had taken place to any significant degree. [36] Thus it appears that, whereas industrialization (and accompanying urbanization and extension of compulsory education) may have been a factor in Europe's demographic transition, it clearly is not the whole explanation, and possibly is not even the main one.

The twentieth century. The demographic transition in Western nations continued into the twentieth century. Yet, despite declining birth rates and a high rate of emigration from Europe, many of those countries were

Demography, and Carr-Saunders, *World Population*.

growing as rapidly as ever (Figure 5-6). Of the four nations represented in Figure 5-6, only Ireland lost population, and that was a direct result of the Irish potato famine in the 1840s. Birth rates there remained moderately high but were counterbalanced by heavy emigration. France maintained a very low rate of natural increase; Sweden and England both had relatively high ones, but Sweden's growth was much more depressed by emigration. The United States, by

comparison, tripled its population between 1850 and 1900, spurred by massive immigration, even though its birth rate continued to decline steadily.

The average growth rate of the world population between 1850 and 1950 was about 0.8 percent per year. Population increased in that time from slightly more than 1 billion to almost 2.5 billion. The estimated populations shown in Table 5-3 indicate that between 1850 and 1950 the population of Asia did not quite double, whereas it more than doubled in Europe and Africa, multiplied about fivefold in Latin America, and more than sixfold in North America.

Toward the middle of the twentieth century, this pattern of relative growth rates began to change. By the 1930s declines in the birth rates in some European countries had outpaced declines in the death rates, and population growth had begun to slacken. By then the combined death rate of Denmark, Norway, and Sweden had declined to 12 per 1000, and the birth rate had dropped precipitously to about 16 (Figure 5-4). North America followed a similar path, both in lower birth rates

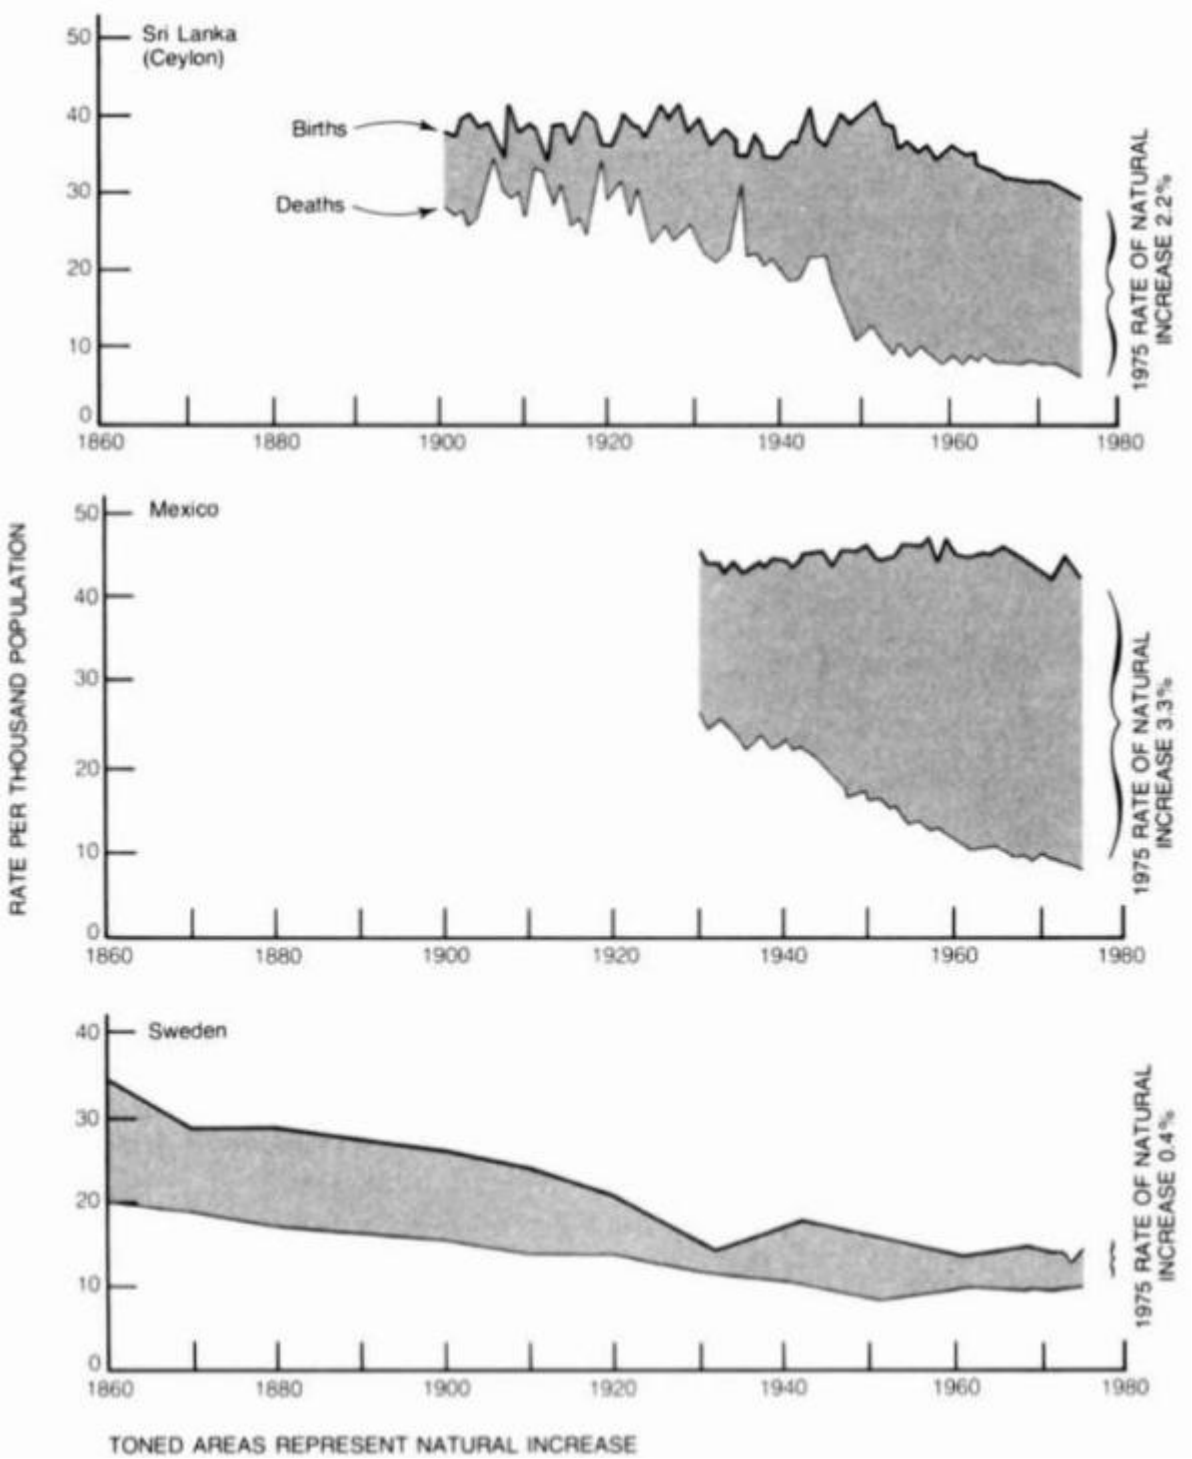

FIGURE 5-7 Different patterns of change in birth and death rates and the rate of natural increase. Death rates dropped gradually in Western industrial countries such as Sweden and precipitously in LDCs such as Sri Lanka (Ceylon) and Mexico. (Courtesy of the Population Reference Bureau, Inc., Washington, D.C.)

and in dramatically reduced immigration after the 1920s.

Stimulated by improving economic conditions and World War II, however, birth rates rose again during the 1940s and remained above replacement level in most developed countries until the late 1960s. Consequently, European growth rates generally averaged between 0.5 and 1.0 percent from 1945 to 1970. Since then, the decline in fertility has resumed, and a few countries had reached zero population growth (ZPG) by the mid-1970s.

As population growth in industrialized nations slowed in response to low birth rates around the time of World War II, a dramatic decline in previously quite high death rates occurred in the nonindustrial nations. In some countries, such as Mexico, the decline started before the war. In others, such as Ceylon (now Sri Lanka), it did not start until the end of the war. Compare, for instance, the trend in Sweden since 1860 with that in Mexico since 1930 (Figure 5-7). This decline in the death rate was caused primarily by the rapid export of modern drugs and public-health measures from the developed countries to the less developed countries. The consequent "death control" produced the most rapid, widespread change known in the history of human population dynamics: the postwar population explosion. [37]

The power of exported death control can be seen by examining the classic case of Ceylon's assault on malaria after World War II. Between 1933 and 1942 the death rate due directly to malaria in Ceylon was reported as about 2 per 1000. That rate, however, represented only a fraction of the malaria deaths, as many were reported as being caused by "pyrexia," a fancy name for fever. Actually, in 1934/ 1935 a malaria epidemic may have been directly responsible for fully half the deaths on the island. The death rate for those years rose to 34 per 1000. In addition, malaria, which infected a large portion of the population, made many people susceptible to other diseases and thus contributed to the death rate indirectly, as well as directly.

The death rate in Ceylon in 1945 was 22 per 1000. The introduction of the insecticide DDT in 1946 brought rapid control over the mosquitoes that carry malaria. Subsequently, the death rate on the island dropped 34

percent between 1946 and 1947, declined by about 50 percent of the 1945 level by 1955, and has continued to decline since then. In 1975 it stood at 8 per 1000. Although part of the drop was certainly due to other public health measures and the control of other diseases, much of it can be accounted for by the control of malaria.

Victory over malaria, yellow fever, smallpox, cholera, tuberculosis, and other infectious diseases has been responsible for similar abrupt drops in death rates throughout the nonindustrial world. The decline has been most pronounced among children and young adults. They are the people most vulnerable to infectious diseases--the diseases most efficiently controlled by modern medical and public-health procedures. (Congenital problems in infants and degenerative diseases of old people reduce the proportionate effects of infectious disease in those age brackets.) The differential reduction of mortality can be seen clearly in data from Jamaica and Ceylon (Table 54).

In the decade between 1940 and 1950, death rates declined 46 percent in Puerto Rico, 43 percent in Taiwan, and 23 percent in Jamaica. In a sample of eighteen less developed areas, the average decline in death rate between 1945 and 1950 was 24 percent. [38] Figure 5-8 shows the dramatic change in death rates from the 1945 to 1949 average to the 1960/ 1961 average in selected Asian nations.

[37] K. Davis, *The amazing decline of mortality in underdeveloped areas*.
[38] Ibid.

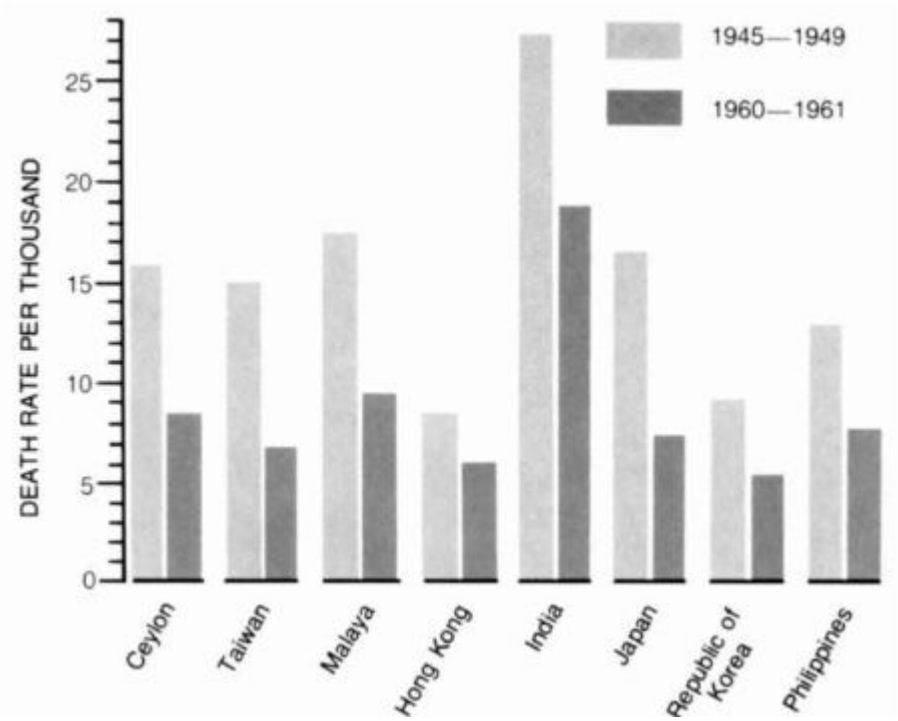

FIGURE 5-8
Changes in death rates in selected Asian nations. The average rates between 1945 and 1949 are

compared with those of 1960 and 1961. (Adapted from *Population bulletin*, vol. 20, no. 2. Courtesy Population Reference Bureau, Inc., Washington, D.C.)

A critical point to remember is that this precipitous decline in death rate is different in kind from the long-term slow decline that occurred throughout most of the world following the Agricultural Revolution. It is also different in kind from the comparatively faster decline in death rates in the Western world since 1650, even though both were achieved primarily through reduction in deaths from infectious diseases. The difference is that the plummeting death rates of less developed countries are a response to a spectacular environmental change in the LDCs, not to a fundamental change in their institutions or general ways of life. Furthermore, that change did not originate within those countries but was introduced from the outside.

The factors that have been associated with a demographic transition (to lowered birth rates) in the developed countries therefore were not and still are not present in most non-Western countries, and birth rates there accordingly have remained high. For instance, the Indian birth rate in 1891 was estimated to be 49 per 1000 per year; in 1931 it was 46 per 1000, and in 1972 it was still around 40 per 1000, despite efforts to reduce it during the 1960s and 1970s (see Chapter 13). And much of that small decline can be attributed to changes in the nation's age composition (see Box 5-4).

In the decade 1930 to 1940, the populations grew in North America and Europe at 0.7 percent per year, whereas those of Asia grew at 1.1 percent, Africa at 1.5 percent, and Latin America at 2.0 percent, even though death rates were still considerably higher in the last three areas mentioned. The annual world growth rate for the decade was 1.1 percent.

Since then, the majority of the human population has moved rapidly from a situation of high birth and death rates to one of high birth rates and low death rates. The average annual world growth rate for the decade 1940 to 1950, presumably depressed by World War II, was 0.9 percent (doubling time, 77 years). It then zoomed to 1.8 percent (doubling time, 38 years) from 1950 to 1960 following the introduction of death control to the less developed regions. During the 1960s the world growth rate fluctuated between 1.8 and 2.0 percent per year. The entire population grew from about 2.3 billion in 1940 to 2.5 billion in 1950, to 3.0 billion in 1960, and 3.6 billion in 1970. [39]

According to the Population Reference Bureau, whose figures are based mainly on United Nations estimates, the world's population size in mid-1976 was 4,019 million, the annual growth rate was 1.8 percent, and the doubling time 38 years. [40] These numbers, however, conceal very large differences in rates of growth among nations and regions, which are described in Box 5-2 and summarized in Table 5-5. (Appendix 1 presents detailed population estimates for 1976, prepared by the Population Reference Bureau.)

Most LDC population figures, it should be noted, are only approximations because census data from many of them are inadequate or nonexistent. There is considerable controversy, for example, about the actual size and rate of growth of the Chinese population. China itself claimed a population of 800 million in late 1974. The United Nations put the population at 838 million in mid-1975 and the growth rate at 1.7 percent. Demogra-

[39]United Nations *Statistical warbook, 1973*, and various other sources.
[40]*1976 World Population Data sheet*.

pher Robert Cook of the Environmental Fund is skeptical of both estimates, and he places the 1975 total at more than 900 million and the growth rate close to 2 percent. [41] (According to his figures, the world population in 1975 was growing at a rate of 2.2 percent per year and doubling in 32 years.) Another demographer, John S. Aird, of the United States Department of Commerce, has claimed that China's population exceeded 930 million in 1972 and was growing at 2.4 percent.

At the other extreme, R. D. Ravenholt, director of the population program for the U.S. Agency for International Development (AID), claims that world population growth reached a peak between 1965 and 1970 and has now begun to decline. [42] He places China's 1975 population at 876 million and its growth rate at 0.8 percent. Ravenholt also offers lower estimates than Cook's of birth rates for many LDCs with family-planning programs. Obviously, large discrepancies in estimates for China alone can induce considerable variation in estimates for the world as a whole. Table 5-6 shows the differences between three of these estimates of world population size and growth.

The most recent U.N. and U.S. government figures indicate that Ravenholt may be correct that the rate of population growth worldwide has begun to slacken since 1970. [42a] Lester Brown of Worldwatch Institute attributes the slowdown to (1) unexpectedly successful results of China's population policies and a correspondingly lower death rate and, especially, birth rate there; (2) a significant decline in birth rates in nearly all developed countries; (3) some success in lowering birth rates in some LDCs; and (4) a rise in death rates in several LDCs, especially in South Asia, caused primarily by food shortages in the early 1970s (see Chapter 7). To the extent that lowered birth rates may be slowing population growth, this is encouraging news. To the extent that reduced growth is caused by a rise in death rates, it is a tragic confirmation of the often-ignored warnings of ecologists and others.

BOX 5-2 Population Growth: 1975 to 2000

By 1975 a striking disparity in population growth rates had arisen between the developed areas and the less developed areas of the world. Most DCs were growing very slowly, at less than 1 percent per year; many LDCs were growing at 3 percent per year or more. At 3.5 percent a population would multiply *more than thirtyfold within a century.* The world population in 1975 was about 4 billion, and the growth rate in the early 1970s was 1.9 percent per year (doubling in 36 years), according to the United Nations. * The following paragraphs outline the situation continent by continent.

North America

Canada and the United States together had a 1975 population of 237 million. A growth rate of 0.9 percent per year gave a doubling time for the area of 77 years. Depending on future birth rates and migration patterns, North America could have as many as 350 million people in the year 2000, or it could have as few as 265 million.

Latin America

This area (the Western Hemisphere south of the United States) had a 1975 population of 326 million and a growth rate of 2.7 percent, the highest rate for any major region. As a whole the population of the area was doubling every 26 years. Some Latin American countries have had extremely high growth rates and rapid doubling times in recent years. Honduras, for example, had a 1975 growth rate of 3.5 percent and a doubling time of 20 years. Doubling times for other representative countries were: Dominican Republic, 21 years; Mexico, 22 years; Peru, 24 years; Brazil, 25 years; Surinam, 27 years; Bolivia, 28 years; and Cuba, 35 years. A few countries in temperate Latin America were growing more slowly-Chile, Argentina, and Uruguay (doubling in 38, 53, and 69 years, respectively). According to various projections, the population of Latin America in the year 2000 will be between 550 and 760 million (see Figure 5-9).

Europe

Europe is the demographic antithesis of Latin America. The 1975 European population (excluding European USSR and Turkey) was 474 million. The growth rate for the continent was 0.6 percent, which gives a doubling time of 116 years. The more rapidly growing countries, such as Ireland, Spain, and Yugoslavia, had doubling times of between 60 and 80 years. But most European countries were doubling much more slowly than that: Czechoslovakia, every 116 years; Italy, every 139 years; Hungary, every 173 years; and Austria, every 347 years. Both East Germany and West Germany have reached zero population growth. In the year 2000 Europe's population is projected to be about 540 million.

The Soviet Union had a 1975 population of 255 million, a growth rate of 1.0 percent, and a doubling time of 70 years. For several years its growth rate has been similar to that of the United States, but it is now higher. The population is projected to reach 315 million by the year 2000.

Africa

The 1975 population of Africa was 402 million people. Its current rate of growth is 2.6 percent, and its doubling time, 27 years. The pattern of growth is approaching that of Latin America, except that generally higher death rates in Africa result in a slightly lower growth rate. Sample doubling times were: Kenya, 21 years; Zambia, 22 years; Morocco, 24 years; Malagasy Republic, 24 years; Nigeria, 26 years; South Africa, 26 years; Egypt, 29 years; the People's Republic of Congo, 29 years; and Central African Republic, 33 years. Projections for the year 2000, based on the assumption that the death rate will continue to decline, give Africa a population of between 730 and 900 million, second only to the total projected for Asia. Some specialists on Africa cite evidence that the relatively high death rates there will drop rapidly in coming years and the birth rates will remain high. If this occurs, growth rates of 3.5 percent or even 4 percent per year could become commonplace in Africa, in which case the population estimates given here would be too low.

Concise report on the world population situation, 1970-1975, and its long-range implications. Doubling times that follow for regions and nations are from *1975 Population Data Sheet*, Population Reference Bureau, Inc.

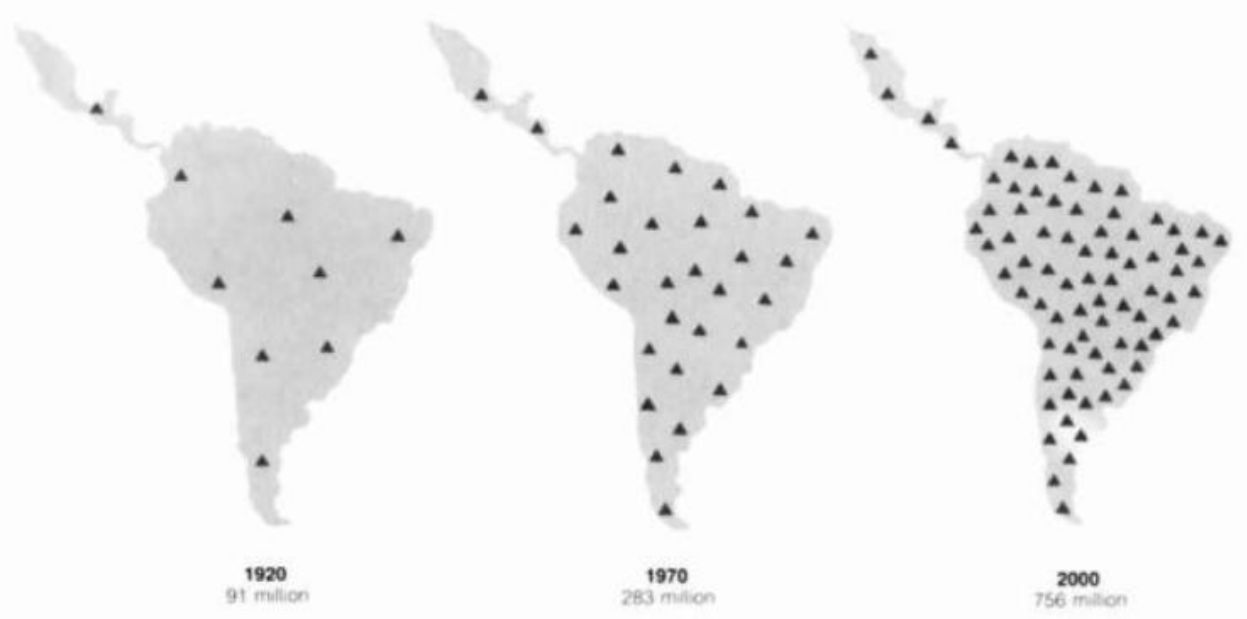

FIGURE 5-9
Population growth in Latin America, 1920-2000. If fertility rates do not drop, the population of

the area will undergo more than an eightfold increase in eighty years. (Adapted from *Population bulletin*, vol. 23, no. 3. Courtesy of the Population Reference Bureau, Inc., Washington, D.C.)

Asia

Today's population giant, Asia, is inhabited by at least 2,273 million--over 2 billion--people. That figure--more than half the world's population-does not include the population of Asian USSR. It may be an understatement, moreover, if India's 1971 census results were incomplete and if some population estimates for China have been too low. Asia's 1975 growth rate was 2.1 percent, and its doubling time was 33 years. Among the Asian nations only Japan shows a growth pattern similar to those of Europe and North America, although Hong Kong, Taiwan, Singapore, and South Korea are moving in that direction. Japan's growth rate in 1975 was 1.3 percent, and its doubling time, 53 years. The doubling time for South Korea was 35 years; for Taiwan, 36 years; Singapore, 43 years; and Hong Kong, 50 years. The People's Republic of China presents a special problem. The size of its population and its growth rate are uncertain.

Estimates of size range from 800 to 950 million people, the 1975 United Nations figure being 838 million. The United Nations estimated the growth rate as 1.7 percent (a 55-year doubling time), but this is basically an informed guess.

For the rest of Asia, doubling times tell the familiar story of the LDCs: Philippines, 21 years; Pakistan, 22 years; Malaysia, 24 years; Indonesia, 27 years; Afghanistan, 28 years; and India, 29 years. Among the most rapidly growing countries today arc the Middle-Eastern, mainly Moslem, countries of southwestern Asia. The influx of wealth from oil in those lands in the 1970s may be effectively suppressing death rates, which until recently were relatively high. Typical 1975 doubling times were: Kuwait, 10 years; Iran, 23 years; and Saudi Arabia, 24 years. Projections for the year 2000 put Asia's population between 3000 and 4500 million and uniformly predict that that continent will continue to be the home of more than half of all *Homo sapiens*.

TABLE 5-6
World Population--Three Estimates

	United Nations	Environmental Fund	U.S. Agency for International Development
Population (mid- 1975, in millions)	3988	4147	3943
Average birth rate (per 1000)	31.8 (1970-1975)	35.0 (1975)	28.2 (1974)
Average death rate (per 1000)	12.8 (1970-1975)	13.0 (1975)	11.8 (1974)
Rate of natural increase (%)	1.9 (1970-1975)	2.2 (1975)	1.63 (1974)
Annual increment in population (mid- 1970s, in millions)	75	86	63

Sources: United Nations estimates appeared in United Nations, *Concise report*; those of the

Environmental Fund, Inc., in *World population estimates, 1975*; and AID estimates in R. T. Ravenholt, Gaining ground.

Even the inadequate and controversial data available are nevertheless more than sufficient for our discussion. Whether there actually were only 3.8 billion people or as many as 4.3 billion in the world in mid-1976, or whether the average worldwide growth rate was 1.5 or 2.2 percent, does not significantly affect our conclusions about what that implies for the future of the planet and its inhabitants.

DEMOGRAPHIC PROJECTIONS AND POPULATION STRUCTURE

Once there was a young man who proposed a novel pay scheme to a prospective employer. For one month's work he was to receive I cent on the first day, 2 cents on the second, 4 on the third, and so on. Each day his pay was to double until the end of the month. The employer, a rather dull-witted merchant, agreed. The merchant was chagrined, to say the least, when he found that the young man's pay for the fifteenth day was more than $160. The merchant went bankrupt long before he had to pay the young man $167,733 for the twenty-fifth day. Had he remained in business, he would have had to pay his new employee wages of more than $10 million for the month.

This is just one of many stories illustrating the astronomical figures that are quickly reached by repeated doubling, even from a minute base. Another is about a reward that consists of a single grain of rice on the first square of a chessboard, 2 on the second, 4 on the third, and so forth, until the board is filled. It turns out that completing the reward would take several thousand times the world's annual rice crop.

Equally horrendous figures may be generated by projecting the growth of the human population into the future. Doubling time for that population fluctuated around 35-37 years between 1960 and 1974. If growth continued at that rate, the world population would exceed a billion billion people about 1000 years from now. That would be some 2000 persons *per square meter* of Earth's surface, land and sea! Even more preposterous figures can be generated. In a few thousand more years everything in the visible universe would be converted into people, and the diameter of the ball of people would be expanding with the speed of light! Such projections should convince all but the most obtuse that growth of the human population must stop eventually.

Age Composition

The discussion of the human population so far has dealt mainly with population sizes and growth rates, but of course there is more to demography than that. Populations also have structure: *age composition* and *sex ratio,* as well as *distribution* and *dispersion* (the geographic positions and relative spacing of individuals), discussed later in this chapter. These structural factors can

strongly influence rates of growth and do have profound effects on the social and economic conditions under which a population lives.

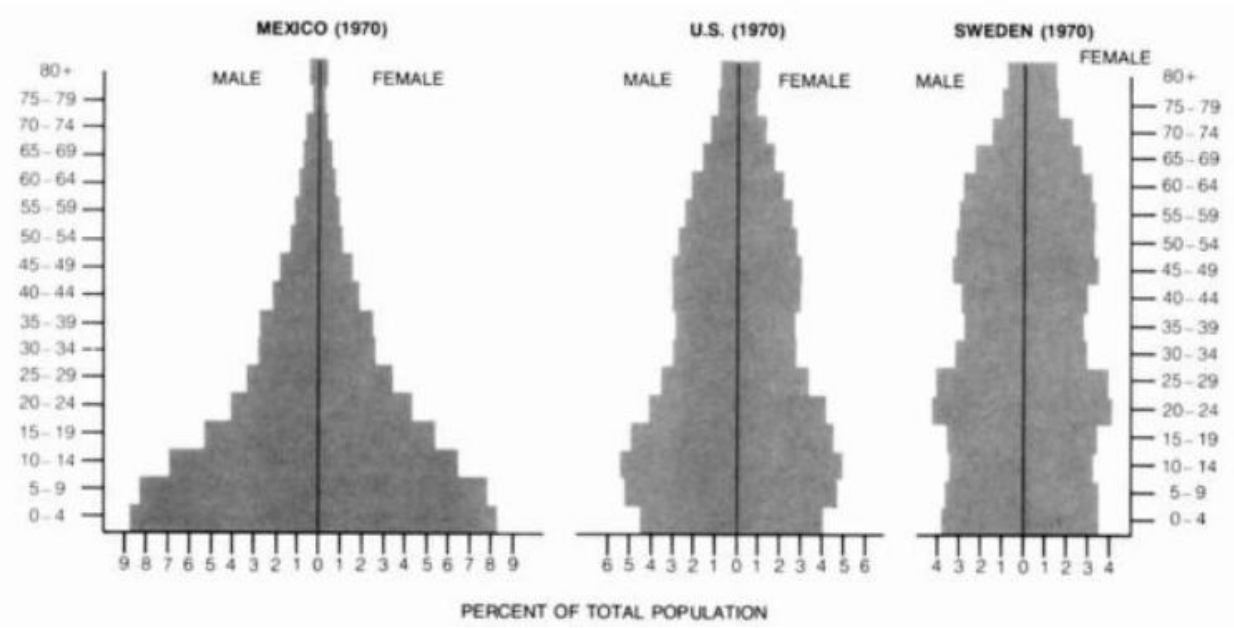

FIGURE 5-10

The age structure of a population is profoundly affected by changing fertility. In a country like Mexico, with a recent history of high fertility, the age structure is pyramidal. In a country like Sweden, with a recent history of low fertility, the structure is quite rectangular up to age 60. The U.S. age structure lies between the two extremes. (Adapted from Freedman and Berelson, 1974.)

Population profiles are a graphic means of showing the age composition of a population--that is, the relative numbers of people in different age classes. Look, for instance, at the age compositions of the populations of Mexico, the United States, and Sweden in 1970, as shown in Figure 5-10. Because the profiles are based on proportions, they all have the same area, despite great differences in the absolute sizes of those populations. This allows you to focus easily on their shapes, which of course reflect the different age compositions. Mexico's profile exemplifies rapidly growing countries with high birth rates and declining death rates. Most of its people are young (48 percent are under age 15). Sweden, however, has had low birth and death rates for many decades. It has a much slenderer population profile than Mexico. Only 21 percent of the people of Sweden are under age 15. The irregular profile exhibited by the United States reflects relatively large fluctuations in the birth rate over the past fifty years, particularly the baby boom of the late 1940s and the 1950s. The recent decline in American fertility is apparent in the constriction at the pyramid's base--the smaller numbers in the 1--4 and 5--9 age classes. The percentage of persons under age 15 was 27 in the mid-1970s, a somewhat higher percentage than in Sweden.

In Mexico--and most LDCs--high birth rates and increasing control over mortality (especially infants and children) have greatly inflated the younger age groups in the population since World

War II. There has not yet been time for individuals born in the period of death control to reach the older age classes, whose death rates are higher than those of the younger age classes. In most LDCs the greatest declines in death rates among infants and children occurred in the late 1940s, and the large numbers of children born in that period began to reach their peak reproductive years in the late 1960s. Their children in turn are further inflating the lower tiers of the population pyramid.

Eventually, of course, either population control will reduce birth rates in those countries, or famine or other natural checks on population will once again increase mortality in the youngest age classes--or, possibly, in all

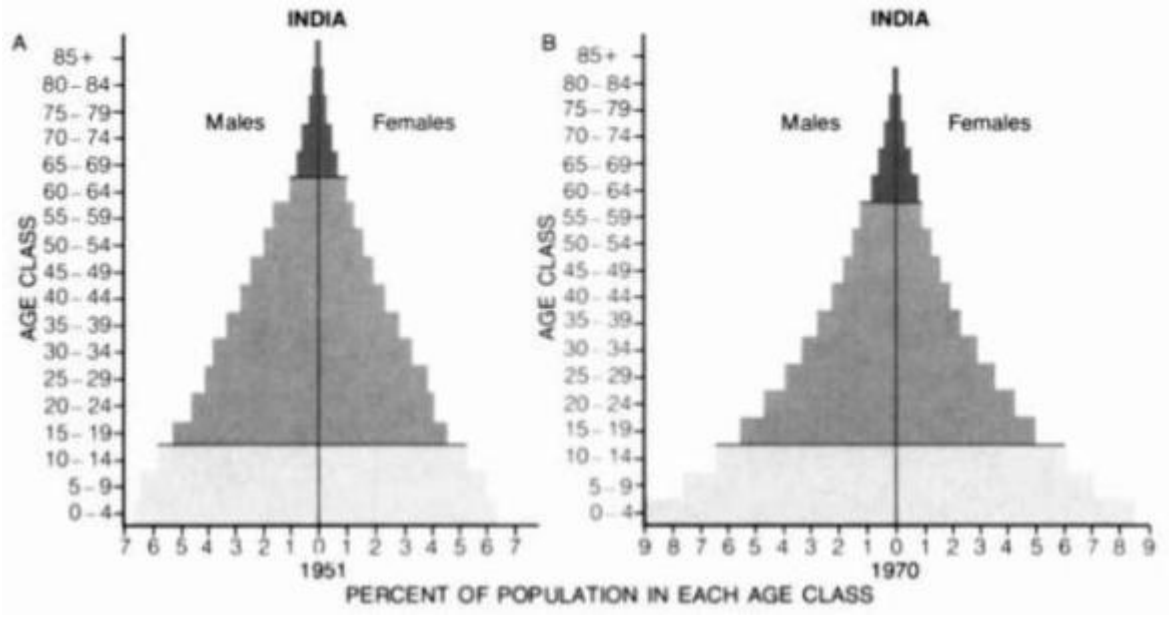

FIGURE 5-11

A. Age composition of the population of India in 1951. Declining death rates had not yet produced the pinched profile characteristic of rapidly growing LDCs like Mexico. (Adapted from Thompson and Lewis, 1965.) B. Age composition of the population of India in 1970; the profile then resembled a typical LDC. (After *Population bulletin*, vol. 26, no. 5, Nov 1970. FIGURE 5-12
Dependency loads in Mauritius (1959), India (1951), Japan (1960), the United States (1960), and the United Kingdom (1959). Note the contrast in proportions of economically active people in a typical LDC, Mauritius, and a typical DC, the United Kingdom. (Adapted from *Population bulletin*, vol. 18, no. 5, courtesy Population Reference Bureau, Washington, D.C.; and Thompson and Lewis, *Population problems*, 1965.)

age classes. If birth rates are lowered, eventually there will also be rises in the death rate as the populations age and the older age classes with higher age-specific death rates become proportionately larger.

In the absence of both birth control and natural checks, however, death rates in the extraordinarily young populations of the LDCs may temporarily fall below those of the DCs. For instance, in the early 1970s the death rate in the United Kingdom was 11.7 per 1000; in Sweden, 10.5; in Belgium, 11.2; and in the United States, 9.4. In contrast, the death rate in Costa Rica was 5.9; in Mexico, 8.6; in Trinidad, 5.9; in Sri Lanka, 6.4; in Singapore, 5.2; and in Hong Kong, 5.5.

[43] The low death rates are a product of the age composition of the populations in those places. They do not, for instance, necessarily reflect a better level of medical care or longer life expectancy.

One additional profile shape is common: the triangle characteristic of countries that have both high birth rates and high death rates. Such profiles must have typified most human populations until fairly recently. They lack the extremely broad base of profiles like that of Mexico (Figure 5-10) and most other LDCs today. India's profile was essentially triangular in 1951 (Figure 5-11). Since then, India's death rate has dropped by about 10 per 1000, and the base of the profile has broadened to produce the "pinched triangle" shape of other LDCs.

One of the most significant features of the age composition of a population is the proportion of people who are economically productive to those who are dependent on them. For convenience, the segment of the population in the age class 15-64 is chosen as an index of the productive portion of a population (Figure 5-12). Figures 5-10, 5-11, and 5-12 provide a comparison of the proportion of dependents in the populations we have been considering. The proportion of dependents in LDCs is generally much higher than in the DCs, primarily because such a large fraction of the population is under 15 years of age. Thus, the ratio of dependents to the total population is higher in the poor countries and lower in the rich countries, although the ratio is somewhat misleading because of the greater utilization of child labor in LDCs. This unfortunate dependency ratio is an additional heavy burden to the LDCs as they struggle for economic development (see Box 5-3).

The high percentage of people under 15 years of age in LDCs is also indicative of the explosive potential for growth of their populations. In most LDCs this percentage is 40 to 45; in a few, as high as 50. By contrast, the percentage of persons under age 15 in DCs is usually between 20 and 30. Thus, LDCs have a much greater proportion of people in their prereproductive years. As those young people enter their reproductive years, the childbearing fractions in those populations will increase greatly. In turn, their children will further inflate the youngest age groups. These masses of young people in the LDCs are the gunpowder of the population explosion.

Birth, death, and fertility rates. The birth and death rates used thus far, which are expressed in births and deaths per 1000 in a population per year, are called by demographers *crude birth rates* and *crude death rates*. They are called crude because they do not contain information about differences in the age composition of populations. They are simply estimates of b and d (Chapter 4); and the difference between them (b -- $d = r$) is the annual growth rate. Crude birth rates and death rates are the most readily available *demographic statistics* (and thus most widely quoted), but although they are often quite useful, comparison of crude rates can be misleading.

An outstanding example of this was the highly publicized decline in the birth rate of the United States during the 1960s, which was widely misinterpreted as heralding the end of the United States population explosion. The birth rate in 1968 was 17.4 per 1000, a record low for the country-below the previous low of the Depression year 1936. (The trend in birth rates between 1910 and 1973 is shown in Figure 5-13.) Between 1959 and 1968 the crude birth rate declined about 25 percent. Closer examination of the data, however, shows that the decrease was caused only in part by a drop in the number of children born to the average couple. Some of the decrease

was because a smaller percentage of the population was in the childbearing years. The relevant demographic statistic here is the *general fertility rate*.

[43]Population Reference Bureau, Inc., *1975 Population data sheet*.

BOX 5-3 Mauritius, Children, and the Dependency Load

Mauritius, one of the Mascarene Islands in the Indian Ocean, has one particular claim to fame--it was once the home of the now-extinct dodo, a flightless bird larger than a turkey. But Mauritius also presents another case history in population biology--this one concerning *Homo sapiens*. By 1969 more than 800,000 people were jammed onto the island--more than 440 per square kilometer--and the population had a growth rate of 2 percent a year. The story of Mauritius' population growth after World War II is similar to that of other less developed countries, and the result by around 1960 was a dependency load of 47 percent. That is, 47 percent of the population was either younger than 15 (44 percent) or older than 65 (3 percent). Although the proportion under 15 had by 1975 been reduced to about 40 percent (the growth rate had dropped to 1.7 percent), the society is still faced with a tremendous burden in the form of vast numbers of children who are nonproductive, or relatively unproductive.*

The huge proportion of young people in the population has put a tremendous strain on the Mauritius school system. Many primary schools had to go on double shifts during the 1960s, and an extreme shortage of teachers developed. In order to staff the schools, teachers had to be put in charge of classes before they completed their training. Most of the country's educational effort went into primary schools; in 1962 only I out of 7 elementary-school students went on to high school.

The education problem in Mauritius is a good example of what demographer Kingsley Davis meant when he said that children "are the principal victims of improvident reproduction." Many LDCs cannot afford to educate their children adequately--in part, because of a more urgent need for using their limited funds for public health and welfare. After the first five years of life, children in the LDCs enter the age class that has the lowest mortality rates. Those children desperately need education--for their own good and for the future of their societies-but the sorry fact is that in the absence of population control, solving health problems in LDCs like Mauritius makes solving the education problem extremely difficult.

High fertility and low income also tend to force children out of school and into the labor pool as early as possible. Even the chances for education in the home are reduced when families are large and mothers overburdened. Child labor is used at a very high level in less developed countries, although the productivity of that labor may be quite low. United Nations statistics, which may understate the case, show that 31 percent of males between 10 and 14 years of age are economically active in LDCs, in contrast to only 5 percent in DCs.

It is a brutal irony that children thus must bear the brunt of the population explosion. Commenting on the complacency with which many of the rich formerly regarded the plight of

the poor, Davis wrote, "the old philosophy that [the children's] coming is a just and divine punishment for their parents' sexual indulgence, and therefore not to be mitigated by deliberate control is one of the cruelest doctrines ever devised by a species noted for its cruel and crazy notions."

Most of the information here is from Kingsley Davis, The population impact on children in the world's agrarian countries.

The general fertility rate (the number of births per 1000 women 15 to 44 years old) is a more refined indicator of birth trends because it compensates for differences in sex ratio (which may be the result of wars or migration of workers) and for gross differences in age composition. Differences in age composition would be revealed if two populations had identical crude birth rates but widely differing fertility rates. This could mean, for instance, that one had a relatively small proportion of people 15 to 44 years old and a high fertility rate, whereas the other had a relatively high proportion in the 15 to 44 age group and a lower fertility rate.

As is shown in Figure 5-14, the fertility rate in the United States was declining along with the birth rate during the period between 1959 and 1968. Thus, not only were fewer babies being born in proportion to the entire population than during the 1950s, but fewer babies were being born in relation to the population of females in

BOX 5-4 Stable Population Models

A stable population is one in which vital rates (fertility and mortality) and age composition remain constant. The population itself may be growing or shrinking, either slowly or rapidly, or its size may be stationary. The models shown in Table 5-7 represent two stationary and five growing populations resembling actual populations that exist today or that may have existed in the past. The resemblance, of course, is only general; the models are hypothetical projections of demographic factors and trends. But they are helpful for seeing how those factors and trends are related.

Model 1, for instance, is thought to be similar to early, preagricultural populations. Recent research suggests that both fertility and mortality may have been slightly lower than shown here, but in other respects the model probably fits reasonably well. * Early human populations are believed to have been close to stationary, as Model 1 is. They grew only very slowly over many thousands of years -- no doubt, with many short-term fluctuations above and below the no-growth level.

Model 2 represents an agricultural population with high birth rates and mortality somewhat lower than primitive levels. If western Europe during the Industrial Revolution had maintained constant vital rates at these levels for a lifetime, the population structure would have resembled this model. Earlier favorable periods in history, such as the heyday of the Roman Empire and Japan before the Meiji Restoration, may have seen life expectancies and vital rates approaching those of Model 2. Less developed countries in the twentieth century also had similar vital rates as modern death control was introduced, but for them this stage was even more transient than it was for industrializing Europe. Demographic stability was clearly never achieved by those LDC populations.

By the 1970s mortality in most LDCs was much lower, and life expectancies and mortality rates resembling those in both Model 3 and Model 4 could be found among them. Life expectancy in India, Bangladesh, and several African countries, for example, was around 50 (Model 3). In some LDCs, on the other hand, life expectancy was approaching 70, a level typical of developed countries. Among those are Singapore, Hong Kong, Taiwan, and several Latin American countries. Many of these countries still have high birth rates and are growing very rapidly, as in Model 4.

The last three models are intended to represent developed countries that have experienced a demographic transition and have high life expectancies and low mortalities and fertilities. A few European countries have had low fertility long enough that their populations resemble Model 5 fairly closely. A life expectancy of 74.8 years, shown in Model 6 and Model 7, is postulated as the highest attainable under optimum conditions with present or foreseeable medical technology. Given this life expectancy, replacement fertility is 2.08 children per woman, and both the crude birth rate and the crude death rate would be 13.4 once stability was achieved. This is the situation in Model 7, a stable, stationary population with low fertility and mortality.

their childbearing years. Yet, the 1968 fertility rate of about 85, unlike the crude birth rate, was still higher than the lows reached during the Depression (when the figure was well below 80) and the population was still growing at about 1 percent per year.

In 1970 the fertility rate began to rise, reflecting a rising proportion of women in their twenties (the prime reproductive years). The rise was brief, however; by the end of 1974 the fertility rate in the United States had dropped precipitously to 68.4. Moreover, this did not reflect a change in age composition but, rather, a significant change in reproductive behavior. For the first time in history, fertility in the United States had dropped *below replacement level* -- below a net reproductive rate of 1. (The NRR at the end of 1974 was 0.9.)

Momentum of Population Growth

Let us review for a moment some of the basic population dynamics discussed in Chapter 4. If age-

TABLE 5-7
Models of Stable Populations

		High-fertility models			Low-fertility models		
Feature	**Model 1**	**Model 2**	**Model 3**	**Model 4**	**Model 5**	**Model 6**	**Model 7**
LEVELS OF FERTILITY AND MORTALITY, INDEPENDENT OF AGE COMPOSITION							
Children born per woman	6.0 [a]	6.0	6.0	6.0	2.5	2.5	2.08 [a]

Feature	Model 1	High-fertility models Model 2	Model 3	Model 4	Low-fertility models Model 5	Model 6	Model 7
(total fertility)							
Life expectancy (years) [b]	21.3 [c]	30.0	50.0	70.0	70.0	74.8	74.8 [c]
CRUDE VITAL RATES, AS AFFECTED BY ACTUAL AGE COMPOSITION							
Births per 1000 population	47.1	46.2	43.1	41.4	17.3	16.8	13.4
Deaths per 1000 population	47.1	34.1	15.5	4.9	12.1	10.7	13.4
Rate of natural increase per 1000	0.0	12.1	27.6	36.5	5.2	6.1	0.0
Infant mortality per 1000 births	361.2	264.9	121.1	28.8	28.8	13.4	13.4
Doubling time (years)	never	57.0	25.0	19.0	133.0	114.0	never
AGE COMPOSITION (% TOTAL POPULATION)							
All ages	100.0	100.0	100.0	100.0	100.0	100.0	100.0
Ages 0-14	35.2	39.3	43.7	46.1	24.0	23.7	19.7
Ages 15-64	61.8	57.9	53.5	51.1	63.8	62.8	63.4
Ages 65 years and older	3.0	2.8	2.8	3.0	12.2	13.5	16.9
Dependency ratio [d]	62.0	75.0	87.0	97.0	57.0	59.0	58.0
Median age (years) [e]	23.2	20.3	18.0	16.9	33.0	34.7	38.2

[a]That level of fertility that, at the given mortality, ensures exact replacement (NRR = 1).

[b]For both sexes combined.

[c]That level of mortality that, at the given fertility, ensures exact replacement.

[d]Numbers aged 0-14 and 65 and over per 100 aged 15-64.

[e]Age so determined that half the population is below and half is above that age.

Source: United Nations, *Concise report*.

Certain interesting relationships emerge from a comparison of the models. For instance, the birth rate drops steadily between Models 1 and 4, although the fertility per woman remains the same. The reason is changing age compositions. Lower mortality results in higher survival rates among infants and children and thus increases the proportion of people younger than the childbearing ages. In a population with high fertility, indeed, the crude death rate can fall to a much lower level than in a low-fertility population because the proportion of old people with high age-specific death rates (even with the best medical care) is very small.

specific vital rates (birth and death) remain constant, the age composition of a population eventually becomes stable, a situation in which the proportion of people in each age class does not change through time. A population with a stable age composition can be growing, shrinking, or constant in size. Box 5-4 shows a series of stable population models in which the reciprocal influences of vital rates and age compositions can be seen. Five of the models represent growing populations; two represent populations that are constant in size.

When a population is constant in size (the crude birth rate equals the crude death rate), demographers refer to it as *stationary*. Colloquially, one says that zero population growth (ZPG) has been achieved. Replacement reproduction means that each married couple, on the average, is having just the number of children that will lead to the parents' replacement in the next generation: NRR = 1. (For a full explanation of NRR, refer to Chapter 4.) Where death rates are at typical DC levels, this is about 2.11 children per woman. The extra 0.11 child per

woman compensates for prereproductive mortality, nonmarriage, and infertility in that generation.

The NRR (R_0) of a human population is the ratio of the number of women in one generation to that in the next. It is calculated by applying the age-specific birth and death rates of the population at a given time to a hypothetical group of 1000 newborn female babies, determining how many live female babies those females would themselves produce, and dividing that number by 1000.

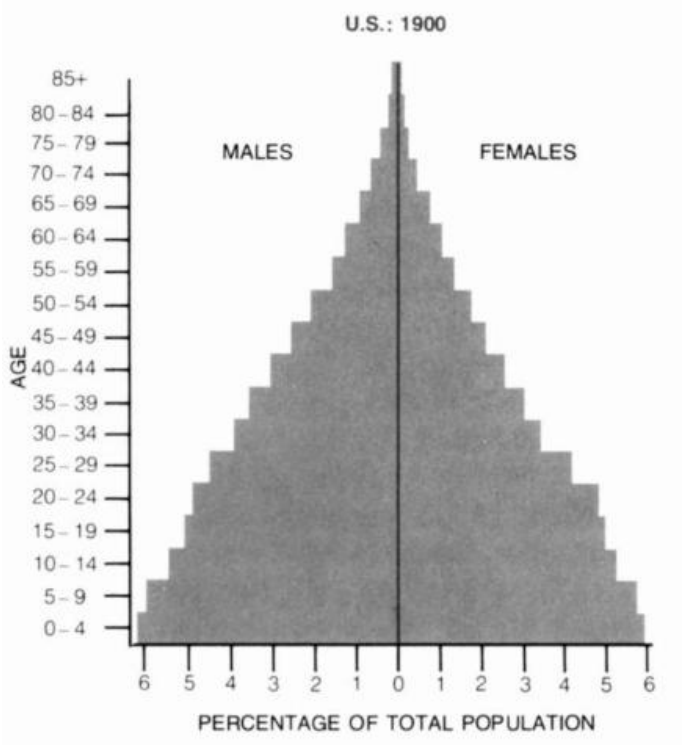
If the average completed family size of a population with typical DC death rates is three children, the NRR will be about 1.3. An NRR of 1.3 means that, barring changes in birth and death rates and assuming a stable age composition, the population will grow 30 percent *per generation* (a generation is usually about 25 to 30 years). As long as the NRR is more than 1, such a population will continue to grow. An NRR of 1 (fertility at replacement level) indicates either a stationary population or one that will become stationary after time has allowed the age composition to stabilize. If the NRR drops below 1 and stays there, the population will shrink sooner or later (how soon depends on the initial age composition).

Note that the NRR describes what the relative sizes of *consecutive generations* will be if the age-specific vital rates (death and fertility) remain constant at the values they had when the NRR was calculated. Even if those rates (and thus the NRR) do not change, the age composition of the population must be known in order for population projections to be made, since *Homo sapiens* has overlapping generations.

Population momentum in the United States. The drop in American fertility to below replacement level between 1972 and 1975 was popularly interpreted to mean that zero population growth (ZPG) had been achieved in the United States. But growth certainly had not stopped (natural increase in 1975 was 5.8 per 1000; immigration brought the growth rate to about 8 per 1000). Nor will it stop until the crude birth rate is balanced by the crude death rate (and immigration is balanced by emigration). Because of the age composition of the population, if replacement reproduction (NRR = 1) were exactly maintained for about seventy years (one lifetime), *then* natural increase would cease. Population growth has *momentum* -- growth does not stop instantaneously when each couple, on the average, just replaces itself.

If low fertility were maintained long enough, the age composition would change in response, and the median age of the United States population would gradually rise from about 28 (in 1975) to 37. The rising proportion of older people in the population would result in higher death rates; and

because there would be proportionally fewer young people reproducing, the crude birth rate would decline slowly. Eventually the birth rate and the death rate (in 1975 about 14.8 and 9.0, respectively) [43a] would converge at about 13 per 1000. Past and projected changes in the age composition of the United States population from 1900, when the population was growing rapidly, to an ultimate stationary population (assuming continued replacement fertility) are presented graphically in Figure 5-15.



If the United States population maintained the below-replacement-level fertility of 1973 to 1976 (NRR = 0.9), growth would end by the year 2025 with a peak population of about 252 million (even if present legal immigration rates continued). [44] After that the population would gradually decline in size.

It is impossible to say at this point, however, whether the low fertility figures for the early 1970s signal the beginning of a sustained trend or whether they are merely examples of the short-term ups and downs that for the past few decades have confounded the demographers and economists who have tried to explain these things. Many factors can influence birth rates in addition to the number of women in their childbearing years. Severe economic conditions, epidemics, and wars may cause declines in birth rates. For instance, the shipment of young men overseas during World War I and the great influenza epidemic of 1918 together led to a drop in the United States birth rate from 28.2 in 1918 to 26.1 in

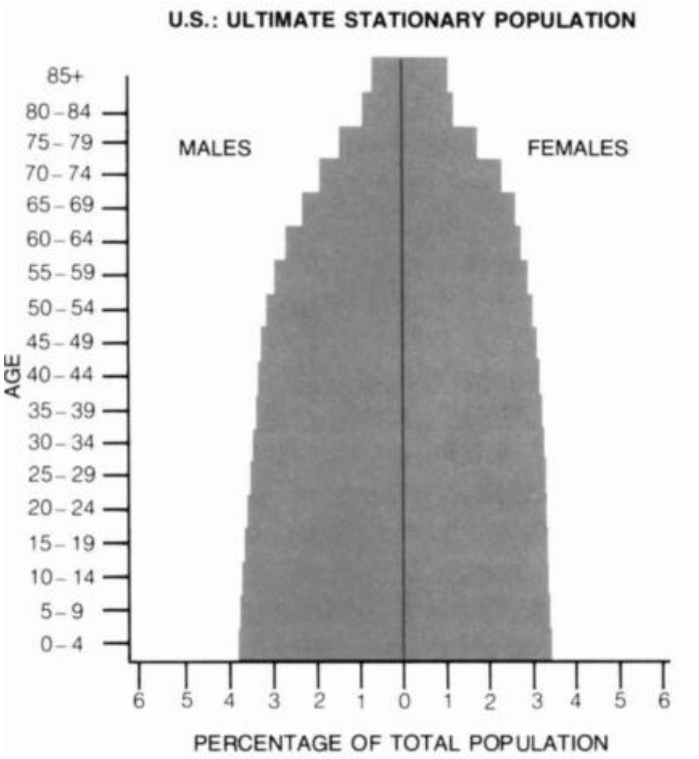

FIGURE 5-15 A. The U.S. population in 1900 had the age composition represented by this pyramid. Its triangular shape, strikingly similar to that of India in 1951 (Figure 5-11), is characteristic of a fast-growing population with high birth and death rates, where the average life

expectancy is less than 60 years. A third of Americans were then under 15 years of age. B. The U.S. population of 1970 gave rise to a pyramid whose sides were pinched in because of the low birth rates that prevailed during the years of the Great Depression. The bulge centered on the 10-to-14-year-old age group is a consequence of the postwar baby boom. C. The U.S. population of the year 2000 will form this age pyramid if fertility stabilizes at replacement levels from now until the end of the century. Five-to-19-year-olds of 1970, who will then be 30 years older, will have produced a second bulge of 5-to-19-year-olds. D. An ultimate stationary population, if it is achieved in the United States during the next century, will have the age composition shown here. A third of the population will be less than 25 years of age, a third will be between 25 and 50, and another third will be over 50. (Adapted from Westoff, 1974.)

1919. Similarly, low birth rates in the United States and Europe in the 1930s have been attributed -- perhaps somewhat erroneously -- to the economic hardships of the Depression. [45] And improvements in economic conditions and the return of servicemen after World War II led the birth rate in the United States to jump from 20.4 in 1945 to 26.6 in 1947.

The present low fertility rate in the United States may result from a combination of social forces now at work in our society: rising public awareness of the consequences of overpopulation, the growth of the women's liberation movement, the extension of family-planning services to low-income groups, and the legalization of abortion. (See Chapter 13 for more discussion of these social influences.) If these are the most important influences on reproduction in the United States, consistently low fertility may continue into the future. If, on the other hand, fertility is determined by economic factors such as the unemployment rate among prospective fathers, then, as economic conditions improve, fertility may rise again and continue to fluctuate over the long term thereafter.

From statistics on births over the past four decades, it is known that the number of women in the 15 to 44 age class in the United States has been increasing and will continue to increase throughout the 1970s (by 12 percent between 1974 and 1980). Moreover, the age 20 to 29 subgroup, whose members bear most of the children, is increasing even faster. It will grow by about 14 percent between 1974 and 1980 and will not reach a peak until after 1980. [46] Therefore, unless fertility in the age 20 to 29 cohort falls considerably below its 1974 level, both the crude birth rate and the general fertility rate in the United States*can be expected to rise during the late 1970s and early 1980s*.

Some evidence is emerging that the extremely low fertility recorded in the early 1970s was in part a result of later marriage and postponed childbearing among young women, combined with a reduction of fertility among women over 30, most of whom had married and started their families at relatively younger ages. Although the marriage rate has been dropping and rates of divorce and separation have risen steadily, by 1975 there was a large pool of young married women -- one-third of all evermarried women younger than 30 -- who had not borne children (in 1960 the proportion was about 20 percent). Demographers J. Sklar and B. Berkov speculated that that age group was likely to start its postponed childbearing in the late 1970s, causing a significant rise in the national birth rate by 1977. [47]

The U.S. National Fertility Survey conducted by the Bureau of the Census in 1974 indicated that 84 percent of all currently childless wives under 30 years old anticipated having one or more children, but among those over 25 the percentage dropped to 73. [48] Since other surveys have shown an aversion among Americans to having one-child families, [49] the further assumption is made that most of those women eventually will bear at least two children.

Sklar and Berkov may be right. A burst of postponed births among married women around the age of 30 could cause a rise in the birth rate and in the general fertility rate between 1975 and 1985. But by late 1976 there was no evidence of such a rise (fertility, indeed, declined further in early 1976). And what really counts in the long run is completed family size (the average number of children per woman, sometimes called total fertility). The 1974 Fertility Survey indicated a strong trend toward the two-child family, especially among younger women (Table 5-8). Wives aged 25 to 29 in 1974 expected an average total of about 2.3 children, and those 18 to 24 expected only 2.17 (approximately replacement level). If their expectations are realized and if the trend continues with younger cohorts, the population is on its way to ZPG, regardless of temporary fluctuations in the birth rate caused by differences in age composition and the timing of births.

Demographer Thomas Frejka, using 1965 as a base year, showed what could happen to the United States

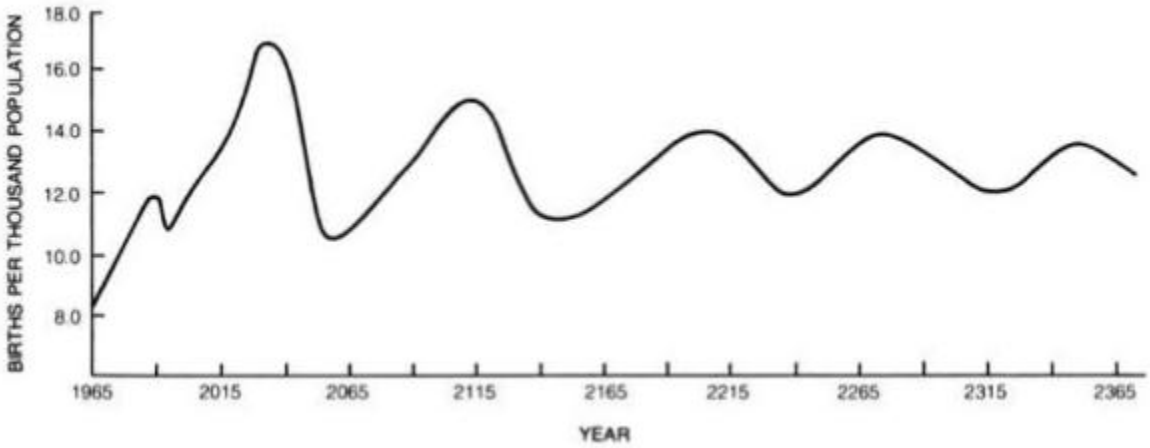

FIGURE 5-16
Projection of changes in the crude birth rate that would be necessary if the total population of the United States were to remain constant during the period from 1965 to 2365. (Adapted from Frejka, 1968.)

population under a variety of assumptions. [50] For instance, instant ZPG (a stationary population) could be achieved only by reducing the NRR to slightly below 0.6, with an average of about 1.2 children per family, between 1965 and 1985. Thus, to bring the crude birth and death rates immediately into balance (so the growth rate was 0), the average completed family size would have to drop far below the replacement level that would *eventually* lead to such a balance. After that, in order to hold the population size constant, the crude birth rate and NRR would have to oscillate wildly above and below the eventual equilibrium values for several centuries (see Figure 5-16). The age composition would correspondingly change violently, undoubtedly having a variety of serious social consequences.

The problems caused by great fluctuations in the birth rate and irregularities in the age composition could be avoided by maintaining the 1975 level of fertility (slightly below replacement). This would produce further growth, but at a slackening rate. Disregarding immigration, growth would end in about fifty years with a peak population of about 252 million, and then there would be a slow decline. Accepting some further growth followed by a period of negative population growth

[50] Reflections on the demographic conditions needed to establish a U.S. stationary population

growth.

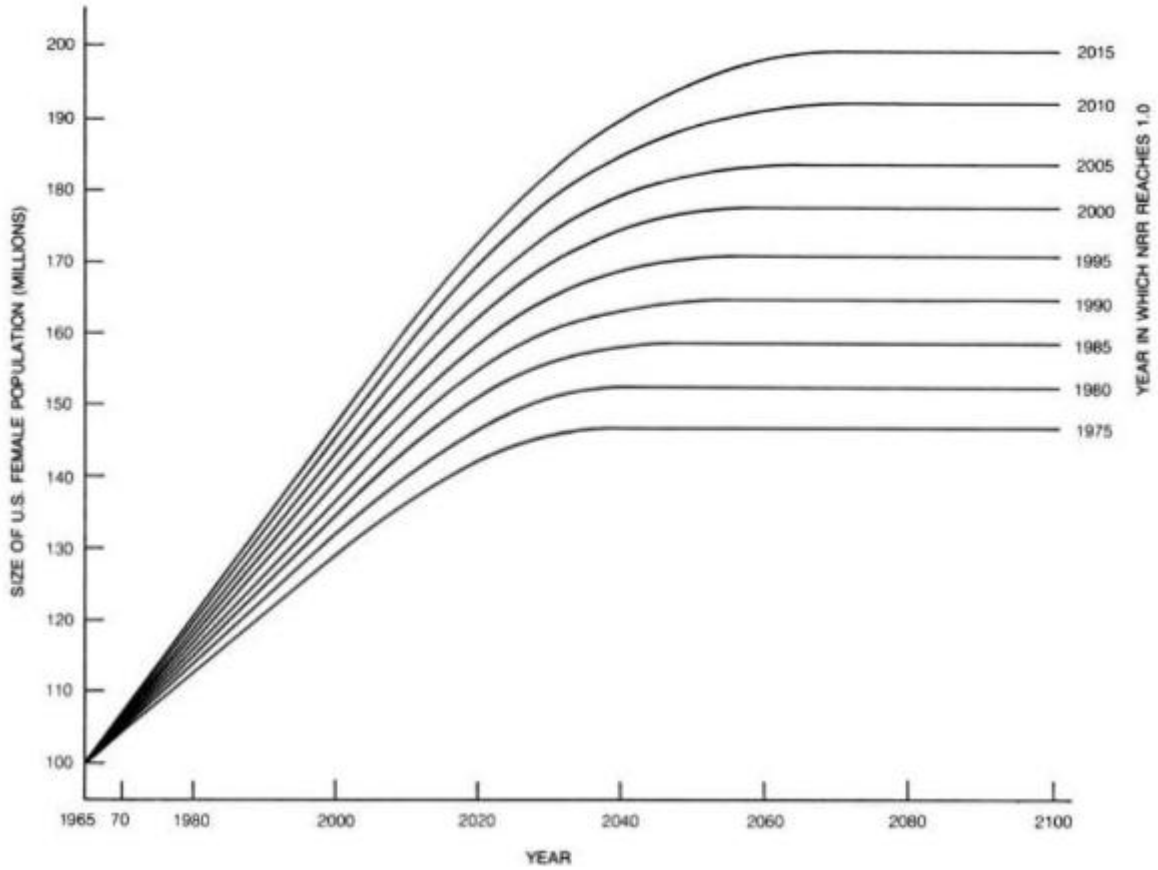

FIGURE 5-17 Projections of the course of population growth in the United States if the NRR reached 1 in various years. The total population size would be slightly less than twice the size of the female population, since there are slightly fewer men than women. (Adapted from Frejka, 1968.)

(NPG, *r* negative rather than attempting to hold the population precisely at ZPG, would seem to be much less disruptive. And, as we discuss throughout this book, there are powerful arguments for reducing the size of the United States population well below its *present* level (to say nothing of any projected future peak).

Frejka also described what would happen if the NRR declined from the 1965 level of about 1.3 to 1 in a series of years starting with 1975 (assuming there was no immigration). The projections in Figure 5-17 clearly indicate that substantial population growth would occur after a pattern of replacement reproduction was established, no matter when that might be. For instance, if an NRR of 1 had been reached in 1985 and maintained exactly, the population would not have stopped growing until 2055, and the ultimate population would have been around 300 million (slightly less than twice the female population size shown in the figure). If the NRR of 1 reached by 1973 were more-or-less precisely maintained, the population would still grow to at least 280 million, not stopping before the year 2035. Of course, the ultimate number of people would be

much higher if the NRR rose again above 1 for any significant length of time, and it would be lower if it remained below 1.

Reflecting the dropping fertility rate since the late 1950s and a rising public consciousness of population

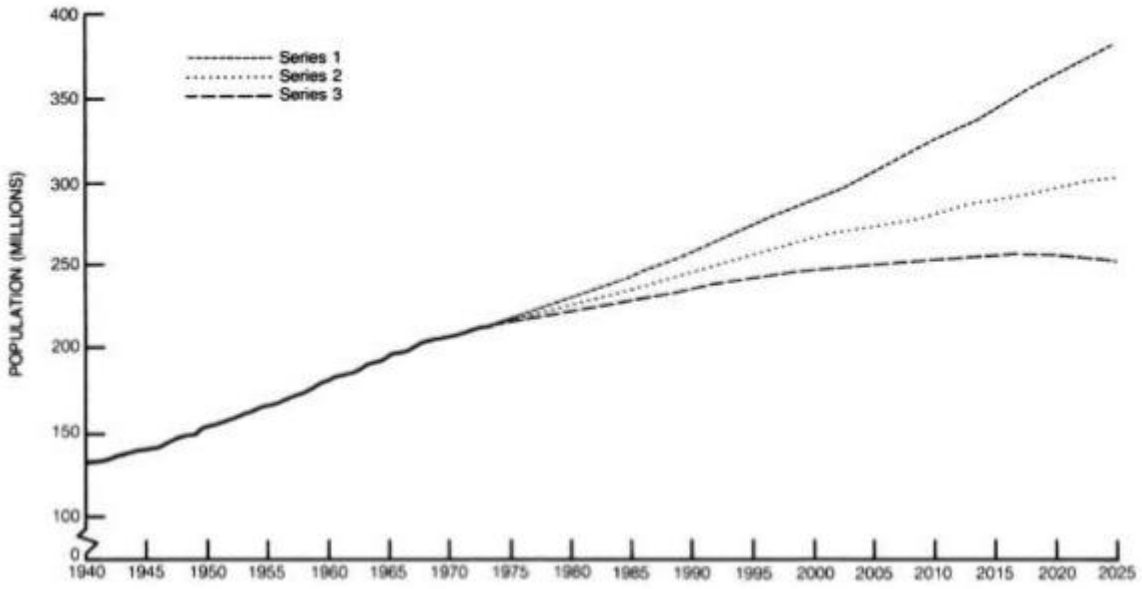

FIGURE 5-18 Estimates and projections of the population of the United States, 1940-2025. (U.S. Bureau of the Census.)

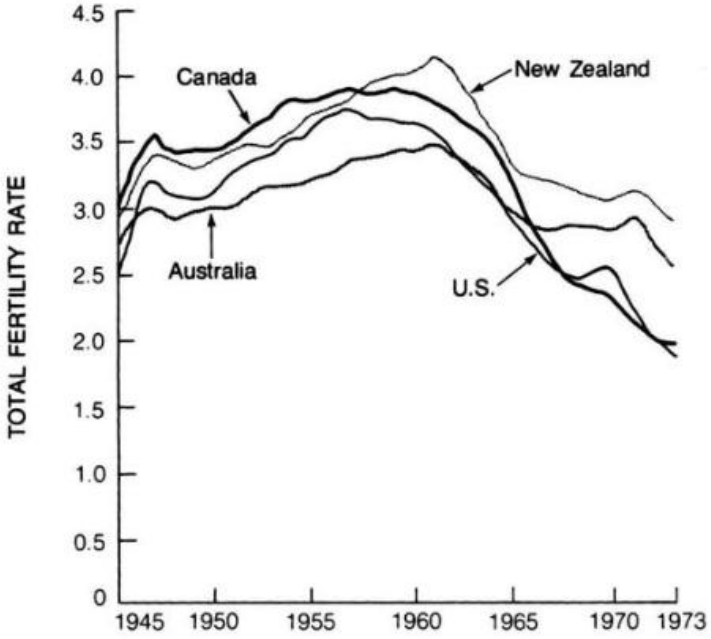
growth, the Bureau of the Census has periodically issued revised projections of U.S. population growth, each a little lower than the last. Since 1970, the bureau has given at least one alternative projection each time that was based on the attainment of replacement fertility in the 1970s, with slight fluctuations around that point between 1970 and 2000 to compensate for age composition differences. Projections issued in 1975 [51] ranged between 245 million and 287 million for the year 2000 (Figure 5-18). All three projections in 1975 assumed continued net immigration (legal) at present levels (400,000 per year) and slight reductions in mortality. Fertility assumptions, however, differed: Series I assumed a completed fertility of 2.7 children per woman (as in the early 1960s), Series II assumed a completed fertility of 2.1 (approximately replacement), Series III assumed a completed fertility of 1.7. Series II (if immigration were ended) would ultimately result in a stationary population around the middle of the twenty-first century. Series III would result in a peak population of about 252 million around the year 2020, followed by negative population growth -- a gradual decline.



A fertility picture resembling that of the United States prevails in other developed countries. Figure 5-19 shows fertility trends in many DCs since World War II. Many demographers now believe that what is happening is a consummation of the demographic transition, which will ultimately end in ZPG for those countries. [52] The postwar baby boom, viewed in this perspective, seems to be a temporary reversal of a long-term trend. Indeed, as the figure shows, it was either a

relatively minor zig or else was virtually nonexistent in all DCs except Great Britain's former colonies -- the United States, Canada, Australia, and New Zealand.

[51]Projections of the population of the United States: 1975 to 2050, *Population estimates and projections, current population reports*, series P-25, no. 601 (October 1975). [52]C. F. Westoff, *The populations of the developed countries*.

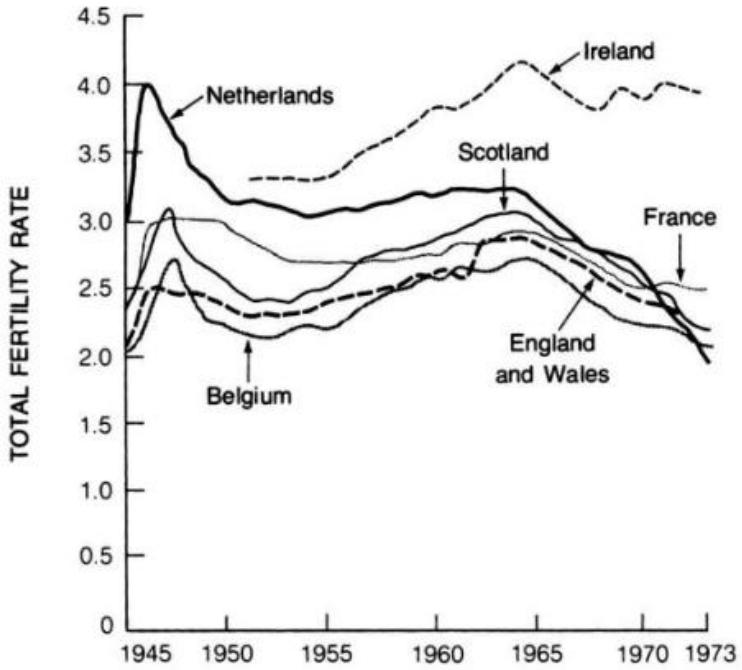
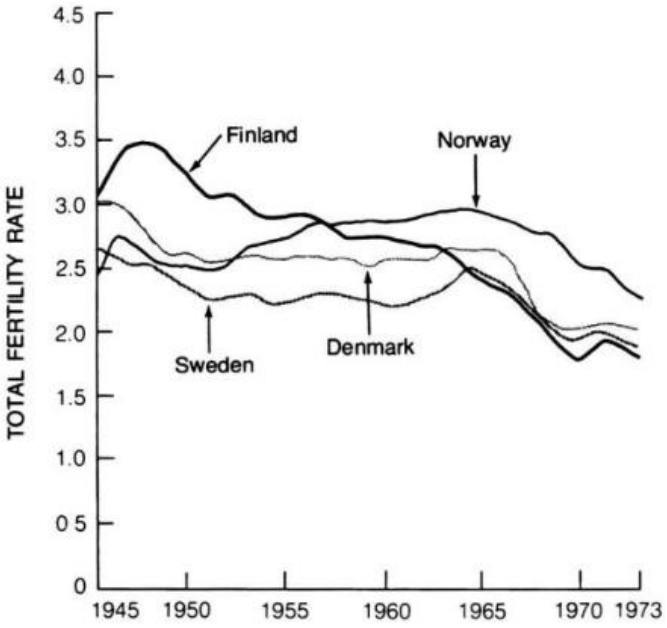
A

B





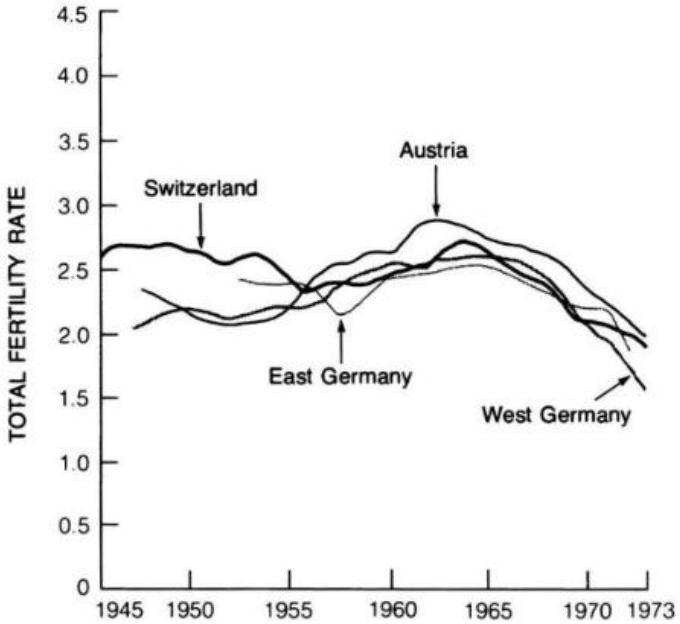


FIGURE 5-19 Fertility since 1945. Total fertility refers to average completed family size. A. Since 1945 the United States has averaged 1.9-3.8 children per family. The postwar baby boom was most pronounced among overseas English-speaking populations (*top*). Sharp declines began in the 1960s. The postwar surge in fertility in Western Europe (*bottom*) was brief. Fertility fell sharply, climbed again slowly, and since the early 1960s has been declining. Fertility in Ireland is quite different, reflecting its unusual demographic past. B. Slow declines in fertility seem to be taking place in Portugal and Italy (*top*). There is no clear trend in Spain or Greece, but data are limited. In the Communist countries of Eastern Europe (*bottom*), fertility has generally been falling, except for a brief, sharp rise in Rumania

C

D

when the abortion law was tightened in 1967. C. Scandinavian countries, except for Sweden, showed only a brief postwar surge in fertility. The decline since then has been sharpest in Finland. Countries of Central Europe have followed a fertility pattern similar to that of Western Europe. West German fertility is now the lowest among all developed countries, and the country has reached zero population growth. D. Two newly developed countries, Japan and Israel, show markedly different fertility patterns. The decrease in Japanese fertility followed the adoption of a liberal abortion law. The curve for Israel applies only to the Jewish population. Fertility of the Arabs in Israel is currently more than twice as high. (Adapted from Westoff, 1974.)

The *total fertility rate* is the average number of children each woman would bear during her lifetime if age-specific fertility remained constant, and a total fertility rate of 2.1 is roughly equal to an NRR of 1 where typical DC death rates prevail. As the figure shows, many European countries have reached replacement fertility, and some have dropped even lower. A few countries with extremely low fertility or relatively high rates of emigration had achieved negative population growth (NPG) by 1975. Among those were East Germany, West Germany, Luxembourg, and the United Kingdom. [53]

In the most highly industrialized countries of Europe, fertility has been at least moderately low for nearly two generations. Relatively little momentum is therefore built into their age compositions. Eastern and southern European countries, the USSR, and especially Japan, on the other hand, have comparatively short histories of low fertility. As in the United States, considerable potential for population growth still exists in those countries.

Population momentum in LDCs. The situation in rapidly-growing less developed countries is radically different, however. The reason for the enormous growth potential inherent in the age composition of most LDCs can be seen by considering their schedules of age-specific vital rates. In those countries, roughly 40 to 50 percent of the populations are less than 15 years old. Those populations of young people will soon be moving into age classes with high age-specific fertility rates, *but it will be some fifty years more before they are subject to the high death rates associated with old age*. Fifty years is about two generations, which means that those youngsters will have children and grandchildren before they swell the upper part of the age pyramid and begin to make heavy contributions to the crude death rate. Therefore, even if the age-specific fertility rates in a population dropped precipitously to a net reproductive rate (NRR; R_0) of 1, ZPG could not be reached for more than fifty years thereafter. You will recall from Chapter 4 that it takes roughly one life expectancy after NRR (R_0,) reaches I before a stable age distribution is reached and growth ends (r equals 0). Hence, *assuming there is no rise in the age-specific death rates*, there must be a long braking time before even very successful birth-control programs can halt growth in those nations. The momentum inherent in their age compositions means that population sizes will expand far beyond the level at which the "brakes" are successfully applied.

Demographer Nathan Keyfitz has calculated the magnitude of that momentum. [54] He demonstrated what would happen if a birth-control miracle were to occur and the average number of children born to each woman in a typical LDC (currently, the average is about six) dropped immediately to the replacement level (perhaps 2.5 children per woman, with present-day LDC death rates). [55] If such replacement reproduction were achieved overnight, a typical LDC would nonetheless continue to grow until it was about 1.6 times its present size.

Should the fertility rate of an LDC drop to replacement level gradually over the next thirty years, however, the final population would be some 2.5 times the present size. These Keyfitz numbers show why it is difficult for many scientists to see how population growth can be brought to a halt by birth-control measures before stresses on social systems or ecosystems bring growth to a halt by raising death rates. Moreover, a drop to replacement level even in thirty years is extremely unlikely to occur in most LDCs. The most optimistic U.N. demographic projections do not foresee such a pattern of fertility decline; but even such a relatively happy outcome would

commit India, for instance, to an ultimate population of some *1.6 billion* people if the Indian NRR reached I around the year 2005.

Tomas Frejka has calculated projected paths toward ZPG in detail for the major regions and many individual countries of the world, assuming attainment of replacement fertility at different times and some decline in death rates from improvements in public health. [56] Figure 5-20 contrasts the amount of momentum built into the populations of developed countries with those of less developed countries.

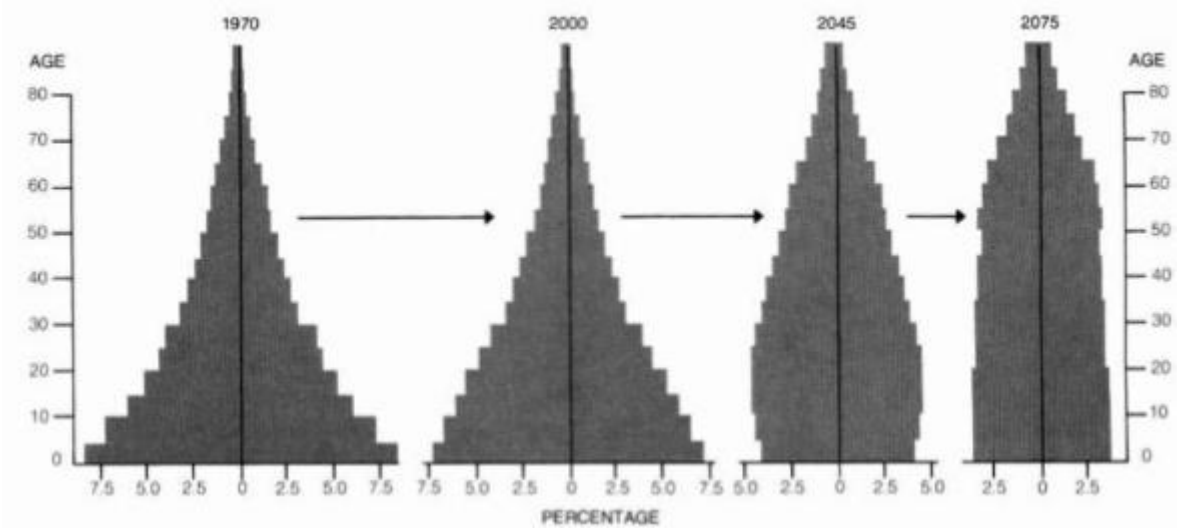
						2000–2005	1.6	3.5



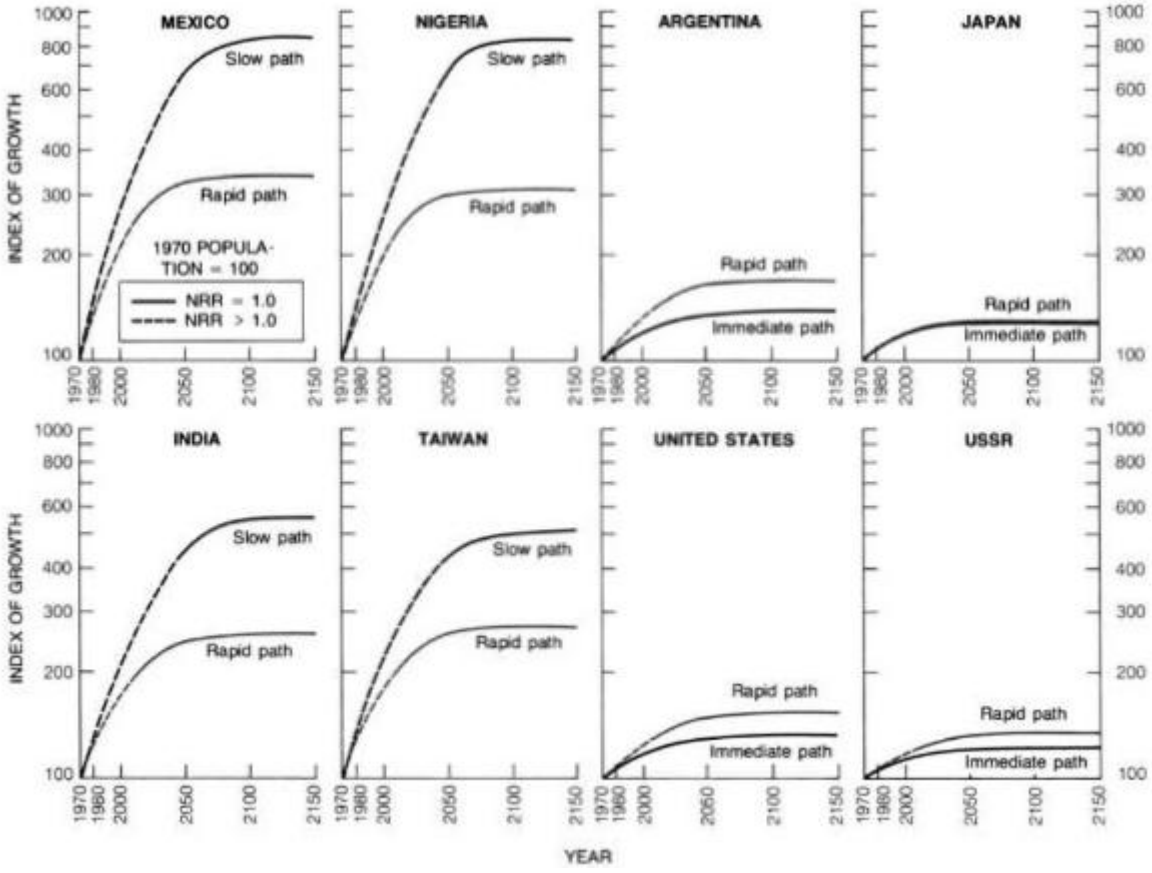


FIGURE 5-21 Age pyramids for India on the slow path to ZPG, 1970-2075. As a population moves toward the nongrowing state, a characteristic age structure emerges. Since the numbers of births and deaths change very little from year to year, all age groups are approximately the same size, although the older groups tend to be smaller because of their higher mortality. (Adapted from Frejka, 1974.)

Frejka's immediate path to ZPG assumes an NRR equal to I starting in the early 1970s. Such a course apparently is now being followed more or less closely in many DCs, including the United States, but is impossible for LDCs, most of which would have to cut their birth rates by more than half overnight to reach it. His rapid path assumes attainment of NRR = 1 by the year 2005. This is not impossible for most LDCs, though it is highly unlikely for many. Under this scenario, the world's population would be nearly 6 billion in the year 2000 and would continue to grow during most of the twenty-first century to at least 8 billion. Frejka's slow path assumes NRR = 1 being reached by about 2045. The slow path would result in a world population of nearly 7 billion by 2000, and an ultimate population of 15 billion, reached sometime in the twenty-second century. Table 5-9 indicates the magnitude of demographic change each path would entail.

A change in fertility obviously would substantially alter the age compositions of now rapidly growing LDCs. The consequences of the slow path for India's population profile are shown in Figure 5-21. Even more radical change would occur -- and more quickly -- if the rapid path were followed.

How the more plausible paths would affect population growth in various individual nations is shown in Figure 5-22. (The actual projected population figures for those and other countries appear in Appendix 1.) Even by the immediate path, the United States population is projected to reach about 280 million, a 36 percent increase after 1970. Contrasting this with the United States Census Bureau projection from the subreplacement fertility rate that prevailed from 1973 to 1976 of a 252-million peak in 2024, [57] it becomes clear what a large difference a very small difference in the fertility rate can make over time. Countries with very high birth rates in

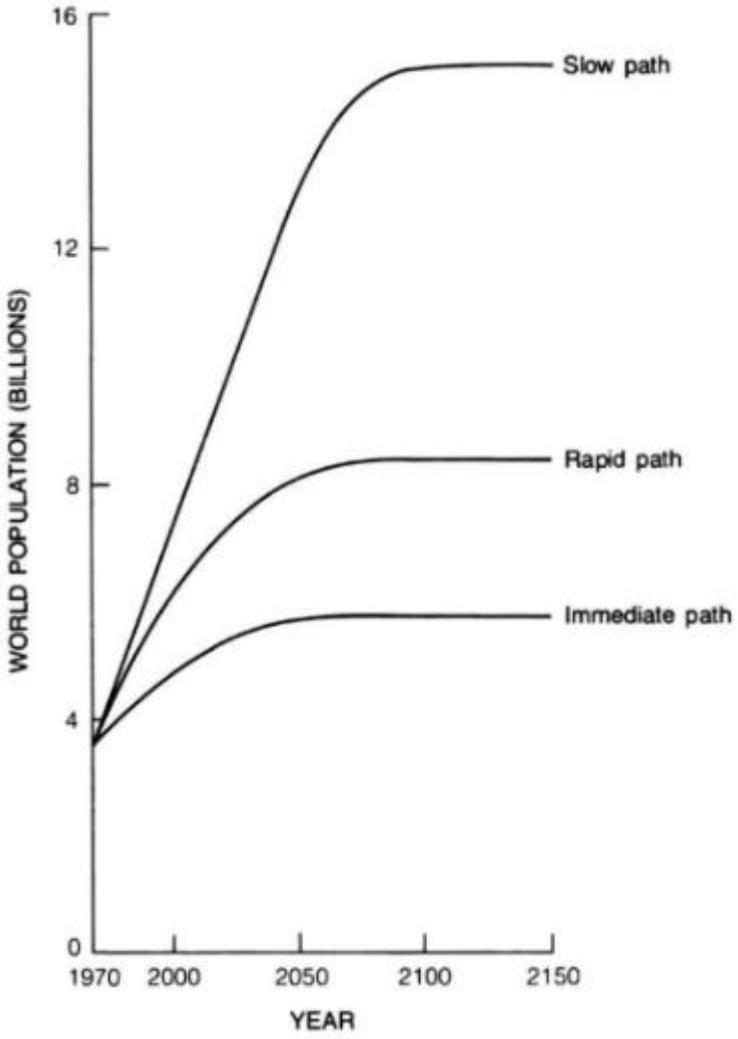

FIGURE 5-23
Population projections are based on three assumptions about when a net reproduction rate of I might be achieved and maintained. Reading from the bottom, the dates are 1970-1975, 2000-2005, and 2040-2045. With an index of 100 for the 1970 population, the indexes under the three projections would rise by the year 2050 to 153, 224, 357, and by the year 2150 to 156, 230, and 426, respectively. (Adapted from Frejka, 1973.)

1970, such as India, Mexico, Nigeria, and even Taiwan (whose birth rate declined significantly during the 1960s), can look forward to multiplying their populations five- to tenfold if they follow the slow path.

Figure 5-23 shows the results of Frejka's projections

FIGURE 5-22 (left) Potential population growth of selected countries by various paths, 1970-2150. The index of growth is the percentage of the 1970 population size. (Adapted from Frejka, 1974.)

on the total world population. It must be emphasized that all of these projections assume an end to population growth through birth control; they do not consider unpredictable discontinuities such as wars and mass famines. Continued growth at high rates like those of the past few decades would lead to preposterously huge populations in a surprisingly short time. Even the essentially impossible immediate path to ZPG (which would require almost halving the birth rate worldwide instantly) commits Earth to a population of nearly 6 billion human beings by 2050. On the more reasonable (but by no means easy) rapid path, the population would soar past 8 billion. The built-in momentum of population growth thus virtually guarantees that the human population cannot be stabilized by means of birth limitation at less than 8 billion people.

United Nations demographic projections. We have examined what is demographically possible in the way of ending population growth by means of birth control, given existing age compositions and mortalities. Now let us consider some likelier future paths of population change. Of primary interest and significance to us are predictions of population sizes during the next century. Such projections have been made by many governmental and private organizations. [58] R. T. Raven-holt

[58] United States Bureau of the Census, *The two-child family and population growth: An international view*.

holt of the Agency for International Development (AID) has made perhaps the most optimistic forecasts (not really detailed projections) we have seen. [59] He claims that family-planning

programs can reduce the average world birth rate below 20 per 1000 and the growth rate to less than I percent by 1985. He postulates a world population of only 5.5 billion by 2000.

Perhaps the most useful available population projections are those made periodically by the United Nations, most recently in 1974 (Figure 5-24). [60] They are not simple extrapolations of past trends or of present rates. Instead, the U.N. projections are computed on the basis of individual components; that is, individual forecasts are made of trends in age-specific fertility, death rates, migration, and so forth. The forecasts are based on the best available demographic data for nations or regions of the world, and the scope of future variation in those rates is estimated on the basis of past trends in developed and less developed areas. Possible major disasters, such as thermonuclear war or massive famines, are not considered, since they cannot be predicted.

All of the data are integrated to produce *medium, low*, and *high* projections, the latter two of which the demographers hope will bracket the actual figures. The accuracy of the projections depends, of course, on how much the realized rates differ from the predicted rates.

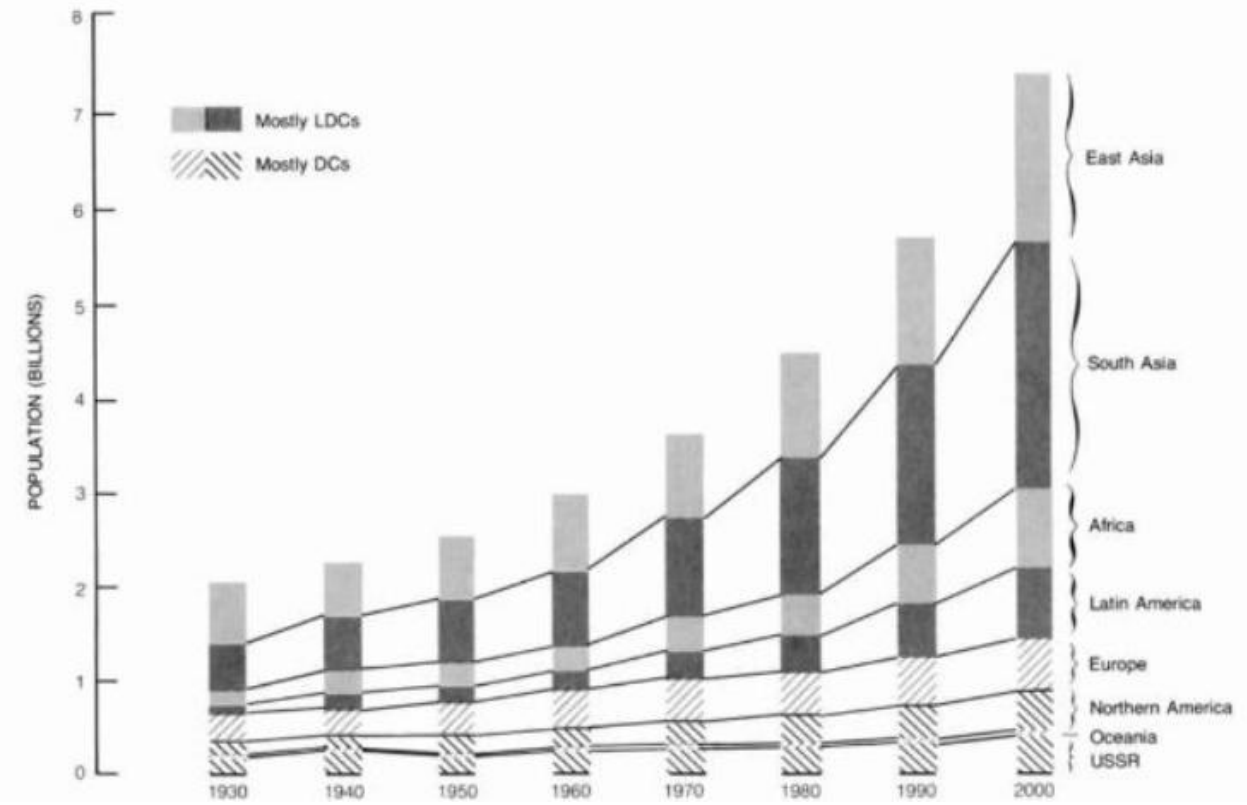

FIGURE 5-25 Projected growth of the world population, based on U.N. 1963 constant fertility projection. (Adapted from *Population bulletin*, vol. 21, no. 4. Courtesy of the Population Reference Bureau, Inc., Washington, D.C.)

Table 5-10 compares the projected low, medium, and high populations for 2075 for the world and for major regions.

The United Nations formerly made another projection, called the constant fertility, no migration projection, which was based on the simpler assumptions that current fertility and the recent downward trend in mortality would continue and that there would be no migration between geographical areas (Figure 5-25). Detailed presentation of this projection seems to have been abandoned, however, as forecasts beyond the year 2000 produced clearly unsustainable numbers -- total world populations of 7.2 billion in 2000, more than 14 billion in 2025, 33 billion in 2050, and 80 billion in 2075! [61]

In the past, population projections and forecasts have erred fairly consistently on the low side. For instance, in 1948 *Time* magazine cited the opinions of unnamed experts that a prediction (by the Food and Agriculture Organization of the United Nations) of a world population of 2.25 billion in 1960 was probably too high. [62] (The actual population in 1960 was about 3 billion.)

In 1949 economist Colin Clark predicted a world population in 1990 of 3.5 billion, and in 1950 demographer Frank Notestein predicted that by the year 2000 there would be 3.3 billion people alive. Both numbers were exceeded well before 1970. In 1957 United Nations demographers

offered the following population projections for 1970: low, 3.35 billion; medium, 3.48 billion; and high, 3.5 billion, The actual population passed the high projection for 1970 sometime near the end of 1968.

In the Depression years of the 1930s it was common for demographers in Europe and the United States to show great concern over the possibility of population declines. Their apprehensions were based on projections of trends in both birth rate and death rate. But declines in birth rates during the Depression were more than compensated for by the baby boom of the 1940s and 1950s. Moreover, no one foresaw the unprecedented effect of death control exported from DCs to LDCs. How widely projected estimates can vary is illustrated in Table 5-11., which shows United Nations estimates made

TABLE 5-11 Projections of World Population in 1980 (in millions) as Made by the United Nations at Several Points of Time, from 1951 to 1968

in different years for the world population in 1980. Not surprisingly, the latest estimates will probably be closest to the actual figure.

In 1974, reversing past experience, the United Nations revised downward its estimates of current population sizes and its projections for the future for most areas. The changes were based on new census results; on the birth-rate declines in Europe, North America, and Oceania; on lower-than-expected census results from India; and improved (though still inadequate) data on China. Population estimates for Latin America, Africa, and the Soviet Union were revised upward. The projections for the medium variant to 2075 appear in Figure 5-26 and in Table 5-12. Also, for the first time the United Nations took its projections to ZPG, on the assumption that a "complete" demographic transition in that direction will ultimately occur in all developing countries as well as in developed ones.

Whether the lowered estimates of the 1970 populations are correct is a matter of some controversy, at least with regard to the less developed areas. China appears to have made substantial progress in lowering fertility (see Chapter 13), but actual data are scanty. The lower census figures from India may have been due to undercounting, to a higher-than-expected death rate, to reduced fertility, or to a combination of all three. The United Nations postulates a trend in India to later marriage, which would have reduced fertility. If the census was incomplete, of course, then India's size and rate of growth assume even

[61] Ibid.
[62] November 8,1948.

more alarming proportions. [63] The indicated decline in fertility, should it prove to be real, is heartening. But, as both Frejka and the United Nations demographers have clearly demonstrated, the momentum of population growth assures that the present population will at least double or triple before growth can be ended by reducing fertility. This assumes that the resource base and the economic and social fabric that support the human population can somehow be sustained under such a strain. On this, even the sober, usually optimistic United Nations appears to have doubts:

It remains justifiable to contemplate also the possibility of severe reversals in the event of major breakdowns in international or national organization. There

[63] A. Adlakha and D. Kirk, *Vital rates in India 1961-1971* estimated from 1971 census data. This study accepts the total count and estimates that mortality was higher than anticipated and that there was a small reduction in fertility. There is evidence of a trend to later marriage, but it may be compensated by there being fewer widows in the reproductive ages.

is no denying that catastrophic events can happen despite all safeguards to avert them . . . . Certainly, international efforts will continue to be directed at the preservation of peace, the assertion of human rights, the stimulation of economic and social improvements, the protection of the environment and relief action in disaster-stricken areas. Failure in these undertakings would have to be immense if the consequences were to have a sizable impact on the high rates of population growth which have to be foreseen. It remains imperative to create the conditions permitting a healthy life for between 10,000 and 15,000 million human beings which will probably inhabit this earth in the coming century. [64]

To be complacent about population growth, therefore, one must not only be unworried by the condition of today's 4 billion people; one must also be confident that Earth can support the population of no less than 8 billion human beings to which humanity is already inescapably committed -- and (more likely) the 10 to 15 billion the United Nations expects!

Since prediction is a favorite pastime of almost everyone concerned with population, we will offer our own. We believe that United Nations projections for the year 2000 (with the possible exception of the low forecast) are too *high*. This is not, however, because we share their optimism about the future impact of family-planning programs on birth rates. Instead, for reasons we explain later, we expect that increases in death rates will either slow or terminate the population explosion, unless efforts to avoid such a tragic eventuality are mounted immediately.

POPULATION DISTRIBUTION AND MOVEMENT

Human beings are not uniformly distributed over the face of Earth. Moreover, their distribution has continuously changed throughout history, with migration and varying rates of population growth. Figure 5-27 shows the pattern of population density that prevailed in 1972. (Population density is the number of individuals per unit area.) For human populations, this figure is normally expressed as number of people per square kilometer or per square mile.

Table 5-13 shows the population density of the world's major areas in 1960 and 1975. Note that, although most people think of the developed world as being more densely populated, it is not (even though Europe is the most densely populated continent). The average density of less developed countries is more than twice as great as the average in developed countries. And both east and south Asia seem likely to overtake Europe in density within a decade or so. Of course, we must be cautious in picturing densities in terms of people per square kilometer because of the human tendency to gather in clusters. Although the United States in 1975 had about 23 people per square kilometer on the average (about 27 per square kilometer in the coterminous forty-eight states), there were many square kilometers that were uninhabited. Furthermore, people ordinarily are not uniformly distributed within any given square kilometer. Some samples of population densities in 1972, both moderate and extreme, were: [65]

	People per square mile	**People per square kilometer**
Earth (land area)	72	28.0
United States	59	23.0
Australia	4	1.5
Japan	744	287.0
Tokyo	20,000	7,722.0
New York City	26,000	10,039.0
Manhattan Island	68,000	26,255.0

The densities and distributions of populations, especially in relation to resources, have played critical roles in many important events in human history. Densities that are perceived as high by the members of populations themselves generate what is commonly called population pressure. Overpopulation is usually perceived in relation not to the absolute size of a population but to its density and to the resource base on which it depends. On many thousands of occasions in prehistory, one tribe or another must have decided that it had nearly exhausted the

berries and game in its home territory and therefore moved in on its neighbors. Many famous migrations in history, such as the barbarian invasions of Europe in the early Christian era, may have been partly due to population pressures. In 1095 when Pope Urban II preached the First Crusade, he referred to the advantages of gaining new lands. The Crusaders were mainly second sons who had been dispossessed because of a growing trend toward primogeniture in Europe (inheritance by the firstborn son only). Considerable evidence, such as indications of attempts at land reclamation, suggests that population pressures were building up in Europe well before the fifteenth century.

Before the arrival of Europeans in what is today the continental United States, the population density was

about 0.13 people per square kilometer. The addition to Europe of the sparsely populated New World at the end of the fifteenth century in effect reduced the overall population density of Europe from about 10 people per square kilometer to fewer than two people per square kilometer in the total area, and at the same time enormously expanded Europe's resource base.

European exploitation of the spatial, mineral, and other material wealth of the New World led to the creation of a basic set of institutions attuned to frontier attitudes. The ensuing economic boom lasted for 400 years. [66] At least as far as land is concerned, the boom is now plainly over. The population density of the European metropolis (western Europe and the Western Hemisphere) increased until it again exceeded 10 people per square kilometer (26 people per square mile) before 1930. Since all the materials on which the boom depended came ultimately from the land, the entire boom is clearly limited. Many of humanity's present difficulties are related to the rate at which the limits are being approached. And many of the lingering institutions and attitudes that evolved in a frontier setting now constitute major threats to the survival of the human population.

Population pressure has also been observed to lead to conflict. Many wars were fought by European nations as they scrambled to occupy the Western Hemisphere. They warred among themselves and against the technologically less advanced native populations in the New

[66]W. P. Webb, *The great frontier*.

World. More recently, in the 1930s and 1940s, population pressure contributed to Nazi Germany's famous drive to *lebensraum* (literally, *room for living*), especially in the East, where it reached its climax in Operation Barbarossa -- the ill-fated invasion of the Soviet Union. Historian D. L. Bilderback has commented that in the early years of Hitler's power, "large numbers of intelligent and humane persons believed that the Eastern adventure was a matter of necessity for their own survival." Whether Germany in 1941 was overpopulated in some absolute sense is not the point. The nation perceived itself as overpopulated.

Germany is probably more pressed for space today than it was then. The Bonn government, however, in contrast to Hitler, is not calling attention to overpopulation as a problem. Indeed, only recently has it begun to realize that by many standards Germany today is overpopulated. During the 1950s and 1960s, West Germany was importing workers in large numbers from southern Europe and North Africa. Today that immigration has been reduced to a trickle, and fertility has declined to below replacement level in both East Germany and West Germany.

Japan's expansionist moves in the 1930s and early 1940s can be traced in part to the high population density on its small islands. The population growth of Japan in the last third of the nineteenth century and the first third of the twentieth century was unprecedented among industrialized nations. It doubled in size (from 35 million to 70 million), and therefore in density, during the sixty-three years between 1874 and 1937. When the attempt to conquer additional territory failed and population growth continued to accelerate, Japan legalized abortion and drastically reduced its population growth. But, with 111 million people in 1975 and still growing by 1.3 percent per year, [67] Japan is again feeling the pinch and is looking more and more toward the continent of Asia for at least economic *lebensraum*.

Population pressures are certainly contributing to international tensions today. The USSR, India, and other neighbors of overpopulated China have been guarding their frontiers nervously since before 1960. Population growth in China has left her few long-range choices but to expand, to starve, or to implement stiff population-control policies. Since the 1960s, China has followed the last course, but whether it will succeed remains an open question.

Australians are clearly apprehensive about the Asian multitudes. This attitude for a long time was reflected in their nation's "whites only" immigration laws and Western-oriented foreign policy. The racial bias of Australian immigration policies was eliminated in the 1960s, but soon afterward there was a movement to stop encouraging immigration altogether. Australians have reason to be fearful of too much immigration. Because there is a generally unfavorable and unreliable climate over much of Australia and because of the nation's history of disastrous agricultural practices, the continent, although large, lacks the resources for absorbing even a *single year's increment* to the Asian population. [68] Such an addition would more than *quintuple* Australia's population, from 13.8 million to 74 million. The number of people added annually to India's population alone (13 to 15 million) is more than the entire population of Australia today.

Population density has increased in all areas of the world and can be expected to continue increasing as the human population grows. But the varying rates of growth from region to region mean that some regions may not even double their population density in the next century (assuming growth follows projected paths), while others will increase their density from three- to fivefold. Table 5-14 shows projected density from 1925 to 2075 for various regions according to the United Nations medium-variant projection. South Asia, for instance, is projected to reach a density nearly three times as high as Europe's today, which is the highest ever known previously in a major region. And Europe today is by no means self-sufficient for resources, or even for food.

Migration

Migration is almost as characteristic of *Homo sapiens* as toolmaking. Perhaps only a few domestic animals are as widely distributed on Earth's land areas as people are.

From their probable origins in Africa, human groups had spread out to occupy all the major land areas of the planet but Antarctica by 20,000 years ago, long before the beginnings of agriculture or written history. There is little question that the human habit of wandering has been a major factor in cultural evolution, as new ideas, and especially technical innovations, have been carried

from one area to another. Agriculture, as one very important example, was transmitted largely through migrations and often by displacement of resident nonagricultural peoples. Today the only remaining groups of people who do not practice agriculture are a few isolated tribes in remote areas where a harsh climate is generally unsuitable for raising crops, such as arctic Eskimos, Bushmen of the Kalahari, aboriginal tribes in Australia's interior deserts, and the Indians of Tierra del Fuego. And all these groups are under severe pressure from modern civilization to abandon their hunter-gatherer cultures.

The impetus for the movement of people in large groups may have several sources, including overpopulation and resource pressure, as discussed earlier. Demographer Kingsley Davis argues that differences between groups in levels of technology and economic opportunity are also major causes of migration. [69] Differential technology can work both ways: people with more sophisticated technology may invade and conquer new areas, or less advanced groups may be attracted to the greater opportunities provided by a more developed society. Ancient Romans, for example, conquered vast areas in Europe, North Africa, and western Asia, seeking mineral wealth and an expanded food base. But, unlike the earlier Greeks and Phoenicians, the Romans did not colonize those regions in any great numbers. Rather, people from the outlying areas migrated to Rome, attracted by the greater economic opportunities there. Perhaps even greater numbers went to Rome involuntarily as slaves.

Waves of Asian invaders swept across Europe during the Roman Empire, as they had for centuries before. Perhaps they were partly impelled by population pressure in Asia, but probably they were also attracted by the wealth of the Mediterranean basin. Migrant barbarians were gradually assimilated into the Roman population, and, as that civilization gradually declined, the technological differences between the barbarians outside and the Romans inside probably faded. Certainly the fall of Rome in the fifth century suggests that, in warfare at least, the barbarians were equal to the Romans.

In the Middle Ages, the known major migrations were those of Islamic peoples -- Arabs and Turks, some of whom in turn were responding to pressure from Genghis Khan's Mongols. But the discovery of the New World by Europeans led to a burst of exploration and exploitation followed by waves of migration from the seventeenth through the twentieth centuries. And, even as Europeans began to settle the sparsely inhabited new lands, they

---

[69] The migrations.

were also claiming, colonizing, and exploiting morepopulated territories in Asia and Africa. Slavery and indentured labor accounted for much of the migration between 1450 and 1870, including movement of as many as 20 million people. [70]

Migration of Europeans to the New World, Australia, New Zealand, and South Africa remained at fairly low levels until the nineteenth century. Davis attributes the great acceleration of movement in that century to the Industrial Revolution (which widened the technological gap between Europe and the other continents and stimulated the search for raw materials) and to

growing economic uncertainty in Europe. The early nineteenth century in northwestern Europe also was a period of declining death rates and rapid population growth. England, Ireland, and (later) Germany and Scandinavia sent millions of migrants to North America, Australia, New Zealand, temperate South America, and South Africa. Between 1840 and 1930, at least 52 million people left their home continent, most of them for North America. Large as this emigration was, it had little effect in retarding population growth in most of Europe, although it fueled population explosions in the receiving countries. In most European countries, emigration appears to have allowed a delay in the beginning of the birth-control movement. The Irish potato famine provided a special stimulus to emigration in the 1840s and 1850s, as 2 million Irish left the country in four years. Emigration continued at a high level, and Ireland is the only European country whose population growth was reversed by it. Had the same fertility prevailed without that safety valve, the Irish population would be more than 12 million today, rather than 3 million.

It is fashionable to suppose that the era of large-scale migration ended before World War II, but that is not the case. Despite the establishment of immigration restrictions and quota systems in the 1920s and 1930s in many receiving countries (including the United States), migration has continued briskly, although there are some important differences in who migrates where. One significant change is the twentieth-century phenomenon of political refugees, who have attended each war, major or minor. One can list numerous examples: Turkish Armenians and White Russians early in the century; European Jews after World War II (not to mention millions of "displaced persons" of various national origins who settled elsewhere after that war), Palestinian Arabs, Chinese, Hungarian "freedom fighters," Cubans, and, in 1975, 150,000 Vietnamese.

Another form of involuntary migration is the expulsion or exchange of minorities by nations. Examples include the Sudeten Germans repatriated from Czechoslovakia after World War II, and the Moslems and Hindus exchanged when India and Pakistan were partitioned. Davis has estimated that altogether more than 70 million people were displaced between 1913 and 1968.

Migration by choice is also proceeding, but there have been changes. Northern and central European countries, which formerly sent emigrants to new lands, since World War II or even earlier have been receiving more migrants than they have sent out. At first the immigrants, imported to meet labor shortages, came mainly from southern European countries -- Portugal, Spain, Italy, Greece, and Yugoslavia. More recently immigration from central and North Africa, India, and Pakistan has increased. Here again, as Davis points out, because the technological gap has widened betweed DCs and LDCs since World War II, migrants from less highly developed societies are moving to more developed ones in search of better jobs. Other possible factors are a reversal of relative population growth rates (earlier in the century, Western countries were growing more rapidly than non-Western countries) and the recent independence of former colonies. A part of this picture, too, is the brain drain, in which professionally trained citizens of LDCs, unable to find satisfactory employment at home, move to DCs.

A similar change in migration patterns has taken place in the United States. Before 1890, immigrants to the United States came predominantly from northern and western Europe. After the turn of the century, most came from southern Europe. The 1965 Immigration Act abolished the national quota system, and since then immigrants from LDCs, particularly Latin America, have far outnumbered Europeans. [71] Figure 5-28 shows

[70] *Ibid.*

[71] Charles B. Keely, *Immigration composition and population policy*.

the national origins of immigrants to the United States in 1972. While national quotas no longer apply, there are quotas for people based on other criteria: relatives of citizens or residents, skilled or unskilled workers in desired occupations, and refugees (except in unusual situations like the Cuban revolution and the Vietnamese evacuation). Hence, age and sex compositions of immigrants as a group have changed, as have their countries of origin. There has been an increase in the proportions of professionals, of married people with families, and of males rather than females since 1965.

The total number of immigrants admitted annually to the United States has been about 400,000 in recent years. Unfortunately, no useful information exists on how many have left the country permanently, so the actual contribution of *net* migration to the population growth of the United States is unknown. Usually, emigration is ignored in discussions of United States population dynamics or immigration policies.

During the nineteenth and the early twentieth centuries immigration was an important element of United States population growth. Between 1900 and 1910, it accounted for more than half the nation's growth. It reached a low of less than 6 percent in the 1930s and 1940s, but by 1973 it again comprised more than a quarter of United States population growth (see Table 5-15).

The above discussion is based only on legal immigration. But the United States also receives large numbers of illegal immigrants, mainly from Mexico (estimates range from 60 to 85 percent of illegal immigrants) but also from several other Latin American and Caribbean countries, the Philippines, China, Korea, Nigeria, Ethiopia, Italy, Greece, Iran, and some other Middle Eastern states. [72]

Although there is no way to know exactly how many illegal immigrants are now residing in the United States or how many enter each year, some estimates have been made. It is believed that by 1974 some 8 million illegal aliens were living in the United States, [73] despite the

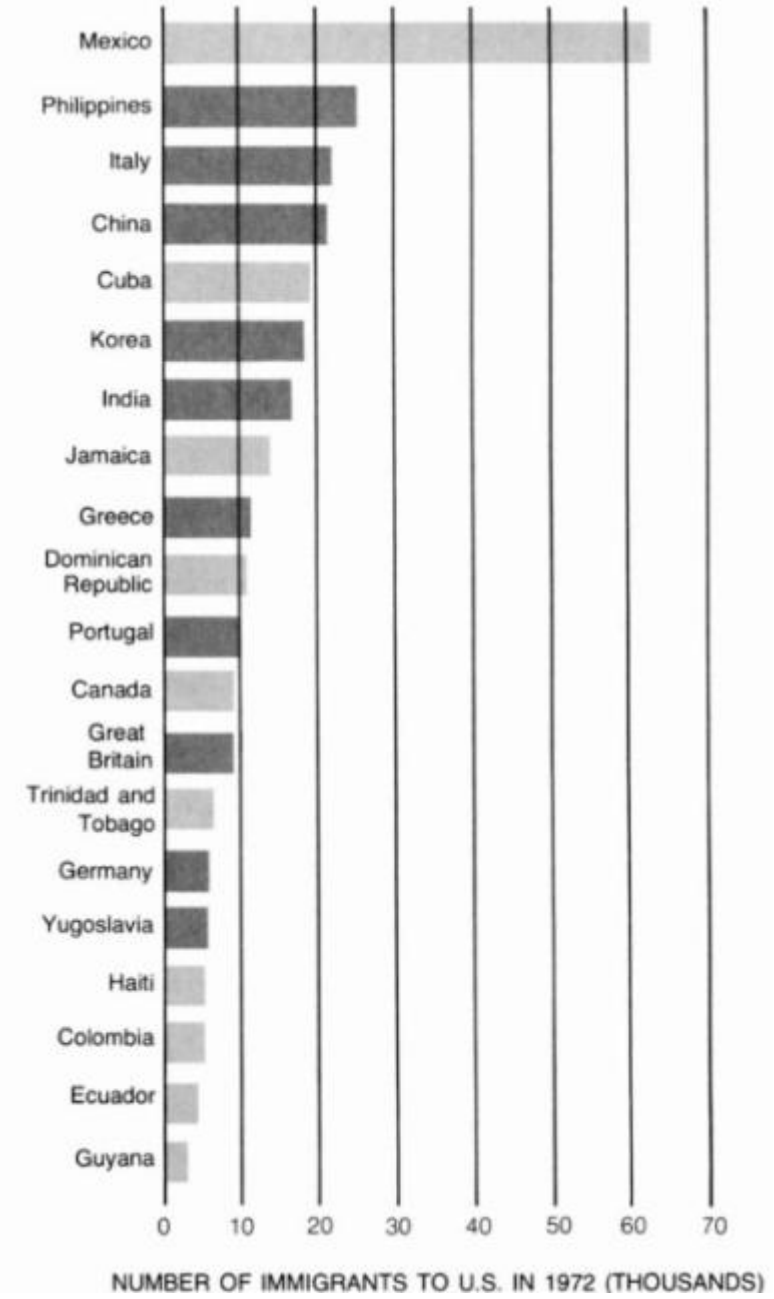

FIGURE 5-28

Sources of recent immigration to the United States are ranked here in descending order, with the top 10 countries of origin in the Western Hemisphere distinguished by shade from the top 10 in the Eastern Hemisphere. The figures for each country in the Western Hemisphere (except Cuba) represent the number of visas issued in fiscal year 1972; the figure for Cuba includes 16,380 "adjustments of status" granted by the Immigration and Naturalization Service to aliens subject to numerical limitations. The figures for the Eastern Hemisphere represent the number of visas issued in fiscal year 1972 (excluding recaptured visas) together with the number of adjustments of status and conditional entries granted to aliens subject to numerical limitation. (Data from U.S. State Department, 1973; from Davis, 1974.)

deportation of hundreds of thousands each year (more than 600,000 in 1973 and 800,000 in 1974). Estimates of annual clandestine arrivals range from 400,000 to 3 million. Illegal immigrants have often been encouraged to enter the country by prospective employers, covertly or overtly, to take very low-paying, menial jobs that are nevertheless more attractive than what is available in their home countries. Many jobs now held by illegal aliens are in urban areas, and some require highly skilled workers. The influx of foreign workers causes problems as they compete for jobs with welfare recipients and other low-income citizens, thus depressing the United States wage scale and sending funds out of the country. All of these problems were exacerbated by the recession of 1974/ 1975.

The demographic impact of illegal immigrants is bound to be large if they continue to arrive at the current rate. Even at the lowest estimated level of entry, their numbers equal those of legal immigrants. Demographic projections made by the organization Zero Population Growth have indicated that, if immigration proceeded at the rate of 1.2 million per year (400,000 legal and 800,000 illegal immigrants), and fertility remained at the 1975 level of 1.9 children per woman, the United States population would soar to 346 million in 2050. [74]

Like the unknown numbers of emigrants who leave the United States, illegal immigrants are left out of most estimates of United States population size and growth (with the major exception of the *World Population Estimates* of Robert C. Cook for the Environmental Fund). Efforts to pass legislation in Congress to strengthen regulations against illegal immigrants and to penalize employers for hiring them have failed so far. [75] Illegal immigrants do not enter the United States only; several countries in Europe and South America also attract them, mainly for the same reasons.

Migration, of course, can have no effect on the growth of population worldwide; there is no migration to or from Earth. But it can have significant effects on the rates of growth of individual countries, on their age compositions, and on population densities. [75a] Migration obviously increases the growth of receiving countries and reduces that of sending countries. In the case of the United Kingdom, mentioned above, net emigration produced negative population growth by 1975, even though the age composition and fertility rates should have produced a slow positive growth and immigrants from less developed former colonies were still being admitted. [76] But the number of immigrants had been reduced by tightened regulations, and the number of emigrants (mostly native-born) sharply rose in response to deteriorating economic conditions. Most emigrants went to Australia, Canada, and New Zealand.

Emigration from rapidly growing LDCs also has the effect of dampening population growth in the country of origin, perhaps providing enough of a safety valve to delay establishment of needed population programs.

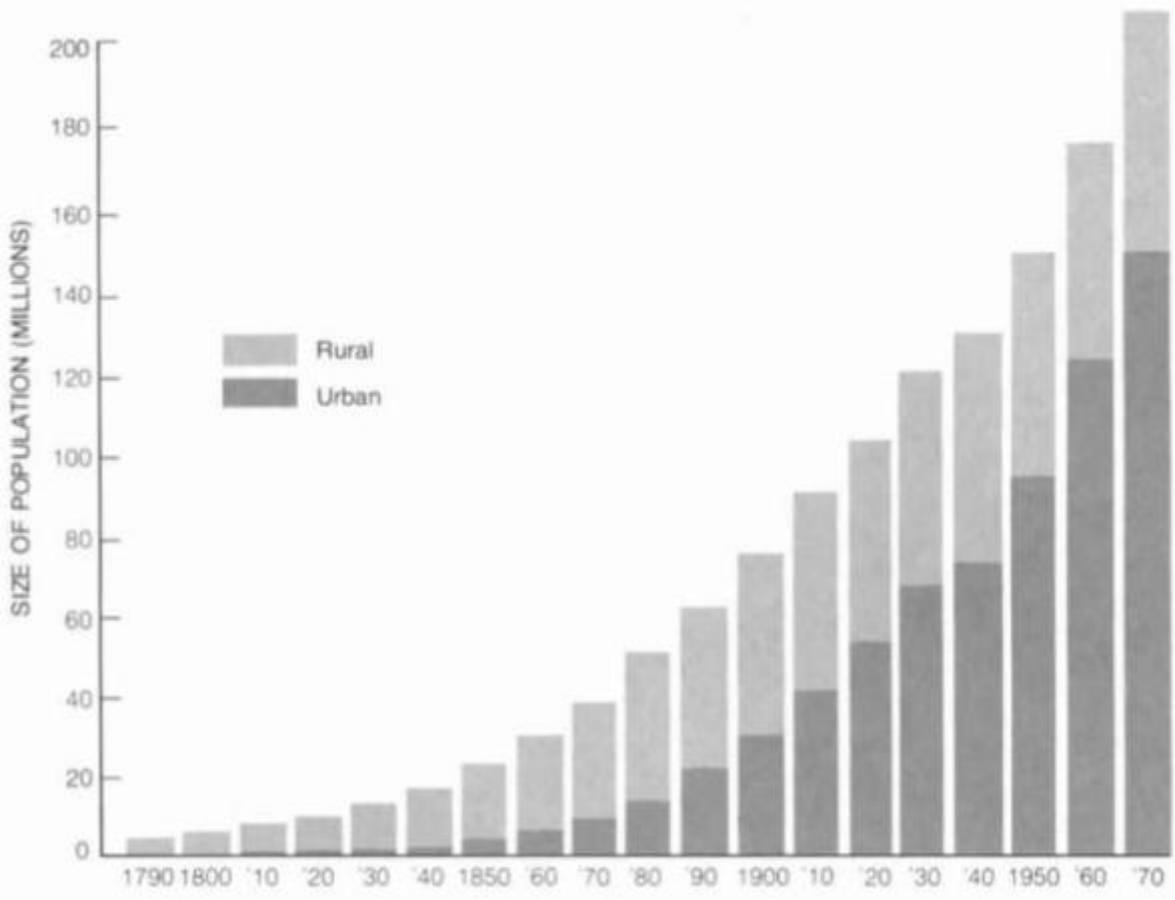
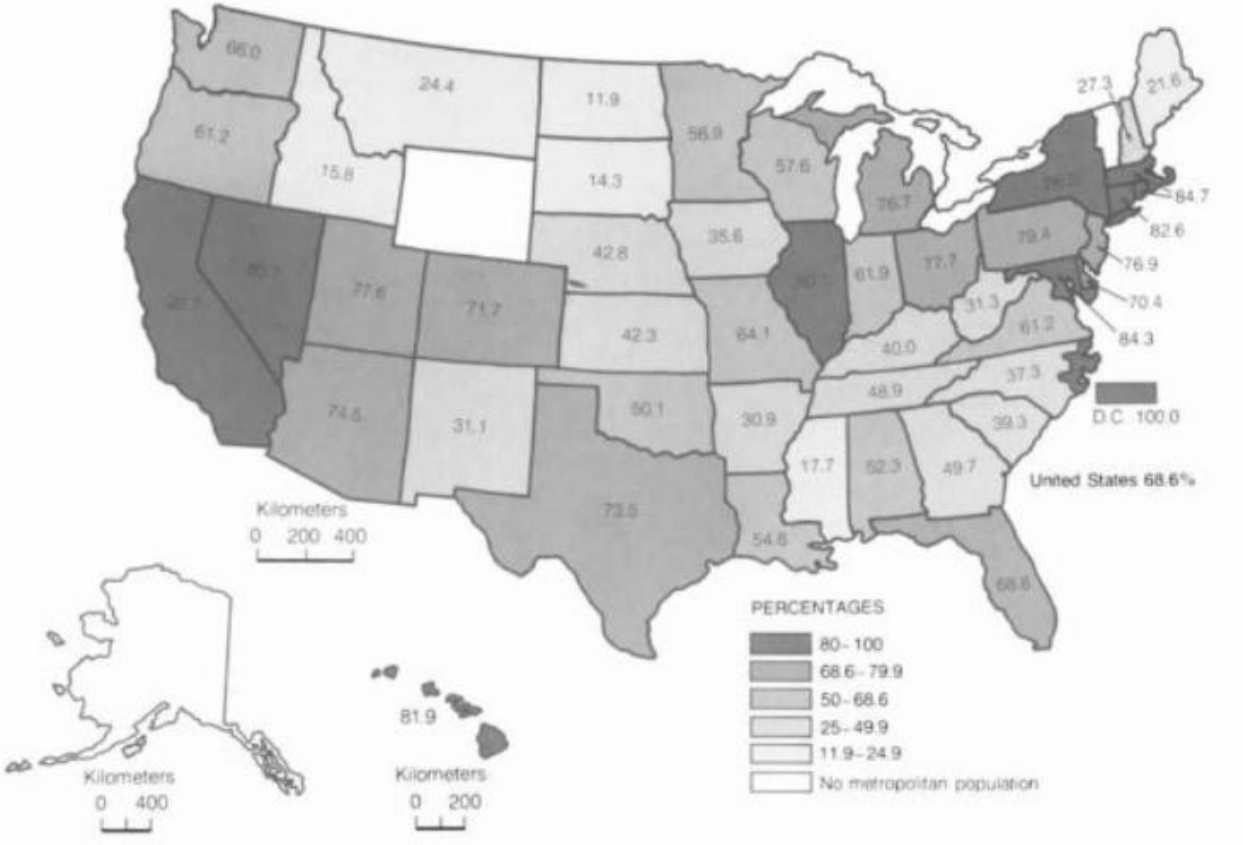
This appears to have been the case for Mexico, which only established a family-planning program in 1974, although the nation's birth rate has been around 46 per 1000 for some time. Similarly, several Caribbean islands (Puerto Rico, Barbados, and Trinidad, for example) have for decades exported substantial fractions of their natural increase, mainly to the United States or Canada. Birth rates have fallen in several Caribbean nations since 1965, but the possibility remains that they might have fallen considerably sooner and faster without the safety valve of emigration.

Urbanization

One of the oldest of all demographic trends is the one towards urbanization. Preagricultural people by necessity were dispersed in small groups over the landscape. Hunting and gathering required perhaps a minimum of 5 square kilometers of territory to produce the food for one person. Under such conditions and without even the most primitive transportation systems, it was impossible for people to exist in large concentrations. But the Agricultural Revolution changed all that. Because more food could be produced in less area, agricultural people began to form primitive communities. The ability of farmers to feed more than their own families was obviously a prerequisite of urbanization. A fraction of the population first had to be freed from cultivation of the land before cities could develop.



But the division of labor and specialization in a nonfarming population does not seem in itself to have led immediately to urbanization. For example, some scholars believe that Egyptian agriculture and society were such that considerable numbers of people were freed from the land by the time their culture reached the stage usually considered civilized (about 3000 B.C.). But it was another 2000 yews before they developed the kind of complex, interrelated society recognizable as a city. Similarly, it is doubted whether the Mayan civilization produced cities. It is thought that, in ancient Mesopotamia, at least, and perhaps in Cambodia, the development of large and complex irrigation systems helped lead to the formation of cities. Then, as today, shortages of water formed the bases of political disputes, so people may have gathered in large groups for defensive purposes. Mesopotamian cities also would have served as storage and redistribution centers for food. As anthropologist Robert M. Adams has written, "the complexity of subsistence pursuits on the flood plains may have indrectly aided the movement toward cities. Institutions were needed to mediate between herdsman and cultivator; between fisherman and sailor; between plowmaker and plowman." [77] It has also been suggested that mobilizing, working, and using metals may have stimulated concentrated settlement patterns. Whatever the actual impetus for urbanization, the first cities arose along the Tigris and Euphrates rivers between 4000 and 3000 B.C.



The trend toward urbanization continues today, as it has ever since those first cities were formed. Because of differing fertility patterns and generally much poorer health conditions, cities traditionally have been unable to maintain their populations through natural increase, let alone to grow. Hence, growth of cities before the late nineteenth century was almost entirely due to migration from rural areas. The move to the cities has at times been stimulated by agricultural advances that made possible the establishment of larger, more efficient farms. It seems also to have been stimulated by population growth in rural areas, which necessitated either the subdivision of farms among several sons or the migration of "surplus" offspring to the cities. In the past, advances in agriculture generally have been accompanied by advances in other kinds of technology, which provided new opportunities for nonagricultural employment. Beyond providing places for those displaced from the land, cities have always been attractive in themselves to people who hoped to improve their economic conditions. [78]

The movement into large urban concentrations has been especially rapid in the past century. For instance, in the United States about 6 percent of the population lived in urban areas in 1800,15 percent in 1850, and 40 percent in 1900. Today, nearly 75 percent of the population lives in cities

or their suburbs (Figure 5-29). Recent Census Bureau evidence indicates, however, that the trend to

[77]R. M. Adams, *The origin of cities*.
[78]For a fascinating study of the history of cities, read Lewis Mumford, *The city in history: Its origins, its transformations, and its prospects*.

POPULATION IN STANDARD METROPOLITAN STATISTICAL AREAS 1970

urbanization in the United States may have ended -- and may even have begun a reversal. [79]

Other industrialized nations are also more or less heavily urbanized, ranging from 56 percent in eastern Europe to 86 percent in Australia and New Zealand. Most LDCs are much less urbanized, but the variation among them is even greater. Tropical South America reaches European levels -- 59 percent -- whereas East Africa is only 12 percent urbanized. The trend to urbanization is accelerating rapidly in those countries, however, attended by a variety of severe social problems. Altogether, almost 40 percent of the world's population was urban in 1970. [80] Table 5-16 traces the urbanization of major regions since 1925 and projected to 2025.

An additional change is in the proportion of the world's people who live in very large cities (those with 1 million or more inhabitants). A generation ago most such cities were in developed countries. By the 1970s more of the million-cities were in LDCS, and their aggregate population exceeded that in DCs. Table 5-17 shows the growth of million-cities between 1960 and 1975.

One problem that is inevitably encountered when discussing urbanization is the definition of an urban area. This varies from country to country, and from time to time. Furthermore, urban areas in different countries or different areas of the same country often are quite dissimilar. Los Angeles, New York, and Chicago have certain features (good and bad) in common-good art museums, major universities, slums, disadvantaged minorities, numerous TV stations, clogged

streets and freeways, dangerously congested airports, diverse specialty shops, high crime rates, and air pollution, to name a few. But their differences are as apparent as their similarities. The air-pollution problems of Los Angeles

and New York differ fundamentally because the smogs over the two cities have different compositions and the cities are in different physical settings. Water-supply problems are unique in each of the three cities. Los Angeles has a seemingly hopeless surface transportation problem and smoggy "sunshine slums." MexicanAmericans are one of its largest minority groups. Chicago has substantial problems with migrants from the Ozarks. New York has had great difficulty in satisfactorily absorbing masses of immigrants from Puerto Rico and the rural South, many of whom have ended up as welfare recipients. The problems of government in the three cities have their own peculiar twists, but all have more or less serious financial problems.

Urbanization seems to have one almost universal effect, the breaking-down of the traditional cultures of those who migrate to the cities--a loss of roots, or alienation. In rural or tribal societies each individual has a well-defined role in the organization of the society, a role that he or she has matured into and that is recognized by all other members of the society. In contrast, anonymity is a major feature of the city. City-dwellers typically are on close terms with no more people than are village-dwellers, and they tend to go to great lengths to

FIGURE 5-29 (*left*) Urbanization of the United States. In 1970, some 73.5 percent of Americans were living in towns or cities, and 68.6 percent were living in large cities and their surroundings (metropolitan areas). Since 1970 the percentage of urban Americans has passed 75. (A. Adapted from *Population bulletin*, vol. 19, no. 2. Courtesy of the Population Reference Bureau, Inc., Washington, D.C. B. avoid "getting involved" with the vast majority of the human beings with whom they come into daily contact.

Urbanization in the United States in some ways differs dramatically from urbanization in other countries. For instance, the difference between city-dwellers and country-dwellers in the United States has become increasingly blurred, especially in recent years, with urban culture becoming dominant. Rapid transportation and mass media have exposed the country folk to the ways of the city. Furthermore, in the United States especially, the phenomenon of suburbanization has developed. Suburbanites, who take advantage of high-speed automobiles, plentiful and cheap fuel, freeways, and affluence, have attempted to enjoy the advantages of city and countryside simultaneously, by working in the former and living close to the latter.

Suburbanization has been extremely rapid since World War II and has led to some severe problems in the United States. While affluent and middle-class taxpayers have left the cities, poor and unskilled people squeezed out of rural areas largely by increasingly mechanized agriculture, have flooded to the cities seeking jobs in industry. As tax returns to city governments have dwindled, it has become more and more difficult for cities to maintain even basic services. In an effort to restore their tax losses, many cities have concentrated their urban renewal funds on building high-rise office buildings used mostly by commuting suburbanites, while the slum areas housing the poor have become even more crowded, neglected, and crime-ridden. Thus, the

contemporary United States city consists largely of office buildings and slums, surrounded by affluent suburbs, freeways, and industrial areas. The central city is strangled during the day by traffic as suburbanites commute to the city and factory workers commute out of it. Nevertheless, American cities have access to the resources to solve their urban problems, difficult though they are. Their problems are largely the result of poor planning or no planning at all.

European cities, too, have been suburbanized, but not to the same degree as those of North America. Because it has greater population density, and consequently less land to spare, Europe has avoided the greatest excesses of urban sprawl. Different urban government arrangements and zoning regulations have also played a part in keeping cities relatively compact. Moreover, urbanization has proceeded more slowly in Europe than elsewhere. This is not to say there are no urban problems in Europe. Even though public transport systems are generally far superior to those in the United States, traffic congestion (largely from automobiles) is almost unmanageable in the centers of many of the largest cities. Housing shortages have plagued European cities at times; public or publicly subsidized housing has made up a substantial portion of housing built since World War II in some countries. In London, there is a serious shortage of housing as well as a growing number of abandoned buildings, some slated for demolition. Homeless families by the thousands have asserted squatter's rights by occupying the derelict

structures -- in some cases, even with government assistance.

While rapid urbanization has caused problems in industrialized countries, it is virtually a disaster in many LDCs. [81] There, urban problems are largely the result of cities' being overwhelmed by massive, unanticipated immigration from the countryside. Between 1950 and 1960, the populations of cities in the DCs increased 25 percent, while those of cities in the LDCs increased 55 percent. In most LDCS, especially since the end of World War II, there has been an increasing flood of impoverished peasants into urban areas. Yet employment opportunities there have not materialized. The result has been the development of huge shantytowns around the fringes of cities.

In Latin America the shantytowns are given different names in each country: favelas in Brazil, tugurios in Colombia, ranchos in Venezuela, and barriadas in Peru. In Peru, at least a million squatters live in such settlements--a substantial fraction of Peru's population of about 15 million (Figure 5-30). They are virtually a universal phenomenon around large cities in Central America and tropical South America. Most of these urban migrants become permanent residents, and among them, women outnumber men. The majority of arrivals are between 15 and 30 years old.

The trend in Africa has been similar, with hundreds of thousands migrating to the cities annually in search of better lives. Nairobi, the capital of Kenya, had a 1968 population of 460,000 and was growing at a rate of 7 percent per year. (That is more than twice the growth rate of Los Angeles in the decade 1950 to 1960.) During the 1960s, Accra, the capital of Ghana, was growing at almost 8 percent per year; Abidjan, capital of the Ivory Coast, at almost 10 percent; Lusaka, capital of Zambia, and Lagos, capital of Nigeria, both at 14 percent. [82] Unlike Latin American urban migrants, African migrants are usually young men who stay in the city only temporarily

and then return to their families in the countryside. Lack of employment and housing for families are probably the reasons for the turnover.

FIGURE 5-30 A shantytown in the Rimac district of Lima, Peru. Many squatter houses, originally straw shacks, are being rebuilt in brick and masonry whenever the earnings of the owners permit. (Photo courtesy of William Mangin.)

[81]Atlas report, Cities in trouble, *Atlas*, December 1975. See also George J. Beier, *Can third world cities cope? for a concise analysis of the situation*.

[82]"Bulging African cities where dreams die", *San Francisco Chronicle*, November 20, 1968.

The rate of urbanization in Asia has also been rapid in this century, but in most Asian countries the increases have been from a rather low base. For instance, at the turn of the century about 11 percent of India's population was urban. Today more than 20 percent of India's people live in cities. This deceptively low rate of urbanization conceals what for India is a problem of immense proportions (Figure 5-31). As in Africa, many of India's (and other Asian) urban migrants remain in the cities only temporarily.

Some of the world's fastest-growing cities are in southeast Asia, especially in Indonesia. Hong Kong and, to a lesser degree, Singapore have had rapid urbanization compounded by high rates of immigration -- often illegal -- from China. Although both cities have prospered as manufacturing and trading centers, they have succeeded in providing housing and services for their burgeoning populations only through strenuous efforts. Table 5-18 shows the projected growth of the world's largest and fastest-growing cities between 1970 and 1985-only fifteen years. In that time, many will double their populations and one (Bandung, Indonesia) will more than triple its population.

In most rapidly growing LDCS, the trend to the cities seems to be caused in large part by the same hope for a better life that has drawn people from rural areas of the southern United States and Puerto Rico to a slum life in New York, Chicago, and other northern metropolises, or from rural southern Europe to industrial northern Europe. But in the cities of less developed countries, where there is little industry, economic opportunities are much more limited than in the cities of the United States or Europe.

In the LDCS, communications and transportation are much less efficient than in DCs, and the peasant cultures are less influenced by the urban. The overwhelming majority of urban-dwellers in LDCs are migrants from the countryside who have brought their peasant cultures with them. [83] Unlike the majority of DC urbanites, whose specialized education, training, and skills assure them of places in the city's complex social web, the LDC immigrant has no such skills to offer. In the United States, unskilled rural immigrants are in the minority.

Although they may have employment problems, most are at least literate and can be absorbed into the industrial society.

Cities in developed countries are a source of wealth and power, generated through technology and manufacturing. The goods they produce are exchanged for raw materials and food from the countryside. In contrast, many LDC cities subsist in times of shortage primarily on food imported from other countries. Attracted by the opportunity to obtain a share of the imported food, inhabitants of the countryside move into the cities when the countryside can no longer support them. Inevitably, they find that their limited skills render them incapable of contributing to the economy. As a consequence, they are not much better off than they were where they came from. In some LDC cities, squatters now make up a majority of the population. According to the United Nations, they constitute at least one-third of the urban populations of all less developed areas and are increasing by about 15 percent per year -- doubling every five or six years. [84] Miserable as their condition seems to be, at least those who have settled with their families

evidently prefer to remain in their squatter settlements rather than return to what they left. Many, of course, may have burned their bridges behind them and have no way of successfully returning to their former homes. Many migrants to LDC cities do, however, maintain contact with their home villages and contribute financially to their rural relatives.

Evidence is accumulating that many squatter settlements are far more successful as a way of life than would appear to Western eyes. Among the permanent migrants, modified village societies are often established within squatter settlements, thus transferring village culture to the city (a factor that may explain why their attitudes and reproductive patterns generally resemble those of rural people). Such established settlements are very different from rural slums in the United States or other DCs, which are often characterized by an absence of community coherence and efforts toward neighborhood improvements.

Squatter settlements often start out with the most

rudimentary of dwellings but progress to more permanent structures as their owners can afford to build them. The shantytowns are built by their inhabitants, who organize a community social structure in order to bring in needed services from outside, such as water, food, public transportation, schools, and health care. [85] This pattern is especially common in Latin America. In some of the more successful cities, governments have cooperated with the settlements in providing these services and assisting the people in their community projects. Around Lima, for instance, settlements are being steadily improved through the joint efforts of the squatters and the Peruvian government. [86] Such cooperation among governments and squatters is relatively rare, unfortunately. More commonly, governments try to ignore the shantytowns, or -- more ambitiously -- try to clear the slums and thereby "remove" the problem (without success). Where slum clearance has been attempted, the result has often been social disaster -- or at least an extremely expensive program of building urban housing for the poor. [87]

FIGURE 5-31 A street in Calcutta. These people live in makeshift shacks built on the sidewalk. Some of the shacks also function as shops where the "owners" sell food and handmade articles. (Wide World Photos.)

One of the major obstacles to improving conditions for urban squatters is the apparent inability of governments to find solutions in any but traditional Western approaches. Just one outstanding example is the sanitation facilities -- or lack of them -- in most LDC cities. Sewer systems serve only 28 percent of the LDC urban populations; 30 percent of those populations have no facilities at all. [88] Calcutta, for instance, relies on a crumbling sewer system built at the turn of the century for 600,000 people -- less than one-tenth of the present population. [89] Calcutta first tried slum clearance, but has since turned to making modest improvements in the bustees (as the shantytowns are called), providing latrines and minimal water service. [90] Most LDCS, however, seem unable to conceive of sanitation except in terms of unsanitary latrines or western-style sewer systems, which are well beyond their means, technologically and financially, and which

use too much water. So nothing is done. A program is urgently needed to develop intermediate technologies to solve this problem-perhaps along the line of the *clivus multrum* dry toilet (see Chapter II).

Urban projections. Even more alarming than the present urban situation are projections of trends in urbanization. For instance, one projection has led to an estimate for Calcutta in the year 2000 of 66 million inhabitants, more than *8 times* today's population. Needless to say, that total will not be reached -- but there is a realistic expectation that the population of this teeming city (Figure 5-31), in which several hundred thousand people live in the streets today, will increase from 7.5 million to 12 million by 1990. Calcutta is already a

[88]Richard Feacham, *Appropriate sanitation*.

[90]Atlas report, Cities in trouble.

disaster area, and the consequences of further growth at such a rate are heartrending to contemplate.

The population of relatively prosperous Tokyo is projected to reach 40 million in the year 2000 (compared to 15 million in 1970). In a desperate attempt to create land for expansion, Tokyo has been using 7000 tons of garbage a day to fill Tokyo Bay. Flat, empty land is at a premium in mountainous, overpopulated Japan. Middle-class apartments are already so scarce that people have to wait two years to obtain them. Tokyo's dense crowding seems destined only to get worse.

Demographer Kingsley Davis has made some extrapolations of urbanization trends and has produced some startling statistics. If the urban growth rate that has prevailed since 1950 continues, half of the people in the world will be living in the cities by 1984. If the trend should continue to 2023 (it cannot!), everyone in the world would live in an urban area. Most striking of all, in 2020 most people would not just be in urban areas; half of the world's human beings would be in cities of more than I million population, and in 2044 everyone would exist in "cities" of that size. At that time the largest "city" would have a projected population of 1.4 billion people, out of a projected world population of 15 billion. [91] (The word city here appears in quotation marks because, should such a stage be reached, world living conditions would make the term meaningless in its historical sense.)

Such projections, of course, are merely extensions of recent trends. They are helpful in showing the direction in which *Homo sapiens* is headed. But, if anything, they make it clear that those trends cannot long continue. The movement to urbanization in the developed world may indeed be ending now. In much of Europe it has markedly slowed in the past decade, and in the United States it appears to have reversed slightly in the 1970s.

How long the cities of less developed countries can go on absorbing masses of unemployable peasants in makeshift slums without major social breakdown is an open question. Much probably

could be done to alleviate their explosive urban growth by concentrating development effort in rural areas and smaller towns in order to provide useful employment there. But the key to solving the problem in the long run is clearly to reduce the rate of population growth as quickly as feasible. From at least one point of view, burgeoning LDC cities are both symptomatic and symbolic of humanity's predicament. There one finds juxtaposed many of the contradictions of today: wealth and poverty; modern technology and industry and illiteracy; abundance and hunger.

The future of the human population depends on much more than population dynamics. Those dynamics are limited by the physical, biological, and social environments in which the population finds itself. Furthermore, human actions can change both kinds of environments for better or worse. These interactions are explored in some detail in the following chapters.

CHAPTER 6

Land, Water, and Forests

We abuse land because we regard it as a commodity belonging to us. When we see land as a community to which we belong we may begin to use it with love and respect.

-- Aldo Leopold, 1948

Among physical resources, land is central in importance. By land we mean not only physical space but also the characteristics that govern the uses to which land can be put. Those characteristics include the topography (the shape of the terrain--for example, flat, hilly, or mountainous), the quantity and quality of soil, the availability of water, and the nature of local climates. Of course, those features are interrelated, and together they influence and are influenced by the vegetation that grows on the land: soil is a product of the underlying rock, the climate, the topography, and the creatures living on it and in it; the availability of water depends on how much falls as rain and snow, on how much evaporates, and on how much is retained, where, and for how long; the latter properties depend on local soil and vegetation as much as they influence them.

Many of the basic physical principles underlying these relations am described in Chapter 2, Chapter 3, and Chapter 4. In this chapter we discuss the characteristics of Earth's land and its supplies of fresh water as resources--that is, in terms of their availability and suitability for the support of the human population. The closely related topics of forests and the production of timber are also treated here; production of food is the subject of Chapter 7.

LAND

Earth has a land area of 149 million square kilometers (58 million square miles), which in 1975 was occupied at an average density of about 27 people per square kilometer

(70 per square mile). This does not seem to be such a high density--it amounts to almost 4 hectares (or 10 acres) per person.

But land is a resource only insofar as its specific characteristics enable it to serve some human need. A very rough classification of global land area suggests that only about 30 percent of the land surface is potentially arable (farmable); 20 percent is uncultivable mountainous terrain; 20 percent is desert or steppe; 20 percent is characterized by glaciers, permafrost, and tundra; and 10 percent consists of other types of land with soils unsuitable for cultivation. [1]

Much of the land that is uncultivable is also so inhospitable as to be nearly uninhabitable--the Arctic and Antarctic, steep slopes, swamps, certain desert regions, and so on. For good reason, then, the human population is spread very unevenly over Earth's land surface. People have concentrated--and continue to concentrate today--in the areas that are most hospitable.

Some of the most serious land problems arise from competing, mutually exclusive uses for the same advantageously located pieces of land. Many of our cities, for example, arose in the centers of the best farmland, so some of that valuable resource has been lost beneath highways, suburbs, and airports as the cities have spread. Coastlines are in demand as desirable places to live, as a recreational resource for those who do not live there, as economical sites for electric power plants, as outlets for commerce, and as bases for the utilization of marine resources (Figure 6-1). Unfortunately, the coasts are also the location of relatively fragile communities of plants and animals, such as those in salt marshes and estuaries, upon which much of the productivity of the sea depends (see Chapter 4). Leaving essential ecological systems such as these intact may prove to be one of the most important uses of land; it may also prove to be one of the uses that is least compatible with other human activities. To assume that human beings should dare to exploit every bit of land that appears potentially capable of being exploited would be dangerous (although not unprecedented) arrogance.

In summary, there appears to be a good deal of land available if one does not inquire too carefully about what kind it is. But the most useful sorts of land are already in short supply in most parts of the world.

We note also that United States consumers (and those in many other nations that rely heavily on imports of food or raw materials) must be considered to be "occupying" a good deal of land outside their national boundaries. In this sense, DCs "occupy" coffee plantations in Brazil and rubber plantations in Laos, land used for bauxite mines in Jamaica and copper mines in Zambia, rangeland for cattle and sheep in Argentina, lumber-producing forests in Ivory Coast and Indonesia, and land used for growing soybeans in Colombia and peanuts in Nigeria.

Classification of Land by Climate, Vegetation, and Use

Closer examination of Earth's land resource can take several directions: we can classify it according to climate and vegetation, according to present use, and according to characteristics of soils. In this section of text we consider climate, vegetation, and land use, and we treat soils in the next section.

Vegetation and cultivation. Table 6-1 shows a classification of the land area of the globe into bioclimatic regions, carried out by Soviet scientists who have long been active in the field of biogeography. The term bioclimatic is merely an explicit recognition that regional climates and vegetation patterns are intimately interconnected. An alternative classification strictly by vegetation patterns, corresponding very closely in its categories to the biomes described in Chapter 4, is given in Table 6-2. In these classifications, land refers to the area of continents and islands, including the lakes and streams they contain. In Table 6-1 the lakes and streams constitute a separate category; in Table 6-2 they are apportioned among the biomes in which they occur. When land covered by lakes, streams, and glaciers is subtracted from the category of land area, the global land surface amounts to 133 million square kilometers. As Table 6-2 indicates, about 10 percent of that land surface is under cultivation.

In 1967 the report of the President's Science Advisory Committee panel on the world food supply estimated the

North and Central America	316	21.1	4.66	2.39	0.76	51
South America	245	17.5	6.80	0.77	0.31	11
USSR	255	22.3	3.56	2.27	0.89	64
	---	---	---	---		

Region	Population in 1975 (millions)	Land area (million km^2)			Cultivated area per person (hectares)	Cultivated land as % of potentially arable land
		Total	Potentially arable	Cultivated		
Total	3967	131.5	31.9	13.89	0.35	43

Note: Cultivated area is called by FAO "arable land and land under permanent crops." It includes land under crops, land temporarily fallow, temporary meadows for mowing or pasture, market and kitchen gardens, fruit trees, vines, shrubs, and rubber plantations. Within this definition there are said to be wide variations among reporting countries. The land actually harvested during any particular year is about one-half to two-thirds of the total cultivated land. Populations of some islands omitted.

Source: For population: *1975 Population Data Sheet*, Population Reference Bureau, Inc., Washington, D.C. For land: President's Science Advisory Committee, *The world food problem*; Economic Research Service, United States Department of Agriculture, *Foreign agricultural economic report 298*, Government Printing Office, Washington, D.C., 1974.

amount of potentially arable land on Earth to be 3.19 billion hectares. [2] This amounts to only 24 percent of the total ice-free land area but is perhaps three times the area actually planted and harvested in any given year. About 1.67 billion hectares--more than half of the estimated total--lies in the tropical areas. Warm-temperate and subtropical areas account for another 0.56 billion hectares, and cool-temperate areas account for most of the rest (0.91 billion hectares). The distribution of cultivated and potentially arable land in relation to population and area of continents is shown in Table 6-3. Most of the land classified as potentially arable but not now under cultivation is in Africa and South America.

It is easy to be misled by the foregoing estimate of potentially arable land into an overoptimistic prognosis of how much more land can be brought under cultivation. Several factors make optimism unwarranted. First, rather obviously, the best agricultural land is already being cultivated. Neither subsistence nor commercial farmers are stupid; they farm first where food can be produced with the smallest investments of labor and money (this is the definition of the best land). Most land classified as potentially arable but not now under cultivation suffers from one or more important specific defects: it may be remote, subject to erosion, steep or uneven, rocky, of short growing season, deficient in water, endowed with soils deficient in nutrients, or intractable in other respects. (In Africa, for example, tsetse flies make substantial areas uninhabitable; they carry sleeping sickness and are very difficult to eradicate.) Land with such deficiencies is called marginal, and the difficulty of bringing marginal land into profitable cultivation is the major reason the amount of cultivated land has in fact been expanding so slowly (only about 0.15 percent per year worldwide between 1950 and 1970). [3]

Some of the shortcomings of marginal land can of course be overcome by technology. Irrigation can supply missing water, fertilizer can supply missing nutrients, terracing can level slopes and reduce erosion--but such measures are expensive. The costs of opening new land in seven sample projects in LDCs in the early 1960s ranged from $87 to $2400 per hectare, and the median was $540. [4] If the very optimistic assumption is made that in

[2]President's Science Advisory Committee, *The world food problem*.

[3]University of California Food Task Force, *A hungry world: the challenge to agriculture*.

[4]President's Science Advisory Committee, *The world food problem*, vol. 2, pp. 435-439. In 1974 the United Nations estimated that the total cost of a 20-percent expansion of land under cultivation, renovation of existing irrigated areas, and development of new irrigation schemes would cost $90 billion. For potential gains to be exploited rapidly enough, an annual investment of between $8 billion and $8.5 billion would be required. (*Assessment of the world food situation, present and future*, item 8, provisional agenda, U.N. World Food Conference 1974). Since the United Nations total corresponds to a cost of only $300 per hectare of newly cultivated land, it would appear to be a substantial underestimate.

1975 land suitable to feed four persons per hectare could be brought under cultivation for $1000/hectare, then an investment of $20 billion annually would be required to keep up with present world population growth of about 75 million per year. Of course, the greater the amount of marginal land brought under cultivation, the lower will be the quality of the remaining unused pool and the higher will be the economic costs of further increments to cultivated land.

Another basis for skepticism about the potential for expanding cultivated land is that much of the land classified as potentially arable is already in use as pasture or economically productive forest. Grazing land makes up perhaps two-thirds of the presently uncultivated but potentially arable land worldwide, and accessible forest about one-third. [5] Putting grazing land under the plow delivers a smaller net yield than opening virgin land, since the former is already producing some food. Clearing forest for cultivation increases food production at the expense of actual or potential production of timber, a versatile raw material also subject to increasing demands. (The ecological consequences of changes in land-use patterns are discussed in Chapter 11.)

Land use in the United States. With a land area of 9.16 million square kilometers (about 3.5 million square miles) and a population in 1975 of around 215 million people, the United States has an average population density slightly less than that of the world as a whole-with about 24 people per square kilometer, or 62 per square mile. [6] As noted in Chapter 5, most of these people are concentrated in urban regions on the coasts and around the Great Lakes, leaving large segments of the central United States sparsely populated (by the superficial measure of land area per person). The land area of the forty-eight contiguous states (which for some purposes is more relevant than the area including Alaska and Hawaii) is 7.69 million square kilometers, and the corresponding population density is 28 people per square kilometer--about the same as the global average.

TABLE 6-4
Ownership of Land in the United States (including Alaska and Hawaii)

Owner	Area (million hectares)	Percentage of total
Federal government		
Department of Interior	219	

Owner	Area (million hectares)	Percentage of total
Department of Agriculture	75	
Department of Defense	12	
Other	3	

Total federal	309	33.7
State governments	46	5.0
County and municipal governments	8	0.9
Indian tribes	20	2.2
Individuals and corporations	533	58.2

in Table 6-4. The holdings of the federal government amount to more than a third of the total. Most of the federal land is grazing land and forest, controlled by the Bureau of Land Management in the Department of the Interior and by the United States Forest Service in the Department of Agriculture. Land in private ownership is about 60 percent of the total, while the original occupants of the territory now comprising the United States--tribes of American Indians--control about 2 percent. If Alaska is excluded, the fraction of territory held by the federal government falls to about 20 percent, Indian land is 3 percent, and the fraction in private hands rises to about 70 percent. [7]

The uses of land in the United States around 1970 are summarized in Table 6-5. The category labeled "cropland" represents the sum of cropland actually in use as well as that which is deliberately held idle for economic or political reasons. Some 12 to 14 percent of the cropland total was idle in the early 1970s, but essentially all of it had been pressed into service by 1975. [8] Urban and transportation uses of United States territory appear

[5]Borgstrom, *Too many*, p. 299.

[6]The area given is without lakes and rivers; with them, the figure is 9.37 million square kilometers. (United States Department of Commerce, *Statistical abstract*, 1975), p. 5.

rather minor, as they involve less than 3 percent of the total land area, but it should be noted that some expanding urban centers are located in the midst of or adjacent to the best agricultural lands. The nation can ill afford to lose those prime croplands. California, where the problem of such encroachment has been particularly severe, had lost about 700,000 hectares of prime agricultural land to cities, suburbs, and highways by 1975. And of California's 8.2 million hectares of remaining prime and "potentially prime" agricultural land, another 400,000 hectares were zoned for urban development by 1985. [9] The loss of arable land to urbanization nationwide has been estimated at 5.1 million hectares between 1958 and 1974. [10]

Soil

The nature and quantity of vegetation that can be grown on a given piece of land depend strongly on the characteristics of the soil. Study of the properties and distribution of soil types is therefore essential both for an understanding of existing patterns of vegetation and for determining strategies and prospects for success in increasing the yield of plant materials used by human society.

Soil functions as a source and as a storage reservoir of water and mineral nutrients for plants, as a medium in which chemical transformations influencing the availability of those nutrients takes place, and as an anchor for the support of terrestrial as well as many aquatic plants. In composition, it is a mixture of inorganic minerals, organic matter, soil animals and microorganisms, gases, and, of course, moisture. [11]

Soil origins and structure. As described in Chapter 2, the main source of the inorganic particles in soil is the weathering of the various types of rock--igneous, sedimentary, metamorphic--by exposure near Earth's surface to temperature changes; the physical action of ice, water, and roots; and chemical attack by rainwater, surface water, and atmospheric gases. Uplifting of unconsolidated sediments from the seafloor is another, rarer source of soil materials. These sources of the mineral components of soil are called *parent materials*; the parent materials can be either *residual* (meaning the soil is formed where the weathering takes place) or *transported* (meaning the materials have been moved to the place of soil formation by the action of wind, water, ice, gravity, or a combination of these). *Alluvial* is the term given to soils deposited by river flow. *Colluvial* refers to soils whose parent materials were deposited by landslides.

Most soils are not uniform in vertical profile but rather are characterized by zones called *horizons*. The uppermost layer or zone is called the *A horizon*. It is the home of most of the soil organisms and the location of the greatest abundance of roots. It has usually been somewhat depleted of soluble substances by leaching. The next zone proceeding downward is the *B horizon*. It receives downward-moving minerals leached from above and, often, upward-migrating substances from weathered parent materials below; therefore it is called the zone of accumulation. The *C horizon* consists of the weathered rock material. The bedrock below, usually but not always the true parent material, is the *D horizon*.

[11] The best introductory consideration of soil we have found (on which much of this section is based) is J. Janick, R. Schery, F. Woods, and V. Ruttan , *Plant science*, chapters 12 and 16.

[9] California Land Use Task Force, *The California land*, Chapter 3.

In soil studies more detailed than our treatment here, the horizons are often subdivided by the addition of subscripts running 1 to 3, top to bottom, (that is, A_1, A_2, A_3). In that notation, the fresh dead organic matter (called *litter*) is the A_{00} horizon; and the partially decomposed organic matter (called *duff*), just above the A_1 horizon, is the A_0 horizon.

Soils in which the layered structure is well developed and distinct are called *zoned* or *normal*; those without this well-developed vertical profile are called *azonal*. Alluvial and colluvial soils are often azonal.

Another important characteristic of soil is *texture* (meaning the size of the individual mineral particles). An international classification system defines particles with diameter less than 0.002 millimeters as *clay*, those with diameters between 0.002 and 0.02 millimeters as *silt*, and particles between 0.02 and 2 millimeters in diameter as *sand*. [12] The term *loam* is used to

describe mixtures of the different size classes of soil particles. A standard classification scheme based on the proportions of clay, silt, and sand in soil is illustrated in Figure 6-2.

Soil texture influences the rate at which water percolates through soil and the amount of water a soil can contain. Coarse soils are characterized by rapid infiltration, and hence low surface runoff, but they cannot retain much water. The fine-textured clays are penetrated by water only slowly but have a high storage capacity. The *pore space* in soil, which is filled in varying proportions by water and air, is typically around 50 percent in many kinds of soils; what is more important than the total volume of the pore space is the characteristic size of individual pore spaces. Few large pores make a much less satisfactory soil than many small ones. Soil organisms and organic matter are crucial in maintaining the better situation by preventing excessive coagulation of soil particles into large clods.

Soil organic matter. Dead organic matter in soil not only influences pore size, but itself serves as a sponge that soaks up and retains moisture. Through its decomposition by bacteria, it acts also as a source of carbon dioxide, water, and mineral elements. Certain constituents of

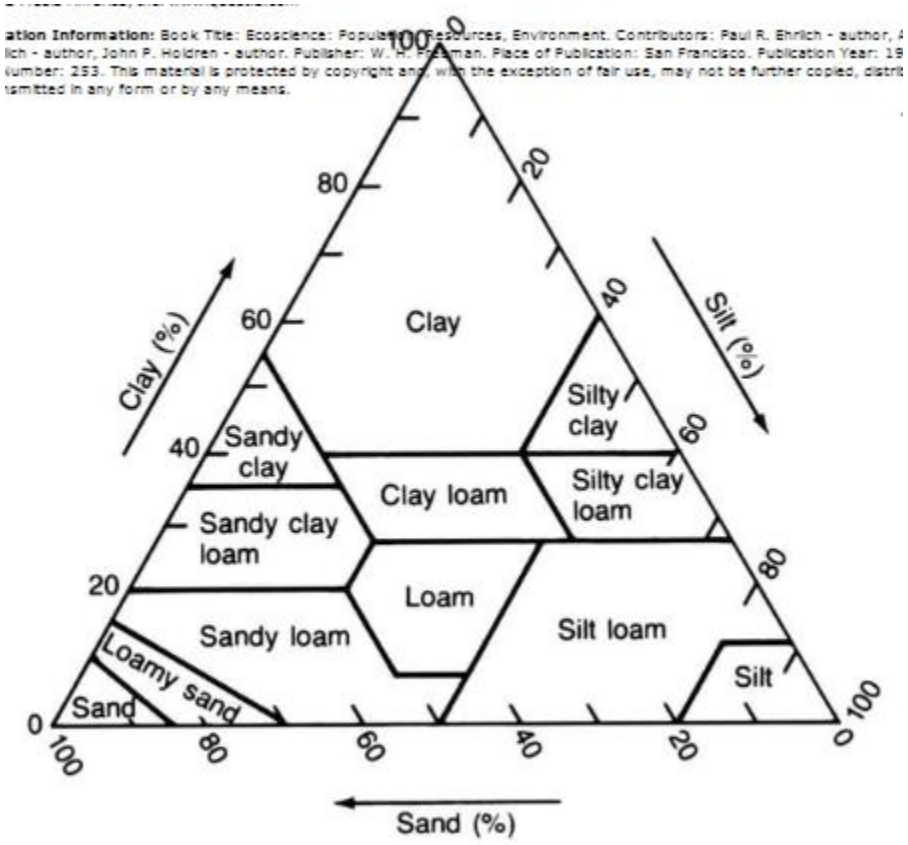

FIGURE 6-2 Soil classification by texture. (From Janick et al. Data from U.S. Department of Agriculture.)

dead organic matter, such as waxes, fats, lignins, and some proteinaceous materials, resist decomposition and are converted instead into the dark colloidal substance called *humus*. (A colloidal substance consists of particles larger than molecules but small enough to remain

suspended in solution.) The physical and chemical properties of humus affect the character of soil out of proportion to its fraction by weight, in part because of the large surface-to-volume ratio associated with particles of such small size. The fraction by weight of dead organic matter in soil is typically in the range of 0.4 to 1.1 percent. [13]

Living soil organisms (other than the roots of plants) make up an even smaller fraction of the mass of soil (typically 0.1 percent or less). [14] (In absolute terms this is not a small quantity, however, as it amounts to several tons of living organisms per hectare.) These include: bacteria and algae, whose critical roles in nutrient cycles are described in Chapter 3; fungi, which perform some of the same functions as bacteria in nutrient cycles, as well

[12] See Janick et al., *Plant science*, p. 219, for a more complete classification, ranging up to "boulder" (diameter greater than 256 millimeters).
[13] P. Sanchez and S. Buol, *Soils of the tropics and the world food crisis*.
[14] Janick et al., *Plant science*, p. 224.

as being the principal producers of humus; and larger organisms such as mites, millipedes, insects, and worms, which physically cultivate the soil and help break down organic litter (see also Chapter 11).

Soil chemistry. The chemistry of a soil is governed in large measure by the properties of its clay particles and the similarly tiny particles of humus. Clay particles are platelike, with a layered internal structure that leaves negative electric charges arrayed on the surfaces of the plates. Humus particles are also negatively charged on their exteriors. These electrical properties account for the characteristic of soil exchange capacity (the ability to retain and exchange cations such as H^+, Ca^{++}, Mg^{++}, K^+, and Na^+).

This function is crucial in governing soil fertility. Without the negative charges on particles of clay and humus, the positively charged nutrient cations released to the soil by the decay of organic matter or added to the soil in fertilizer would quickly be leached away, out of reach of plant roots. Bound to the negative charges on clay and humus, however, those ions are made available to plants gradually when they are replaced at the negatively charged sites by hydrogen ions from the soil. There is actually a replacement heirarchy--hydrogen, calcium, magnesium, potassium, sodium--in which each ion listed tends to displace any that appears to its right in the list, if the two are present in equal amount; hydrogen tends to replace all of the metallic ions. If a particular cation is present in very large quantities, however, it can even replace ions to its left in the heirarchy by sheer force of numbers (that is, by mass action, to use chemical terminology).

The magnitude of exchange capacity is merely a matter of how many negatively charged sites are available in a soil. The unit of measure is milliequivalents per 100 grams, which means the number of milligrams of hydrogen ion (H+) that will combine with 100 grams of dry soil. Different types of clay have widely varying exchange capacities (in the range of from 10 to 100 milliequivalents/100 g), whereas humus has the greatest of all (from 150 to 300 milliequivalents/100 g). [15] This chemical role of humus is perhaps even more crucial than the

roles humus plays in maintaining soil texture and retaining water. The importance of all three functions provides ample reason for viewing with alarm the depletion of soil humus by certain agricultural practices (see Chapter 11).

A major source of hydrogen ions in the soil is the production of carbonic acid from the solution of carbon dioxide in water. Another source is nitric and sulfuric acid added by polluted rainfall or formed from nitrogen and sulfur compounds produced by decomposition of organic matter or added in fertilizer. Yet another is organic acids exuded by plant roots or produced by decomposition. Excessive concentrations of hydrogen ions (indicated by low pH--that is, strongly acidic soil) replace nutrient cations on clay and humus colloids faster than those nutrients can be taken up by plants; the result is that the nutrients are leached away. Acidic soils are common in humid climates. A shortage of hydrogen ions (high pH--strongly alkaline soil), on the other hand, can leave some nutrient ions too tightly bound to clay and humus to be absorbed by plants. Other nutrients, such as iron and manganese, become trapped in compounds that are extremely insoluble in basic solutions.

Crops differ rather widely in the pH ranges they tolerate. Most of the grains flourish best in slightly acidic soil, potatoes and berries in quite acidic soil, alfalfa and asparagus in neutral soil.[16] When soil is too acidic for the crops desired, it is common practice to neutralize the soil by adding lime.

Classification of soils. Differences in soils around the world arise from the mineral compositions of the parent materials and from differing climatic conditions, which together influence the organic and inorganic processes of soil development. Several major types of soil-forming regimes have been identified: the main ones are podzolization, laterization, calcification, gleization, and salinization.

Podzolization is the set of processes associated in its extreme form with cool climates, abundant precipitation, and acid upper soil layers strongly leached of mineral nutrients and the oxides of iron and aluminum. The nutrients, oxides, and humus accumulate in the deeper

[15]Janick et al., *Plant science*, p. 222, see also A. N. Strahler and A. H. Strahler , *Environmental geoscience*, Chapter 11.
[16]Janick et al., *Plant science*, p. 309.

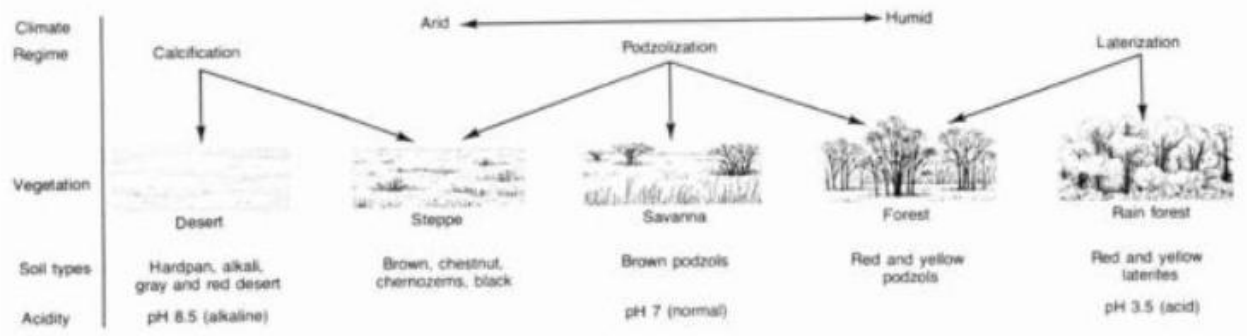

FIGURE 6-3 Relation of soil-forming regimes, vegetation, and soil types. (Adapted from Janick et al., 1974.)

layers. Fungi are the main soil-forming organisms. Those soils are characteristic of northern forests, although they exist in some circumstances well into temperate and subtropical regions.

Laterization is a set of processes associated with the humid tropics and subtropics. High mean temperatures in these regions permit sustained and rapid bacterial action, which minimizes the accumulation of plant litter and humus. In the absence of the organic acids associated with humus, the soil is neutral, rendering the oxides of iron and aluminum relatively insoluble; those oxides accumulate in the upper soil horizons as hard clays and rocklike material called *laterite* (from the Latin for brick), a mixture of $Fe_2O_3 \cdot nH_2O$ and $A1_2O_3, \cdot H_2O$.

Calcification occurs in climates where evapotranspiration exceeds precipitation. There is little leaching of the metallic cations, and microbial activity is slow, so the soils tend to be alkaline and rich in humus. Calcium carbonate in solution is carried upward from the water table by capillary action in the season of little surface moisture and is left in the upper soil horizons in solid form when the water evaporates.

Gleization is the set of processes characteristic of poorly drained environments in cool or cold climates. The low temperatures permit heavy accumulation of organic matter, and the excessive wetting produces a sticky clay underneath.

Salinization is the regime characterized by accumulation of highly soluble salts in the soil. This situation arises naturally from poor drainage in regions of low precipitation and high temperatures (deserts), and it can be brought about by faulty agricultural practices-irrigating too parsimoniously in dry climates, or using salt-laden irrigation water. Soils in the salinization regime are weakly to strongly alkaline. [17]

The geographical boundaries separating the spheres of influence of the different soil-forming regimes are often not distinct. An enormous variety of soils results from variations within regimes and from overlaps between regimes, and a quite complicated classification scheme and taxonomy for soils (the United States comprehensive system of soil classification) has been devised to help soil scientists cope with this diversity. [18] Figure 6-3 is a schematic illustration of how a few of the principal *soil types* emerge from the soil-forming regimes. Characteristics of a somewhat broader selection of *soil types* encountered in the literature of soil science and biogeography are summarized in Box 6-1. [19]

A somewhat more utilitarian soil classification scheme, widely used in the United States, is based on the capability of a soil to sustain various uses--the categories run from Class I (the best soils for agriculture) to Class VIII (suitable only for recreation and wildlife). [20]

Exhaustion, erosion, and regeneration. The limitations in the extent and quality of the soils with which civilization began would be serious enough,

[17]For more extensive treatments of these regimes, see Strahler and Strahler, *Environmental* chapter 12; Janick et al., *Plant science*, chapter 12; C. B. Hunt, *Physiography*, chapter 6.

BOX 6-1 Characteristics of Common Soils

	Pedalfers (soils of humid regions)
Tundra soil	Dark-brown, peaty layer over gray horizons mottled with rust; substrate permanently frozen. *Climate:* frigid, humid. *Vegetation:* lichens, mosses, herbs, shrubs. *Process:* gleization (development of organic-rich, sticky, compact, clayey layer due to excessive wetting).
Alpine meadow	Dark-brown, organic-rich layer grading down at 30 to 60 centimeters to gray and rusty soil, streaked and mottled. *Climate:* cool temperate to frigid. *Vegetation:* grasses, sedges, herbs. *Process:* gleization, some calcification (deposition of calcium carbonate).
Bog and half-bog	Brown, dark-brown, or black peaty material over soils of mineral matter mottled gray and rust. *Climate:* cool to tropical; generally humid. *Vegetation:* swamp, forest, sedges, or grasses. *Process:* gleization.
Podzol, brown podzol, gray-brown podzol	Leaf litter over a humus-rich layer over a whitish-gray to grayish-brown leached layer; B horizon clayey and brown. Acid. *Climate:* cool, temperate, humid. *Vegetation:* northern forests, coniferous and/or deciduous. *Process:* podzolization (bases--Al and Fe--leached more than silica from A horizon and accumulated in B horizon).
Red and yellow podzol	Thin, dark organic layer at surface over yellow-gray or gray-brown leached layer 15 to 90 centimeters thick, over clayey B horizon over parent material mottled red, yellow, and gray. *Climate:* warm

	Pedalfers (soils of humid regions)
	temperate to tropical humid. *Vegetation:* coniferous forest or mixed deciduous and coniferous. *Process:* podzolization superimposed on lateritization (silica leached more than the bases).
Prairie and reddish prairie	Brown in the north; reddish-brown toward the south. Grades down to lighter-colored parent material with no horizon of carbonate accumulation. *Climate:* cool temperate to warm temperate, humid. *Vegetation:* tall grass. Process: weak podzolization.
	Pedocals (soils of arid regions)
Chernozem	Black to gray-brown, crumbly soil to a depth of 90 to 120 centimeters, grading through lighter color to a layer of carbonate accumulation. *Climate:* subhumid, temperate to cool. *Vegetation:* tall grass. *Process:* calcification (accumulation of carbonates in lower horizons).
Chestnut, brown, reddish chestnut, and reddish brown	Brown to black surface layer in north; reddish in south; lighter color at depth and grading down to layer of carbonate accumulation. Chestnut thinner than chernozem, and brown thinner than chestnut. *Climate:* semiarid; cool to hot. *Vegetation:* mostly short grasses in north; grasses and shrub in south. *Process:* calcification.
Desert, sierozem, red desert	Light gray or brown in north; reddish in south; low in organic matter; carbonate layer generally within 30 centimeters of the surface. *Climate:* arid, cool to hot. *Vegetation:* mostly desert shrubs. *Process:* calcification.
	Other soils
Rendzina	Dark-gray or black, organic-rich, surface layers over soft light gray or white calcareous material derived from chalk, soft limestone, or marl. *Climate:* variable. *Vegetation:* mostly grassland. *Process:* the lime in these soils is derived from the parent materials.
Laterite	Thin organic layer over reddish, strongly leached soil, generally clayey

	Pedalfers (soils of humid regions)
	and enriched in hydrous alumina or iron oxide or both; low in silica; generally many feet thick. *Climate:* tropical wet. *Vegetation:* mostly forest. *Process:* lateritization (see Red and Yellow Podzol).
Saline and alkaline	Soils in which salts including alkali have accumulated, generally in poorly drained areas. *Climate:* variable, but commonly arid or semiarid. *Vegetation:* salt-tolerant species or lacking. *Process:* salinization or alkalization (salts deposited in soil as a result of evaporation).

Source: Hunt, *Physiography of the United States*.

considering the demands that a growing population is placing on this resource. Those limitations are aggravated, however, by the loss of needed soil by urbanization, by erosion, and by the depletion or exhaustion of the fertility of some soils.

Depletion of soil nutrients and humus need not follow from intensive cropping, as demonstrated by the continued fertility of rice paddies in Asia that have been cultivated continuously for thousands of years. That success has been due to several factors: the high clay content of the soil, the annual augmentation of the alluvial topsoil in the paddies by silt eroded from hilltops, the nitrogen fixation by blue-green algae in the flooded paddies, and the practice of returning human and animal waste to the soils from which the nutrients therein came. [21] Intensive cultivation without either natural or artificial augmentation of nutrients can only exhaust soil fertility, however, and even the use of inorganic fertilizers alone does not prevent the depletion of the humus (see also Chapter 11). [22] The practical application of the detailed study of soils is to discover both the potential and the limitations of different soil types for the production of vegetation, and the procedures appropriate to using each type as a permanent or renewable resource rather than as a "mine" to be exhausted and abandoned.

Perhaps even more serious than urbanization and loss of fertility as a global threat to soils is erosion (the removal of the body of the soil itself by the action of wind and, especially, water). Cultivation of soil increases the natural rate of erosion, even when it is conducted properly on good land. Data from the United States Department of Agriculture indicate that erosion rates on cultivated land may be 100 times those on forested land receiving the same rainfall. [23] One of the most careful analyses of erosion in the United States and worldwide suggests that the transport of sediment from the land to the sea has increased more than threefold in the United States over the prehuman rate and by a factor of about 2.5 worldwide. [24] (The study estimated the sediment loads in the 1960s as 180 metric tons per year per average square kilometer of ice-free land globally and 250 metric tons per square kilometer per year in the United States.) The map in Figure 6-4 indicates the cumulative toll erosion has taken in the forty-eight contiguous states.

Loss of soil by erosion is a significant problem for the United States and other industrial nations, but it is worse by far in the poor countries. There even the modest degree of control exerted in the United States by the Soil Conservation Service is often missing, and the pressure of rapid population growth makes itself felt in overgrazing, deforestation for firewood, and the clearing of steep slopes for cultivation. The result has been an appalling increase in rates of erosion both by wind (primarily in desert lands) and by water, precisely in those parts of the world that can least afford the loss. [25] We return to the intertwined problems of cultivation practices, climate, and the loss of soil or soil fertility in Chapter 11.

The rate at which lost soil can be regenerated by natural processes varies enormously, depending on climate, other factors influencing biological activity, and availability of inorganic raw materials. Under very favorable circumstances, in which abundant new material is provided in the form of windborne or waterborne sediment or volcanic ash, a foot of soil may form in as little as from 50 to 100 years. [26] In the more common situation, in which new soil must be formed from parent rocks, the time scale is more likely to be in the range of from 200 to 1000 years per centimeter of soil -- perhaps 10,000 years or more for a foot of soil. [27] In most circumstances, then, the loss of soil is irreversible on a time scale of practical human interest.

WATER

"Water is the best of all things," said the Greek poet Pindar. It is also, in the broad sense, a renewable resource, continually reprocessed and delivered to the land by the hydrologic cycle described in Chapter 2.

The central role of water in sustaining the life processes of the biosphere has been discussed in Chapter

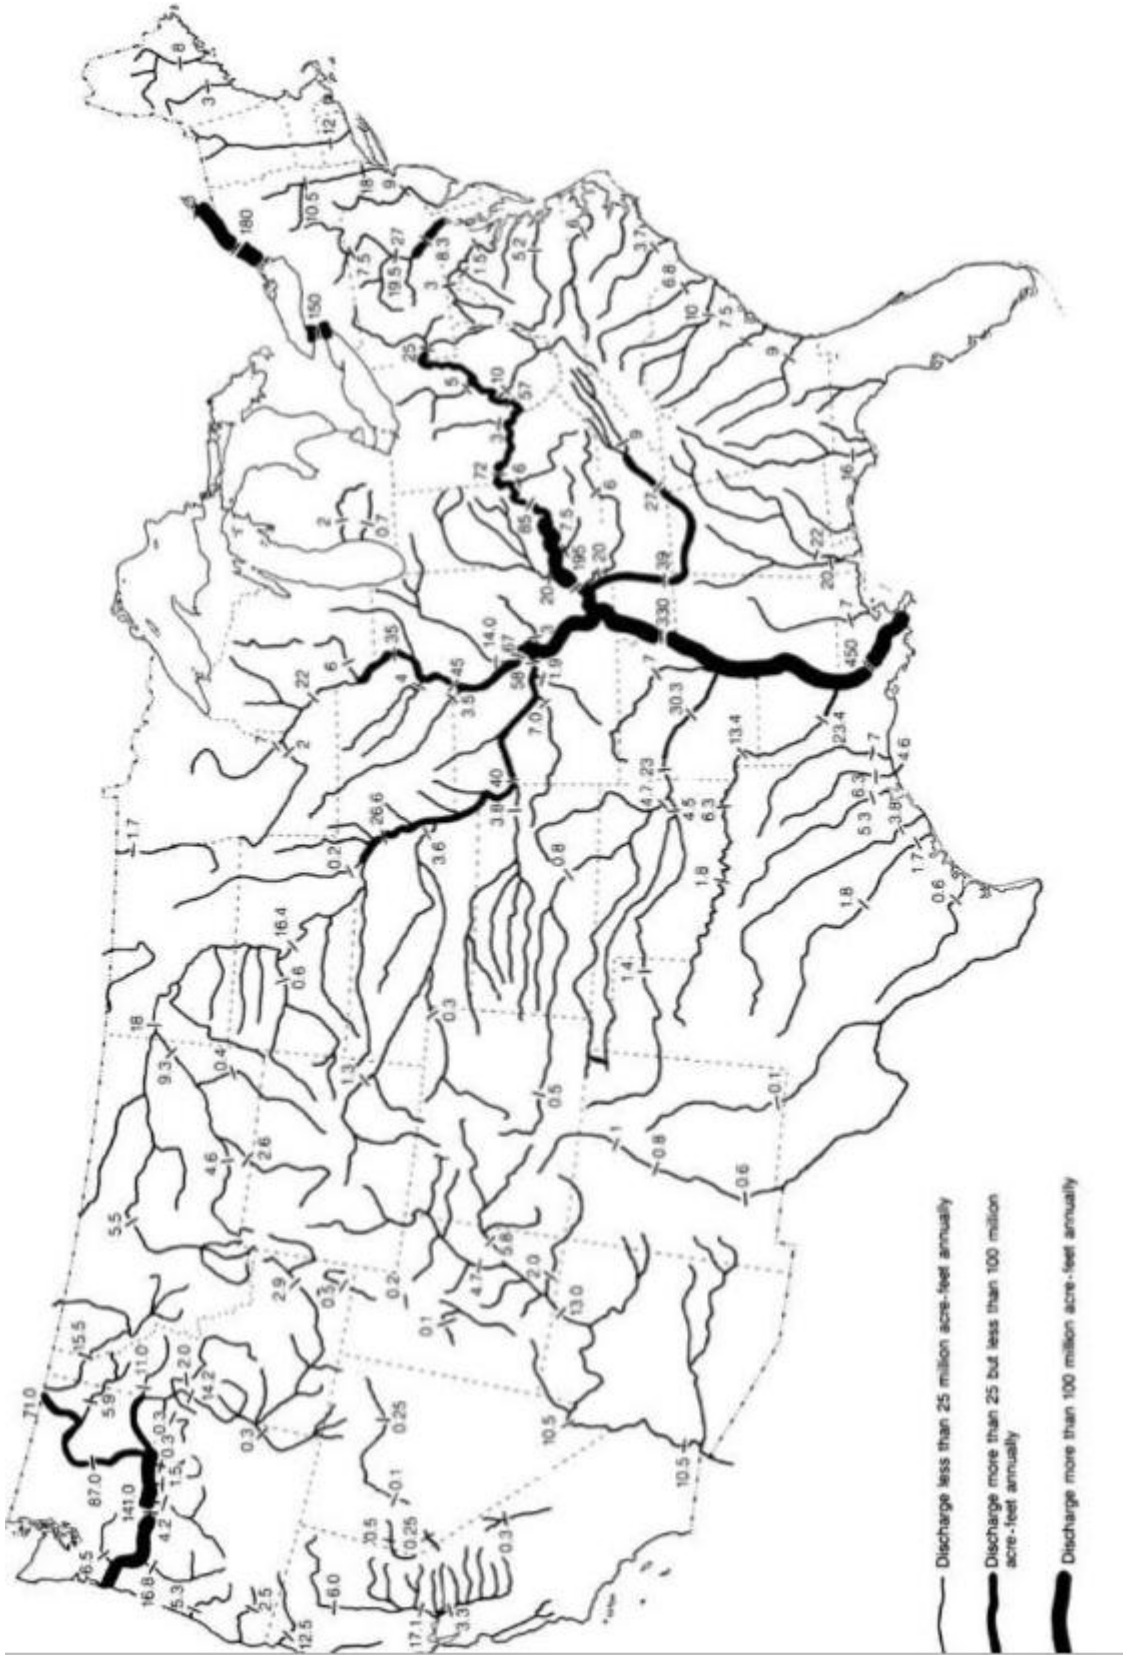
Cumulative effects of erosion in the United States. (Adapted from Hunt, 1974.)

3, and, from a different point of view, in the foregoing section of text on soil. Here we take up the availability and functions of water as it is used directly as a resource by civilization: for changing the natural pattern of biological productivity through irrigation; for drinking, cooking, washing, and bathing; as an industrial raw material and coolant; as a flow resource for diluting and removing waste materials, turning hydroelectric generators, and providing transportation and recreation.

We survey here the availability of water for these purposes, present and projected patterns of water use and supply, and the nature and costs of large-scale watersupply technology. Pollution of water supplies by the activities of civilization is taken up in Chapter 10.

Availability

As we discussed in Chapter 2, the amount of water available for runoff on the surface and underground (including not only what reaches the oceans but also net recharge, if any, of surface reservoirs and underground aquifers) is simply the difference between what falls as precipitation and what returns to the atmosphere as evapotranspiration. The annual runoff from major regions of the world is summarized in Table 6-6. (There is a range of about ± 25 percent in the figures published by various scholars; the estimates in Table 6-6 fall at the high end of the range.) The runoff of the forty-eight contiguous states is about 1700 cubic kilometers per year,



Discharge less than 25 million acre-feet annually
Discharge more than 25 but less than 100 million acre-feet annually
Discharge more than 100 million acre-feet annually

FIGURE 6-5 Flow of rivers in the United States (millions of acre-feet per year). (Adapted from Hunt, 1974.)

TABLE 6-6
Freshwater Runoff in Major Regions of the World

Region	*Annual runoff* (km^3)	*Annual runoff* (*acre feet, millions*)
Africa	7,900	6,400
Asia *	8,000	6,500
Australia	390	320
Europe *	1,200	970
North and Central America	8,200	6,600
South America	16,000	13,000
USSR	4,200	3,600

*Excluding USSR.

Source: Calculated from Study of Man's Impact on Climate, *Inadvertent climate modification*, p. 97; and I. P. Gerasimov, D. L. Armand, and K. M. Yefron, eds., *Natural resources of the Soviet Union*, p. 15.

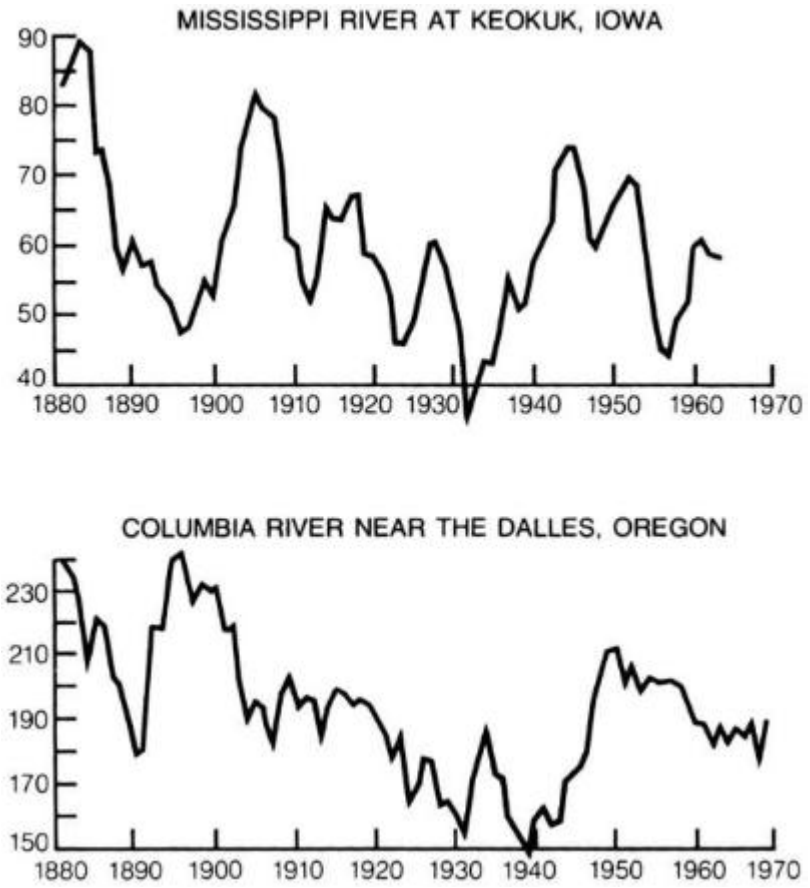


FIGURE 6-6 Historical variation in mean discharge of two American rivers. Data are five-year running averages, plotted at one-year intervals, of mean discharge rate in thousands of cubic feet per second (cfs). One thousand cfs = 2.45 million cubic meters per day = 723,000 acre-feet per year. (Adapted from Leopold, 1974.)

only a modest fraction of the total for North America and Central America together. Including Alaska and Hawaii, the United States runoff is about 2000 cubic kilometers per year. [28]

Dividing the runoff figures by the human population gives what appears at first glance to be a reassuring picture. For example, the runoff for the forty-eight contiguous states works out to about 4700 billion liters per day, or roughly 22,000 liters per inhabitant per day. The global figure is around 31,000 liters per person per day, based on a population of 4 billion.

Geographical and temporal distribution. These often-cited figures are highly misleading, however, because the water is very unevenly distributed, both geographically and in time. Worldwide, much of the runoff is in sparsely populated regions, as exemplified by the vast drainages of northern Canada (the Mackenzie and other rivers), Siberia (the Ob, Yenisey, and Lena), and the jungle of the Amazon. In the United States, the western half of the land area gets only about a third of the runoff. [29] (Flows of major United States rivers appear in Figure 6-5.)

Even more troublesome than the inconvenient geographical distribution of runoff is its uneven distribution in time. Floods and droughts, after all, are age-old problems with water supply.

Difficulties are caused both by the generally predictable annual cycle of runoff, wherein much of the total flow is concentrated in a few months of wet season or spring melt, and by unpredictable year-to-year variations in the exact timing of this pattern and in the total annual flow. The fraction of the total runoff concentrated in a flood period lasting two or three months is from 40 to 70 percent over much of the United States. [30] The problem of variation in total annual flow from year to year in two of America's major rivers is illustrated in Figure 6-6.

A large variation in runoff from month to month and from day to day means that the minimum daily flow that

[28] For various runoff estimates, see Menard, *Geology*, chapter 17; Strahler and Strahler, *Environmental* chapter 13; Hunt, *Physiography*, chapters 5 and 9; T. Van Hylckama, *Water resources*. One cubic kilometer (a billion cubic meters) is 264 billion gallons or 810,000 acre-feet.

[30] Hunt, *Physiography*, p. 75.

Box 6-2 Availability and Dependability: How Much Water Can One Count On?

Several indicators are in widespread use that represent how much water is *usually* available or how much can be made available in theory. (Considerable confusion has been engendered by the inconsistent use of terminology and definitions for these measures in the literature on water.) For example, the United States Geological Survey presents data for the *annual flow exceeded 9 years out of 10*. This figure amounts to about 1000 cubic kilometers for the forty-eight contiguous states as a whole (about 60 percent of the average annual flow), but in some drainage basins within the forty-eight states (those of great variability) the figure is less than a third of the *average* flow. [*] (It may be useful to ponder the difference between average flow and flow exceeded 9 years out of 10 for the individual rivers in Figure 6-6.)

A different indicator is *dependable flow*, which according to the water experts at Resources for the Future (a respected private think tank in Washington, D.C., which deals with resource questions) means the flow that is equaled or exceeded every day of every year. [**] Because of seasonal and year-to-year variations, this would be a very small fraction of annual flow indeed, without society's intervention in the form of dams to store water and regulate flows. As it is, figures for dependable flow by this definition are rarely encountered. One finds, instead, figures for the flow available 50 percent of the time or 90 percent of the time or 95 percent of the time (that is, flow rates equaled or exceeded 50 out of 100 days, and so forth). For example, the flow

available 50 percent of the time for the 48 contiguous states, with the storage facilities of the mid-1950s, was 2.2 billion cubic meters per day -- less than half of the daily average obtained by dividing the average annual flow by 365. † The flow available 95 percent of the time, according to the same analysis, was only 0.35 billion cubic meters per day, or about 7 percent of the average runoff. (The reservoir storage associated with these availabilities was 220 cubic kilometers, or 280 million acre-feet.) As noted in the text, the storage system and available flows had been much improved by 1970.

Finally, Resources for the Future defines *maximum dependable flow* as the average daily flow (the annual flow divided by 365) minus the evaporation losses that would occur in a system of reservoirs large enough to spread the flow out completely evenly over a year. If dependable supply is defined as above, this is literally the largest value it could have. Recent estimates of the maximum dependable flow for the fortyeight states are around 3.6 million cubic meters per day, or 80 percent of the average daily flow. In other words, evaporation losses from a system of reservoirs extensive enough to parcel out United States runoff uniformly over the year would amount to 20 percent of the runoff.

can be counted on year-round -- or even most of the time -- is much smaller than the average daily flow calculated by dividing the yearly figure by 365 (see Box 6-2). To even out the flow by catching floodwaters and releasing them during dry spells, civilization has strung dams along most of the world's major rivers. As the network of dams grows more extensive and the associated reservoirs grow larger, the dependable flow becomes a bigger fraction of the average flow. The flow available 98 percent of the time (98 days out of 100) in the forty-eight contiguous states in 1970 was about 1.5 billion cubic meters per day (about a third of the average flow). [31]

It is important to recognize that increases in available flow achieved by means of reservoirs are bought at the expense of increased loss by evaporation, because of the larger surface area of the reservoirs. In other words, regularity increases; total flow decreases. This problem of evaporation is especially severe in the southwestern United States and other and regions. The evaporative loss at Lake Mead on the Colorado River, alone, was found to be 1 cubic kilometer per year (about 4500 liters for every person in the United States), [32] and losses behind Egypt's Aswân High Dam have far exceeded initial estimates.

BOX 6-3 Sources and Effects of Dissolved Constituents and Physical Properties of Natural Water

Constituent or physical property	Source or cause	Significance
Silica (SiO_2)	Dissolved from practically all	Forms hard scale in pipes and boilers

Constituent or physical property	Source or cause	Significance
	rocks and soils, usually 1 to 30 ppm	and on blades of steam turbines.
Iron (Fe)	Dissolved from most rocks and soils; also derived from iron pipes. More than 1 or 2 ppm of soluble iron in surface water usually indicates acid wastes from mine drainage or other sources.	On exposure to air, iron in groundwater oxidizes to reddish-brown sediment. More than about 0.3 ppm stains laundry and utensils. Objectionable for food processing. Federal drinking water standards state that iron and manganese together should not exceed 0.3 ppm. Larger quantities cause unpleasant taste and favor growth of iron bacteria.
Calcium (Ca) and magnesium (Mg)	Dissolved from most soils and rocks, but especially from limestone, dolomite, and gypsum.	Cause most of the hardness and scale-forming properties of water. Waters low in calcium and magnesium are desired in electroplating, tanning, dyeing, and textile manufacturing.
Sodium (Na) and potassium (K)	Dissolved from most rocks and soils.	Large amounts, in combination with chloride, give a salty taste. Sodium salts may cause foaming in steam boilers, and a high sodium ratio may limit the use of water for irrigation.
Bicarbonate (HCO_3) and carbonate (CO_3)	Action of carbon dioxide in water on carbonate rocks.	Produce alkalinity. Bicarbonates of calcium and magnesium decompose in steam boilers and hot-water facilities to form scale and release corrosive carbon dioxide gas. In combination with calcium and magnesium cause carbonate hardness.

Constituent or physical property	Source or cause	Significance
Sulfate (SO_4)	Dissolved from many rocks and soils.	Sulfate in water containing calcium forms hard scale in steam boilers. Federal drinking water standards recommend that the sulfate content not exceed 250 ppm.

Building a system of water storage and regulation that can deal with year-to-year variations in total runoff is vastly more difficult than evening out the peaks and valleys within a single year, because a much larger amount of water would have to be stored. Even determining the average annual flow can be a difficult and precarious business, as the famous case of the Colorado River Compact illustrates. The compact, signed in 1922, divided up the rights to Colorado River water among seven contending states (Mexico was added later), based on the supposition that the average annual flow at Lees Ferry would be 22.8 billion cubic meters. (The treaty allocated absolute amounts of water, not percentages.) The estimate of the available flow was based on the record before 1922. Unfortunately for the effectiveness of the compact, a long dry spell was then entered; the average flow at Lees Ferry was 16 billion cubic meters per year in the period between 1930 and 1964, and it may well not return in this century to the value assumed by the compact in 1922. [33]

Groundwater. Much cheaper than building reservoirs to even out the variations of surface runoff is the time-honored technique of falling back on natural underground water storage -- groundwater -- in times of low surface flows. Reservoirs of groundwater (aquifers) are recharged naturally by seepage from the surface and underground flows at rates that depend on the permeability of surrounding rock and soil. Generally the residence time of groundwater is thousands of years, so

[33]See, for example, Menard, *Geology*, p. 494.

Constituent or physical property	Source or cause	Significance
Chloride (Cl)	Dissolved from rocks and soils; present in sewage and found in large amounts in ancient brines, seawater, and industrial brines.	In large amounts in combination with sodium gives salty taste. In large quantities increases the corrosiveness of water. Federal drinking water standards recommend that the chloride content not exceed 250 ppm.
Dissolved solids	Chiefly mineral constituents dissolved from rocks and	Federal drinking water standards recommend

Constituent or physical property	Source or cause	Significance
	soils, but includes organic matter.	that the dissolved solids not exceed 500 ppm. Waters containing more than 1000 ppm dissolved solids are unsuitable for many purposes.
Hardness as $CaCO_3$ (calcium carbonate)	In most water, nearly all the hardness is due to calcium and magnesium.	Consumes soap before a lather will form. Deposits soap curd on bathtubs. Hard water forms scale in boilers, water heaters, and pipes. Hardness equivalent to the bicarbonate and carbonate is called carbonate hardness. Any hardness in excess of that is called noncarbonate hardness.
Acidity or alkalinity (hydrogen ion concentration, pH)	Acids, acid-generating salts, and free carbon dioxide lower pH. Carbonates, bicarbonates, hydroxides and phosphates, silicates, and borates raise pH.	A pH of 7.0 indicates neutrality in a solution. Values greater than 7.0 denote increasing alkalinity; values less than 7.0 indicate increasing acidity. Corrosiveness of water generally increases with decreasing pH.
Dissolved oxygen (O_2)	Dissolved in water from air and from oxygen given off in photosynthesis by aquatic plants.	Dissolved oxygen increases the palatability of water. Under average stream conditions, 4 ppm is usually necessary to maintain a varied fish fauna in good condition. For industrial uses, zero dissolved oxygen is desirable to inhibit corrosion.

Source: Hunt, *Physiography of the United States*.

recharge of seriously depleted aquifers is very slow. [34]

When the rate of withdrawal of groundwater from an aquifer exceeds the rate of recharge over a period of time, the water table falls. The cost of drilling wells and of pumping out the water increases rapidly with the depth of the well, so if a water table falls too far below the surface, extracting the water becomes altogether uneconomical. In practical terms, the water in such cases is a nonrenewable resource that has been mined out. This has happened in parts of Arizona and is underway on the high plains of Texas, where extensive use of groundwater has dropped the water table as much as 30 meters. [35] Smaller but still serious declines in water tables have occurred in other parts of the United States and the world. Such declines not only represent the long-term loss of the accessible groundwater resource, but they also can lead to the reduction of

surface streamflow, the drying-up of ecologically important ponds and bogs, the intrusion of salt water into freshwater aquifers in coastal regions, and subsidence. [36]

Water quality. An integral part of the issue of availability of water is its quality. Quite independent of the pollutants that have been added to water by civilization (which are discussed in Chapter 10), the quality of water varies widely because of natural factors. Aspects

[34]Menard, *Geology*, p. 483; Strahler and Strahler, *Environmental*, pp. 305-316.
[35]Van Hylckama, *Water*, p. 153; Menard, *Geology*, p. 491.
[36]Strahler and Strahler, *Environmental*, pp. 312-313; J. F. Poland, Land subsidence in the western U.S., in *Focus on environmental geology*, R. W. Tank, ed., Oxford University Press, London 1973.

of quality that determine the usefulness, or even the usability, of water in various industrial, domestic, and agricultural applications include color, odor, taste, temperature, oxygen content, dissolved salts, and burden of suspended organic and inorganic material. Many of these aspects are interrelated, of course.

The most widespread cause of natural water-quality problems is dissolved salts. Although rainwater itself is almost pure, its passage over and through soil and rock formations causes the water to accumulate a burden of dissolved mineral material whose chemical composition depends in detail on the specific types of soil and rock contacted. Groundwater generally carries a higher burden of dissolved material than surface water. Among the most common materials dissolved in natural waters are silica, limestone, magnesia, gypsum, and iron. They can cause hardness, discoloration, strong tastes, and the formation of troublesome solids in pipes and industrial equipment. The properties and consequences of dissolved materials are considered in more detail in Box 6-3.

Federal standards for drinking water specify that the concentration of all dissolved solids in combination should be less than 500 parts per million by weight. [37] Water containing as much as 2500 ppm can be tolerated by livestock. Some industrial uses require water with a considerably smaller proportion of dissolved solids than the drinking water standard. Water for irrigation is considered excellent to good if dissolved solids are in the range from 0 to 700 ppm, harmful to some plants under some conditions in the range from 700 to 2100 ppm, and unsuitable under most conditions at more than 2100 ppm. [38] By comparison, seawater contains about 35,000 ppm dissolved solids and the Great Salt Lake, nearly ten times that much.

A high content of dissolved solids in natural waters is a much greater problem in the Southwest and the northern plains than elsewhere in the United States (Figure 6-7). This condition results from the high leachability of the native rocks and soils in those areas, a slow rate of runoff (maximizing the contact of a given quantity of water with soil and rock), and a high evaporation rate (concentrating the salts in the diminished water volume left behind). The naturally high salinity in the Southwest has been increased further by certain activities of civilization: the construction of reservoirs has increased the evaporation rate, and the use and reuse of water for

irrigation has increased both the evaporation and leaching rates. The climbing salt content in the lower Colorado River has caused political friction between states and between the United States and Mexico. [39] The inability of present water-users in this drainage to tolerate further increases in dissolved salts may limit the exploitation of western coal and oil-shale, because the water-intensive processes involved in extracting, processing, and transporting these resources would increase both evaporation and leaching of salts (see Chapter 8).

Patterns of Use and Supplies

Human and animal needs for drinking water are dwarfed by the quantities of water used for washing and flushing, and they in turn are dwarfed by the amount of water used in manufacturing and agriculture. The amounts of water needed for several functions and tasks are listed in Table 6-7. Most of the enormous water requirement for crop production is, of course, water the crop plants evaporate in conducting their life processes, *not* free water contained in the harvested plant or water fixed in the plant's carbohydrate. The even larger amount of water used for milk and beef production is almost entirely needed to grow the feed for the cows and steers. Of special importance in determining the water needs of an expanding world agriculture is that crops grown in and or nutrient-deficient regions require *more* water per unit of edible produce than those grown in the more favorable conditions characterizing most agriculture today. [40]

To examine patterns of water use in detail, it is necessary to distinguish among three phenomena: (1) *withdrawal* of water from surface or underground flows and reservoirs, wherein part of the water may be returned after use to the same flows and reservoirs and can be used again; (2) *consumptive* use of some of the water that has been withdrawn -- usually by evaporation but sometimes by embodying the water in a product or polluting it

beyond possibility of reuse; (3) *flow requirement*, wherein the water is used *in place* for dilution of wastes, generation of hydropower, navigation, maintenance of habitat and wildlife, and recreation.

Withdrawal and consumption. The fraction of a withdrawal that is actually consumed varies widely among the different sectors of water use. For electric utilities, which use water mainly for carrying away the waste heat inevitably produced at power plants (see Chapter 8), the consumption was only 0.6 percent of withdrawals in the United States in 1970. [41] The figure is so low because most of the cooling was by the oncethrough technique, in which cool water from a river, lake or ocean is warmed 8° to 10° C and then returned to its source. Although the water is not consumed in the

TABLE 6-7
Some Water Requirements

Use	*Amount of water used(m^3)*
Drinking water (adult, daily)	0.001
Toilet (1 flush)	0.02
Clothes washer (1 load)	0.17
Refine a ton of petroleum	2-50
Produce a ton of finished steel	6-270
Grow a ton of wheat	300-500

Use	*Amount of water used(m^3)*
Grow a ton of rice	1,500-2,000
Produce a ton of milk	10,000
Produce a ton of beef	20,000-50,000

Note: 1 m^3 = 1000 liters = 264 gal. Tons are metric tons (= 1000 kg).

FIGURE 6-8 Freshwater withdrawals in the United States, 1970. The upper numbers represent surface water; the lower numbers, groundwater. All numbers represent billions of gallons per day (the annual amounts divided by 365). (Data from Murray and Reeves, U.S. Geological Survey, circular 676 quoted in Strahler and Strahler, 1973.)

process, its cooling capacity is effectively gone until it has managed, perhaps some distance away, to give up the added heat to the atmosphere. The consumed fraction of electric utility water withdrawals will increase sharply in the future, however, because regulations restricting thermal discharges to rivers, lakes, and the ocean are forcing power plants to rely more heavily on evaporative cooling systems.

Industry consumes about 11 percent of the water it withdraws, a fraction that is expected to decrease in the future as economic and regulatory incentives encourage repeated reuse of water (recirculation), once withdrawn. [42] Domestic and commercial consumption of water from municipal systems is about 22 percent of withdrawals. Irrigation, by far the largest actual consumer of water in the United States, consumes about 75 percent of the water it withdraws. As noted above, moreover, much of the water returned after irrigation carries a bigger burden of dissolved salts than the water withdrawn.

Withdrawals of fresh water for all purposes in 1970 in the United States are shown in Figure 6-8, broken down into drainage basins and into withdrawals from surface and groundwater. Notice that most withdrawals in the Northwest and Northeast are from surface water, whereas withdrawals from groundwater are roughly equal to those from surface water in the Southwest.

Table 6-8 presents, for the same geographical divisions of the country, data for total withdrawals and consumptive use compared with mean annual runoff and annual runoff exceeded 9 years out of 10. All these data are annual flows divided by 365, to give mean daily flows in millions of cubic meters. Naturally, the runoff figures for each region represent water that originates there and do not include inflow from upstream regions (for example, flow into the lower Colorado basin from the upper

Colorado River). Of eighteen regions, there is 1 (the lower Colorado) in which consumptive use exceeds mean annual runoff, 3 in which consumptive use exceeds the flow available 9 years out of 10, and 6 in which total withdrawals exceed flow available in 9 years out of 10. These are the main potential trouble spots for water supply in the United States.

Not represented in Figure 6-8 or in Table 6-8 are withdrawals of salt water amounting to about 200 million cubic meters per day nationwide, mostly for cooling electric power plants.

Table 6-9 shows the breakdown of freshwater withdrawals and consumptive use in the United States in 1970 according to the category of use: municipal(in-

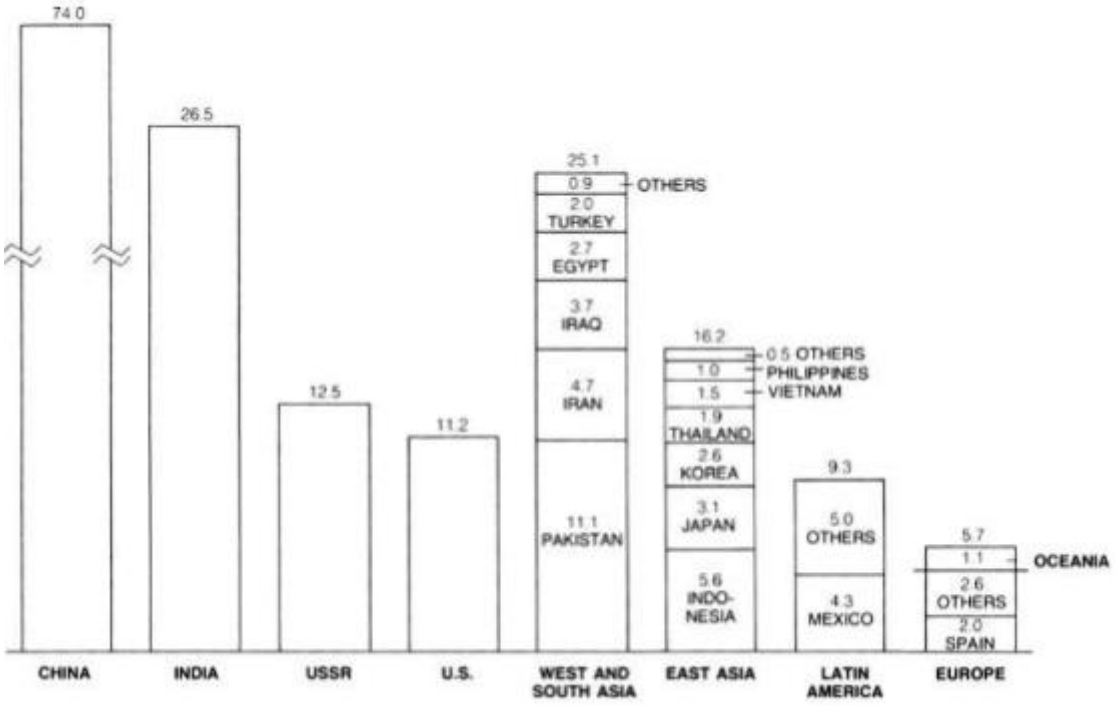

FIGURE 6-9 Irrigated land area of the globe (million hectares), 1963-1965. (Data from Borgstrom, 1969.)

cluding domestic, commercial, and some industrial uses), rural domestic, electric utilities, other self-supplied industrial, and irrigation. Irrigation accounts for about 40 percent of withdrawals but 87 percent of the consumptive use.

Projections made for the year 2000 by the United States Geological Survey show a doubling of withdrawals over the 1970 figures but an increase of about 50 percent in consumptive use of water, implying a greater degree of reuse. [43] Almost half the projected increase in withdrawals is expected to be used for cooling electric power plants; a slower rate of growth in electricity generation, which now seems likely (see Chapter 8), would significantly reduce those projected withdrawal requirements.

Even the higher forecasts of water use might be met by the national water supply, but they would certainly aggravate existing regional difficulties in the drier parts of the country. That shortages of water already exist in the arid regions bodes ill for schemes to develop their massive fossil-fuel resources and to expand irrigated land for food production. Nevertheless, on a national basis problems of water quality will probably remain more important than problems of absolute supply.

Irrigation. As the biggest consumer of water and a cornerstone of agricultural production in many parts of the world, irrigation deserves special attention. The practice of irrigation appears to be as old as agriculture itself. [44] The most rapid expansion of the area under irrigation has probably been in the past two centuries, however. In the nineteenth century, the amount of land under irrigation worldwide increased from about 8 million to 45 million hectares. By the mid-

1960s the irrigated area was about 180 million hectares, distributed as indicated in Figure 6-9. This amounted to about 5 percent of all cultivated land.

In the United States, only about 10 percent of the harvested acreage is irrigated, but that land produces more than 25 percent of the cash value of crops grown. [45]

[43]National Commission on Materials Policy, *Material needs*, p. 8-5.
[44]Borgstrom, *Too many*, pp. 184-185, is the source of most of the information in this paragraph. See also Eric Eckholm, *Losing ground*, chapter 7.
[45]Edward Groth, III, *Increasing the harvest*.

The importance of irrigated land worldwide is probably similarly disproportionate to its fraction of the total cultivated area.

The amount of irrigated land worldwide in the mid1970s was about 200 million hectares, out of perhaps 340 million hectares that are considered potentially irrigable. [46] The extension of irrigation to the remainder is expected to cost at least $1200 per hectare on the average, the price naturally rising as the more difficult areas are developed. [47] The quality of existing irrigation systems varies widely, moreover, and some land already counted as irrigated needs more water than the existing systems deliver if it is to be fully productive.

Waterlogging and salt accumulation on irrigated land in many parts of the world make it questionable to some observers whether optimistic projections of the continued expansion of the land area under irrigation will be realized. [48] Iraq, Pakistan, and India have each suffered severe damage by waterlogging and salination to millions of hectares of irrigated land, and a noted Soviet soil scientist goes so far as to assert that 60 to 80 percent of all irrigated lands worldwide are becoming gradually more saline, hence less fertile. [49] Sophisticated drainage technology could alleviate this problem in many circumstances, but it increases the expense and requires highly trained engineers to implement. [50] Paradoxically, failure to get rid of irrigation water properly once it has been provided may in the long run prove to be a bigger threat to world agriculture than not providing enough.

Flow requirements. The figures discussed so far have included withdrawals and consumption. They have not included the various uses for flow in stream channels that were identified earlier. Of these so-called *flow requirements*, the most demanding under most circumstances is for the dilution of wastes. The criterion generally used to determine the flow requirement for waste dilution is that the amount of dissolved oxygen in the water should not drop below 4 milligrams per liter (4 ppm, by weight). [51] This is the amount needed under most conditions to maintain a varied aquatic fauna.

Obviously, the amount of flow needed to dilute wastes to concentrations such that their bacterial or chemical decomposition does not deplete dissolved oxygen below this level depends directly on how much waste is discharged. The most commonly used quantitative measure of waste material in water is *biochemical oxygen demand* (BOD), which refers to the weight of oxygen

needed to oxidize the wastes. A common unit of BOD is the *population equivalent* (the 0.113 kg, or 0.25 lb, of oxygen needed to oxidize the daily wastes of a "standard" urban person). [52] *Percentage of treatment* means the fraction of the BOD that is removed by waste-processing before the effluent is actually discharged to waterways.

If treatment of municipal wastes in the United States in 1960 averaged 70 percent and that of industrial wastes, 50 percent, the dilution requirement then would have been 2300 million cubic meters of water per day. [53] This compares to a daily flow (the annual total divided by 365) exceeded 9 years out of 10 of 2800 million cubic meters. Thus, counting both flow requirements and consumption (the latter about 300 million cubic meters per day), most of the reliable flow in the forty-eight contiguous states was already being used by society in 1960.

Most forecasts of future flow requirements for dilution of wastes assume extremely effective treatment--95 percent or more for both municipal and industrial wastes. [54] This means all wastes would receive tertiary treatment, which would require heavy investments in the construction of new treatment plants (see Chapter 10). Such forecasts must also estimate levels of population growth and economic growth, as well as the mix of industrial activities. Obviously, there are many possibilities, but all credible scenarios indicate substantial water deficits over most of the southwestern and south-central United States by the year 2020, even with 97-percent waste treatment

[46]University of California Food Task, *A hungry world*, p. 71.
[47]Ibid.
[48]See, for example, Eckholm, *Losing ground* Chapter 7; Borgstrom, *Too many*, Chapter 8; see also Chapter 11 in this volume.
[49]V. Kovda, quoted in Eckholm, *Losing ground*, p. 124.
[50]For an interesting discussion of what seems possible in theory, see R. Revelle and V. Lakshminarayana, *The Ganges water machine*.
[51]Hunt, *Physiography*, p. 83; H. Landsberg, L. Fischman, and J. Fisher, *Resources in America's future*.
[52]An excellent discussion of water quality and waste treatment is N. Wollman and G. Bonem, *The outlook for water*, chapter 8. See also Metcalf and Eddy, Inc. *Wastewater engineering*, McGraw-Hill, New York, 1972, and Chapter 10 in this volume.
[53]Wollman and Bonem, *The outlook*. Accurate figures for what the avenge percentages of waste treatment actually were in 1960 do not seem to be available, but according to Wollman and Bonem they probably were no higher than those given here.
[54]See, for example, Ridker, *Future water needs*.

everywhere. High-growth scenarios extend the deficit region throughout the north-central region, as well. [55] Failure to achieve higher levels of treatment, if such failure is coupled with substantial economic growth, could cause national dilution requirements to exceed mean total runoff for the 48 contiguous states before the year 2000. [56]

Increasing the Supply

Several approaches to alleviating water shortages are possible: (1) One can redistribute the flow more evenly in time by building storage reservoirs or, in some circumstances, by revegetating denuded regions so that water is released more gradually. (Both of these strategies buy increased regularity of flow at the cost of a decreased total quantity of flow, owing to increased losses to evaporation.) (2) One can redistribute the water geographically by transferring it in pipelines or canals from one drainage basin to another. (3) One can try to move the people to the water--that is, to employ land-use planning tools to concentrate the population where the water is. (This approach is not considered further in this chapter; some discussion of land-use planning appears in Chapter 14.) (4) One can tap groundwater more extensively by means of wells. (5) One can render seawater or salty groundwater suitable for municipal, industrial, and agricultural use by desalting. (6) One can try to increase the efficiency with which water is used, for example, by minimizing the number of gallons needed to grow a given amount of cotton or to manufacture a given amount of steel.

Water projects. The extent to which water projects had increased the regularity of the flow of water in the United States had reached about 40 percent of the theoretically attainable figure by around 1970. [57] The construction of dams for this purpose (and others) is expensive and becomes increasingly so per unit of control gained, as the best sites are used first. Costbenefit analysis to determine whether it is economical to build a large multipurpose dam (for flow regulation, flood control, hydropower generation, irrigation, recreation) is complicated. It is easily botched or misused by special interests, even independent of environmental issues and the difficulty of incorporating these into an economic framework. [58] Not surprisingly, then, costbenefit analyses of water projects have generated many controversies. [59] (The environmental aspects of dams are considered briefly in connection with a discussion of hydropower in Chapter 8 and in more detail in Chapter 11.)

Diversion of water from regions of surplus to regions of deficit raises all the economic and environmental issues of flow-regulation projects, and more. Such interbasin transfers are common in the western United States, with 20 percent of the population in the seventeen western states already being supplied by water moved 160 kilometers or more in 1968. [60] As the distances water is moved grow larger, the associated political difficulties often intensify. People in densely populated, water-short regions like southern California use the political power of their numbers to exert a claim on water from elsewhere (northern California, in this case), where the inhabitants see the environmental costs but receive few benefits of exporting water from their region. Few projects that transferred water across state lines existed in the United States as of the mid-1970s, but projects had been proposed (and were being taken seriously by some people) for moving water to arid parts of the United States from as far away as northern Canada. [61] The Soviet Union has long had plans to divert to the south the flow of several major rivers now emptying into the Arctic Ocean. [62] Those and other large-scale diversion schemes

[55] Ibid.

[56] This forecast is based on an average of 80-percent treatment of both industrial and municipal wastes and the high-growth scenario of Woll man and Bonem, *The outlook*, p. 69. The low-growth scenario with the same treatment levels produces the same result before 2020.

[57] Ridker, "Future water needs", pp. 215-218. The theoretical maximum is expressed as a

quantity of flow maintainable 98 percent of the time if all possible storage facilities are built.

[58]See, for example, Hirshleifer et al., *Water supply*, p. 23, for a good discussion.

[59]T. Parry and R. Norgaard, *Wasting a river*, and Julian McCaull, *Dams of pork*.

[60]Menard, *Geology*, p. 495.

[61]This scheme, the North American Water and Power Alliance, is described unenthusiastically in Menard, *Geology*, p. 496, and does not seem to have much support at this writing. See also Paul R. Ehrlich and John P. Holdren, *Population and panaceas: A technological perspective*; and W. Sewell, *NAWAPA: a continental water system*. Canadians view the scheme with considerable misgivings; see R. Bocking, *Canada's water: for sale?*

[62]P.Micklin, *Soviet plans to reverse the flow of rivers*; M. I. Goldman, *Environmental pollution in the Soviet Union*.

would be staggeringly expensive. (The estimate for the North American Water and Power Alliance--the scheme for transferring water from Canada, mentioned above-was $100 billion in the 1960s and would surely be much higher if reexamined in the light of more recent experience with construction costs.) The ecological effects might well extend to impact on continental and global climates (see Chapter 11).

Desalting. Some 700 desalting plants were in operation around the world in 1975, most of very modest size and almost none used to support irrigation of staple crops. The largest ones produced on the order of 35,000 cubic meters of fresh water per day, at a cost of around 15 cents per cubic meter. [63] In smaller plants, the cost was in the range of 25 to 50 cents per cubic meter. By contrast, farmers typically pay I to 2 cents per cubic meter for irrigation water. So, only for growing high-value crops such as tomatoes, avocados, and orchids can water from desalting be used economically for agriculture. It appears that desalting is too expensive by about a factor of 10 to permit its use for irrigating wheat, rice, or corn. [64]

Some desalting enthusiasts argue that a combination of lower future costs for desalting and reduced water requirements for staple crops (made possible by more refined irrigation schemes and by breeding more drought-resistant, water-efficient crop varieties) will soon change this verdict, opening an era in which the deserts will be made to bloom. [65] Most such analyses appear to rest on the hope of cheap nuclear power as a source of energy for the separation of salt from seawater. (The theoretical minimum amount of energy needed to remove the salt from a liter of seawater, which can be established using basic principles of thermodynamics, is a not too formidable 2.8 kilojoules. The most efficient plants actually constructed to date require about 170 kilojoules per liter for practical reasons not likely to be circumvented easily or soon.) [66] The price of nuclear energy has been rising, not falling, however, and other energy sources are becoming costlier, too (see Chapter 8). At one dollar per million kilojoules, a typical price for "low-cost" commercial fuel energy in 1975, the energy cost alone for desalting a cubic meter of seawater in an efficient plant was 17 cents.

Falling construction costs for large desalting plants were also rather widely predicted in the 1960s, but those have not materialized, either. [67] Moreover, if the water is to be used anywhere but on the seacoast (or directly adjacent to inland supplies of salty water), the costs of moving it and lifting it in elevation must be taken into account. Lifting costs alone are on the order of 1

cent per cubic meter per hundred meters of lift. [68] Under these conditions, one could scarcely afford to use seawater for irrigating staple crops on land above a few hundred meters elevation, even if the sea were fresh water to start with.

Water conservation and other strategies. The use of wells to develop groundwater supplies can in some instances be an economical alternative to dams and surface reservoirs for the purpose of flow regulation and storage, [69] but any situation in which withdrawals exceed natural recharge is obviously not a satisfactory long-term strategy.

As with so many other resource problems, close examination of the water situation suggests that the most economical and environmentally benign way to increase supplies beyond a certain point is really not to increase supplies at all, but rather to reduce consumption by more efficient use. A substantial fraction of municipal water use in the United States, for example, turns out to be the result of leaks, including dripping faucets, running toilets, and the like. [70] Furthermore, industrial water use could be significantly reduced by increasing recirculation at the expense of withdrawals. [71] There is genuine potential, as well, for reducing significantly the amount of water needed for productive irrigation. [72] At least one approach to this--the use of high-frequency irrigation (delivering small amounts of water at frequent intervals)

through pipes--is said by its supporters to be capable of increasing the efficiency of fertilizer uptake and increasing the variety of soils on which irrigation is possible. [73] Breeding crops more tolerant of salt is another way to reduce the use of fresh water in agriculture, but it is a time-consuming and as yet unpromising approach.

Naturally, the lengths to which society will go to use its water more efficiently depend in part on the price of water, and many economists believe that many present water problems in the United States--caused in large part by excessive consumption--could have been avoided if the price of water had not been kept artificially low by subsidies. [74] It is likely to prove necessary eventually, either by means of much higher prices or by other social restraints, to prevent people from

moving into arid regions with the expectation that society will support their venture by making the necessary water available at negligible direct cost to the consumer.

FORESTS

With the disappearance of the forest, all is changed. At one season the earth parts with its warmth by radiation to an open sky--receives, at another, an immoderate heat from the unobstructed rays of the sun. Hence the climate becomes excessive and the soil is alternately parched by the fervors of summer and seared by the rigors of winter. Bleak winds sweep unresisted over its surface . . . . The face of the earth is no longer a sponge, but a dust heap, and the floods which the waters of the sky pour over it hurry swiftly along its slopes, carrying in suspension vast quantities of earthy particles which increase the abrading power and mechanical force of the current, and, augmented by the sand and gravel of falling banks, fill the beds of the streams, divert them into new channels, and obstruct their outlets.

-- George Perkins Marsh, *Man and nature*, 1864

Intimately related to freshwater supplies are another renewable resource--forests. Forests are not, of course, the same from place to place--as was seen in Chapter 4, the term forest has a multitude of meanings. [75] At the same time, diverse as they are, *forests* the world over tend to play similar roles in relation to human activities: maintenance of ecological diversity, preservation of watersheds and the prevention of erosion (and subsequent siltation of dams), moderation of climate, supplying wood for fuel and structures and paper, and providing hunting grounds and areas of aesthetic value for recreational purposes, to name a few. [75a] The multiple uses of forest land are often to one degree or another incompatible, but, for any or all of them to continue, preservation or regeneration of forests is necessary. Therefore, much of the discussion on the uses of forests tends to focus on what happens when they are destroyed--that is, on deforestation.

That deforestation results in heavy soil erosion, floods, and changes in local climate has been known--but not always heeded--for centuries. The annual floods that have plagued northern China since ancient times are a result of deforestation during the early dynasties. [76] The once-fertile hills of central Italy have been arid and subject to regular, occasionally devastating floods since the Middle Ages, when the trees were removed. It is interesting that medieval writers and many others since accurately predicted the results of deforestation without replanting or provision for reseeding and protection of seedlings and saplings. The ancient Greeks and Romans apparently were relatively conscientious in maintaining the forests and understood their value in protecting watersheds. But this understanding seems to have been partially lost during the Middle Ages, when the demands of growing populations for fuel, construction materials, and grazing land brought destruction of the forests in much of southern Europe. This destruction led the great naturalist Alexander von Humboldt to observe, in the middle of the nineteenth century, that the youthfulness of a civilization is proved by the existence of its woods. [77]

World Forest Reserves

Today, similar demands are threatening forests around the world. Many irreplaceable tracts have disappeared entirely. Most of Europe, northern Asia, the eastern one-third of the United States,

and vast areas of the American Northwest were once covered with forests. Only fractions of the forests of the eastern United States and of western Europe remain today, largely preserved through conscious conservation and reforestation policies, which were pioneered in Europe. Table 6-10 shows forested areas and estimated timber stocks for the world as of 1973.

The Soviet Union has the greatest remaining reserves of temperate and subarctic forest, including nearly half of the world's coniferous forest. About two-thirds is virgin, largely because it is relatively inaccessible. However, the best-quality trees for lumbering are in the European USSR, and as a result, those have been heavily exploited. Large reserves of coniferous forest also remain in North America, from Nova Scotia to Alaska. Forest management practices have, in theory, been established in most DCs, including the USSR and the United States, to preserve their forest for the future--but the success of such practices is in dispute. Interestingly, problems and conflicts over timber harvesting in the communist Soviet Union are quite similar to those that are so vexing in the capitalist United States. [78]

Australia and New Zealand in recent decades have also lost large tracts of forest, and much of what remains is being heavily exploited by intensive forestry. In addition, where replanting is done, native forest ecosystems are replaced with tree-farms of fast-growing, imported species harvested by broad-scale clearcutting. [78a]

Vast forest reserves also still exist in the tropics, especially in the Amazon valley, southeast Asia, and central Africa. Inaccessibility and economic factors have until recently protected those areas from destruction. Latin America, for example, harvested less than 4 percent of the wood produced worldwide in 1967-1969, despite having almost a third of the world's reserves. [79] Nevertheless, some of Latin America's more accessible forests have now vanished or have been selectively depleted of the most valuable species. The rate of clearing tropical rain forests has accelerated in the past decade or so to the point where many fear they will all but disappear by the end of the century.

It is important to recognize that the greatest cause of outright deforestation in the world today is almost

[78]Philip R. Pryde, *Conservation in the Soviet Union*; M. I. Goldman, *Environmental pollution in the Soviet Union*.

certainly not large-scale commercial lumbering, but rather a combination of land-clearing for agricultural production and the gathering of wood by desperate peasants in need of fuel. While debates rage in the DCs about multiple-use and optimum harvesting practices, the very existence of forests is in jeopardy over large expanses of the world, where hunger and the need for warmth take precedence over more subtle concerns. [80]

Forests in the United States

In the United States, lumber interests are accelerating their harvests, often at considerable expense to the forest environment, in their efforts to meet rising demand for construction wood and for paper. Table 6-11 shows both annual growth and annual removals of timber in the United States from 1952 to 1970, with projections to the year 2000. While growth has exceeded removals overall and may continue to do so, softwood sawtimber (coniferous trees more than 12 inches in diameter) has suffered serious deficits, which are expected to continue. Thus, the stock of those trees, which supply most of the wood for construction and pulping, is dwindling. [81] How much of the demand for wood in the United States (in the economic sense, the desire and ability to purchase it) is related to real needs is in dispute. For instance, if wood is cheap enough, the use of it as a structural material will increase and the demand for nonforest products (metals, concrete) that can meet the same needs will decrease. Much of the pressure generated by the industry for more logging in the national forests appears to have been created by a fear of loss of markets to other industries rather than by any genuine national need. [82] On the other hand, the United States has been a net importer of timber since 1941, and the fractional dependence on imports is growing. [83]

The U. S. lumber industry. Few subjects have been the source of more enduring environmental controversy in the United States than the needs and practices of the

TABLE 6-11 Annual Growth and Removal of Wood in the United States, 1952-2000

lumber industry. The controversy goes back to the middle of the nineteenth century, when the wholesale plundering of American forests was in full swing, due both to unscrupulous industry practices and to irresponsible farm clearing. A few voices protested--John Muir, Henry David Thoreau, Carl Schurz (President Hayes' Secretary of the Interior)--but the demolition of the forests continued. [84] In 1907 establishment of the Forest Service under Gifford Pinchot, a man who believed that exploitation and preservation of forests could be compatible, marked a turning point. The trend began toward sustained-yield forestry--harvesting trees like other crops--and toward consideration of nonlumbering uses of forest such as for wilderness, watershed preservation, and recreation.

That hopeful trend, however, has not led to any sort of equilibrium based on a comprehensive American forest policy. The timber industry, for instance, constantly pressures the Forest Service to open up more national

forest for harvesting--pressure that succeeds all too often. [85] At the same time pressures for recreational use are escalating, and the general public concern for conservation is increasing.The degree of compatibility of different uses varies a great deal, [86] and decision-making in this area is complex, to say the least. In general, however, decisions by the Forest Service (and other government groups) have tended to favor the lumber interests, even though the Forest Service has not become a pawn of those interests to the extent that some other federal agencies (such as the Interstate Commerce Commission) have become subservient to the industries they are supposed to regulate. The political muscle of the lumber companies and the emergence of a generation of Forest Service officials trained to regard forests as crops have nonetheless kept timber harvesting at the top of the list of the multiple uses to which those forests are, according to law, to be put.**National forest policy.** That one legitimate and important use of national forest land is supplying the United States with wood is not in dispute. But a series of related questions are in hot contention. They include:

How much of our national forest land should be assigned to growing crops of timber, and which areas should be put to that use?
How should demand for export be included in estimates of the need to cut on those lands?
To what extent should the intensive, high-yield forestry practices employed by industry on private lands be permitted on multiple-use public lands?
What methods of harvesting should be employed?

These questions are interrelated and can only be answered satisfactorily by a comprehensive forestmanagement policy. The way to proceed seems clear-toward a high-intensity, low-harvest-acreage policy similar to one suggested by Marion Clawson. [87] The concept is relatively simple. Growth of wood for extraction from our forests would be concentrated in the better forest sites (those producing the greatest yields and suited to rapid regeneration). Sites less suitable would be

reserved for alternative uses or held for possible future harvests. The nation's wood would come from a much smaller area than if all of today's so-called commercial forests were harvested, and some prime timberland now seemingly doomed to be cleared could be set aside for wilderness.

Such a policy is desperately needed. The demand for forest products seems certain to rise over the next several decades; it will do so all the faster if we turn more to forests for fuel sources. In 1974 it was estimated that demand for wood would rise at a compound rate of perhaps 1.5 percent per annum between 1970 and 2000. The rise in recreational demand was projected to be much higher--perhaps 4 percent--meaning nearly a quadrupling of use by the end of the century. [88] Furthermore, it now seems likely that for economic reasons (for maintaining foreign exchange) the United States will want to expand its lumber exports to Japan and elsewhere.

If there is to be any chance of meeting those pressures on our forests without a national disaster, their exploitation must be more tightly controlled--not just at the expense of lumbering interests but also through such actions as equitable rationing of access to wilderness, since overuse by hikers and campers can destroy the very values conservation intends to preserve. As is so often the case, however, even when the direction in which policy should go seems clear, economic and political impediments to moving in that direction may be formidable. We return to that in Chapter 14.

Unsound practices. It is often more immediately profitable for a company to harvest timber in a way that essentially converts forest into a nonrenewable resource than to harvest in what may be the soundest method, taking the economic or environmental long view. In a sense, many forests have been treated as "terrestrial whales"--harvested with no consideration for maximum sustainable yield but rather with an eye on maximum return on capital (Chapter 7). For example, many areas

---

[87] Conflicts, strategies and possibilities for consensus in forest land use and management.

[88] Demand estimates are based on L. L. Fischman, *Future demand for U.S. forest resources*.

have been subjected to the wrong kind of selective cutting. The most desirable species have been logged out, leaving only inferior trees to reseed. The result is an inferior forest, at least from the point of view of future harvests. This has been the fate of much hardwood forest in the eastern United States. [89]

This type of selective cutting is often disastrous, but the disaster is not as obvious as where there is clearcutting (the wholesale removal of large tracts of mature forest). Done carefully, with appropriate care for aesthetics, placement of roads, removal of logs, and disposal of trash, and done in forest ecosystems with the appropriate capacity to regenerate (such as the Hubbard

Brook forest discussed in Chapter 11), clear-cutting may be an appropriate way of harvesting timber. Unfortunately, much clear-cutting is done in inappropriate areas, that is, where the result is an impression of vast desolation in formerly scenic places, where placement of roads and dragging of logs play havoc with the soil, where silting of streams destroys valuable populations of game fishes, and where climatic and other factors make reforestation extremely slow or impossible.

Such activities have produced results that, through the dissemination of photographs such as those in Figure 6-10, have convinced much of the public that all lumbering is environmentally irresponsible. Similarly, the behavior of Georgia Pacific and Arcata Redwood companies in hurrying to harvest redwood stands that were "threatened" with inclusion in Redwood National Park was in the best tradition of the nineteenth-century "rape and pillage school" of forest management. [90] Indeed, the assistant to the chairman of Georgia Pacific was in favor of logging within national parks! [91]

Unfortunately, even under appropriate conditions, clear-cutting and tree farming present problems that are analogous in some respects to those found in other forms of intensive agriculture. Use of pesticides, herbicides, and fertilizers on forest plots has caused off-site environmental problems, for example. [92] Tree farming also produces some of the liabilities of other kinds of monoculture. [93] For example, large stands of young trees are more susceptible to disease, pests, and fire than are forests containing trees of varied age.

Loggers defend the practice of clear-cutting large stands on the grounds that certain valuable species of trees need direct sunlight and space in which to grow -that is, cleared land. Presumably, some less destructive procedure can be used in many cases, such as clearcutting small stands, if selective cutting and replanting individual trees is unsatisfactory. A great deal of research on appropriate harvesting procedures in various kinds of forest ecosystems is badly needed. At the rate forests are being cut in some areas, however, the forests may be gone before the research can be done.

Forests are threatened by more than a demand for lumber, fuel, and recreation. Much privately owned forested land (about 80 percent of the forest in the eastern United States) disappears each year under highways, housing subdivisions, airports, and other development projects. Strip-mining destroys thousands of acres in a process much more destructive of the soil than clearcutting. In moist climates erosion and flooding are virtually inevitable after strip-mining and are accompanied by severe water pollution. Reforestation is often not attempted (although with care it frequently can be achieved). In publicly owned tracts in national forests, under the multiple-use policy, trees are cleared for recreational facilities (and many are damaged by the crowds of visitors), access roads, powerline cuts, mining activities, and sheep and cattle grazing. And in some areas, for example near Los Angeles, trees are being killed by smog.

Pressures on World Forests

The situation is far worse in many other countries. Half the trees cut down in the world are used for fuel, regardless of their potential value as lumber. [94] Clearing for agricultural land, especially

in the tropics, is another great threat to this resource. Deforestation may be especially disastrous ecologically in the tropics. Because

of poor transportation facilities and various economic factors, a great number of the felled trees (many of them valuable hardwoods) are not harvested and used as lumber, but are wasted or used for fuel. Brazil's forests once covered 80 percent of the country; by 1965 they covered only 58 percent. [95] A stretch through the Amazon forest is now being cleared for a transcontinental highway, which will open up vast areas of the forest for lumbering and agricultural clearing. Lumbering in Haiti's tropical forest has long since exterminated mahogany entirely, and that of Honduras is nearly gone. Replanting has seldom been practiced in tropical forests in the past, although a few countries are now introducing forest-management practices there. If tropical forests are not to vanish, as did temperate ones in Europe and the United States, conservation and management policies must be established.

A bright spot in the picture may be provided by the People's Republic of China. More than 30 percent of China's land area is said to be suitable for reforestation, and a reforestation program is in progress. [96]

Careful management of forests could assure humanity of the opportunity to benefit from forests more or less in perpetuity. Such management would include preservation of trees of mixed species and ages as much as possible, to discourage losses from pests, disease, and fire; careful selective logging in a long-term rotation scheme or intensive management of clear-cutting in appropriate areas; much more effort put into reforestation; and careful protection of the soil.

THE TAKEN-FOR-GRANTED RESOURCES

The resources we have discussed in this chapter -- land, soil, water, forests -- have for the most part not commanded the attention or the sense of urgency in the United States, either of the public at large or among dedicated environmentalists, that they deserve. Perhaps soil erosion and deforestation lack the glamour of the petroleum crisis or running out of tungsten, but the central role of the soil-water-forest complex in the support of industrial and agrarian societies alike means that high priority should be attached to understanding it and maintaining its integrity. If the United Nations conference on the environment in Stockholm in 1972 is any guide, the LDCs may understand this better than the DCs -- for the lists of environmental problems raised by the poor countries at that meeting were heavy with threats to soil and forests. Sadly, the LDC governments that perceive the gravity of these threats generally are less well equipped to do anything about it than are the DC governments, where recognition is dimmer.

It is true that the wholesale loss of soil and forests is, as a general rule, proceeding faster in LDCs than elsewhere, and some might argue on this basis that the relative complacency of DCs about their own situations with respect to these resources is justified. It is not. Probably the main reason for overconfidence is lack of awareness of the complexity and subtlety of the soil-water-forest complex, and hence blissful ignorance of the ways it might be disrupted and the ways these disruptions could damage human well-being. It is important to recognize that soil is a chemical and biological system as well as a structural foundation for holding up plants; that what grows depends not just on adding water and fertilizer to any plot of land, but on widely varying characteristics of soils that are themselves the product of biogeochemical processes acting over millennia; and that these characteristics can be interfered with, perhaps irreversibly, by human activities operating over much shorter periods of time. (Some ways in which this could happen are described further in Chapter 11.) It is important to recognize, too, how tightly linked are the resources of soil and water and forest. Deforestation produces erosion and water pollution and makes runoff more erratic, reducing availability of water and causing more erosion. This process can become irreversible by altering the environment so drastically that reforestation is impossible.

Society ignores the complexity and fragility of these systems at its peril.

CHAPTER 7
A Hungry World

The human brain, so frail, so perishable, so full of inexhaustible dreams and hungers, burns by the power of the leaf.

-- Loren Eiseley, *The Unexpected Universe*, 1969

Photographs of Earth taken from the moon make the finite nature of our planet apparent in a way that no writing can. But knowing a vehicle is finite and knowing how many passengers it can carry are not the same thing. What is the actual capacity of Earth to support people? Unfortunately, there is no simple answer to this question, although certain theoretical limits may be calculated. Justus von Liebig's principle, known as the "law of the minimum," says, in essence, that the size of a population or the life of an individual will be limited by whatever requisite of life is in the shortest supply. It is not yet entirely clear what that requisite will be for the human population, which, as we have seen, is growing at an extraordinary rate. But the likeliest factor to limit Earth's capacity to support *Homo sapiens* is the supply of food, since this

supply depends on the availability of so many other essential resources: land, water, nutrients, and energy.

Apart from the limits that may ultimately be posed by Earth's absolute capacity to support human beings, there are gross differences between groups of people with regard to their food supplies. The rich are abundantly, even wastefully fed; the poorest live perpetually on the brink of famine.

This chapter describes the present nutritional status of the human population and the outlook for meeting future

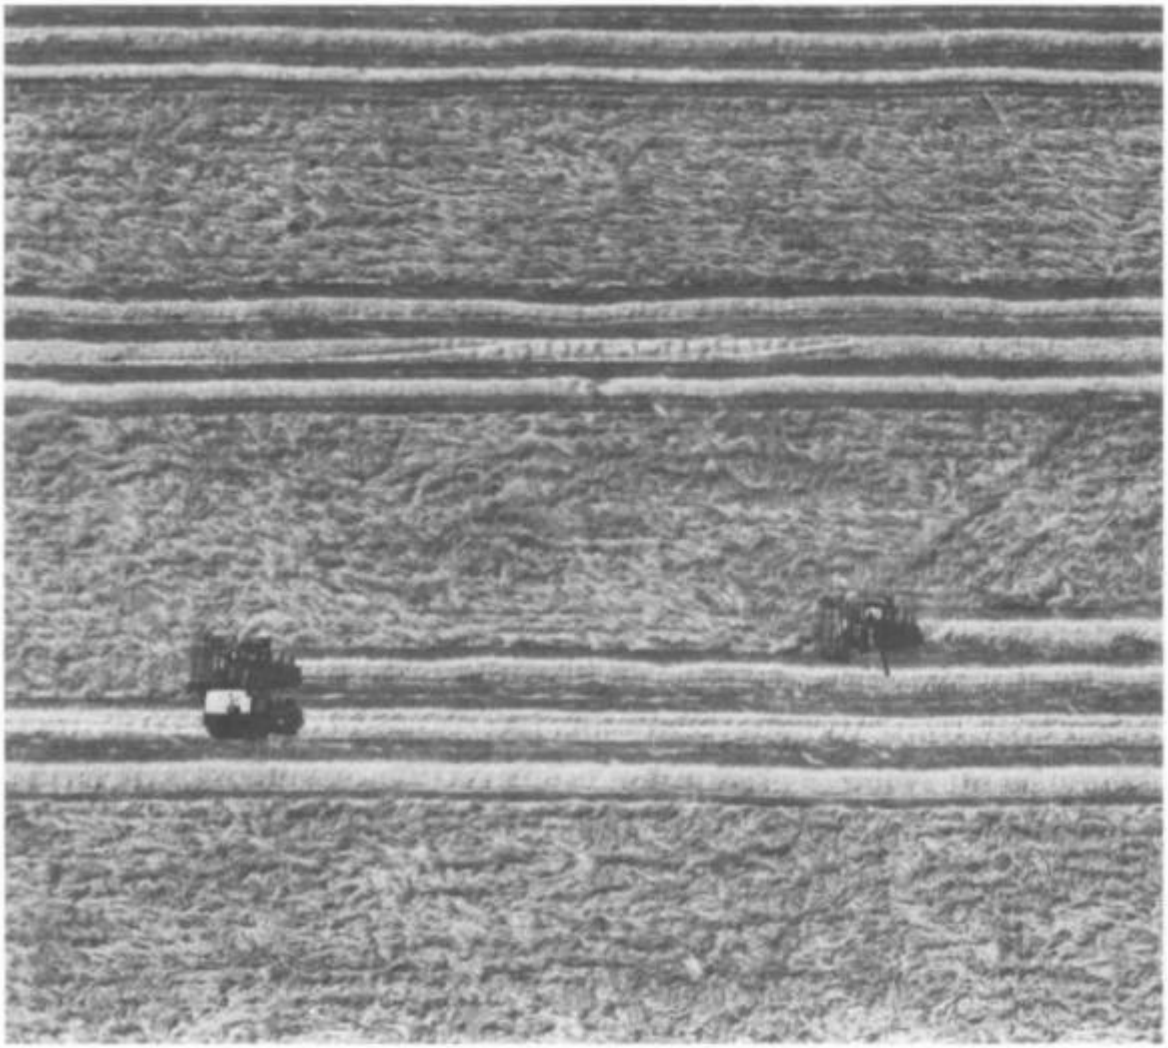

FIGURE 7-1 A. An example of slash-and-burn agriculture. The new clearing in second-growth forest contains many stumps of trees that have been cut high for use as props for growing plants. Some, although stripped of their leaves, will survive; along with invading tree seedlings they will slowly reforest the garden site. (Photo by Ray A. Rappaport.) B. An example of modern mechanized agriculture, which is characterized by high-energy inputs to maintain stability and high yields. These machines are wheat combines. (Photo by William A. Garnett.)

needs for food. It explores how the prognosis might be improved: ways in which food production might be increased, and how patterns of distribution might be changed to provide more food for the hungry millions. First, however, some description of the elements of food production is in order.

THE PRODUCTION OF FOOD

At the most basic level of all, human beings, like all other animals, have always been dependent on the process of photosynthesis for food. Whether primitive people ate berries, roots, fishes, reindeer, or whatever, the energy derived from food had the same ultimate source: the radiant energy of the sun.

Not until the agricultural revolution, however, did humanity begin to exercise some control over plant growth and attempt to concentrate and increase the yield from desirable food plants. (*Yield* refers to production per unit of land area, such as an acre or a hectare.) The earliest attempts at agriculture doubtless were based on the astute observation that certain accidental disturbances of the land by human activities increased the growth of some useful plants. Indeed, the "slash-andburn" agriculture (*milpa* agriculture) practiced today in many humid tropical areas consists of little more than cutting and burning clearings in which seeds or cuttings of various desirable plants are then scattered. It would have been a small step from such a practice to the reduction of competition for the desired plants by simply hoeing weeds, protecting the crop from animals, and making use of the fertilizing effects of excreta and other organic wastes. [1]

Modern agriculture as practiced in most developed nations is, of course, completely different from milpa agriculture (see Figure 7-1). In many respects it is quite different even from traditional temperate-zone agriculture as still practiced in parts of Europe and many less

---

[1] Charles B. Heiser, Jr., *Seed to civilization: The story of man's food*, W.H. Freeman and Company, San Francisco, 1975; Jack R. Harlan, *The plants and animals that nourish man*. For some interesting ideas on the origin of milpa agriculture, see David R. Harris, The origins of agriculture in the tropics, *American Scientist*, vol. 60, pp. 180-193. It is possible that such cultivation, using cuttings rather than seeds, began in the tropical areas of Africa and South America as early as, or even earlier than, the first grain cultivation in Asia and Central America.

FIGURE 7-2
An orange grove in Southern California being replaced by a subdivision. At lower left are undisturbed orange groves; at upper center is finished housing. At right is housing in various stages of completion; at lower right is a freshly cleared area with one orange tree remaining per lot. Since the photograph was taken (in the 1950s), the entire area has been developed. (Photo by William A. Garnett.)

developed countries outside the tropics. The changes in temperate agriculture during the past few hundred years could quite fairly be considered a second agricultural revolution. The science of plant breeding has produced new crop varieties that are adapted to various growing conditions, high in yield, resistant to diseases, and so forth. Mechanical cultivation and harvesting, improved methods of fertilization and irrigation, the use of chemical and biological controls against plant and insect pests, weather forecasting, and many other technological advances have greatly increased the quantity of food that can be produced on a given area of land.

Some of these advances are mixed blessings, however. Many have unwelcome environmental side-effects, which will be discussed later in this chapter and further in Chapter 11. Some methods may contribute to higher productivity, but, if they are not used with care, their contribution is made at the expense of future production as soil depletion is accelerated.

Technology has also increased the quality of many crops, but not necessarily in all respects. For instance, high yields in grains have sometimes been gained at the cost of lowered pest resistance or other undesirable changes in characteristics. In general, high-yielding crops require

considerably more support and attention than traditional strains in order to realize their full potential productivity.

Although human action can modify many of the conditions of plant growth, limits are imposed upon agricultural production by geographic variation in the amount of solar energy reaching the surface of Earth, temperatures of both soil and air, amount of soil moisture available, and so forth. And, because of the key role played by photosynthesis in agriculture, it is inevitable that farming will remain a highly dispersed human activity. Agriculture must remain spread over the face of Earth, because the energy of sunlight can only be utilized in photosynthesis at its point of arrival. Furthermore, especially when populations are large, agricultural production and the transport of agricultural goods will always remain intimately intertwined; food production cannot be considered in isolation from food distribution. It is not possible to concentrate agriculture in regions of need, as it is sometimes possible to concentrate production of other substances required by human beings.

Indeed, high and growing concentrations of human beings tend to be inimical to agriculture; food must be brought to them, and they occupy land that could produce it. As anyone knows who has lived in the country around Philadelphia, Chicago, or Los Angeles, for instance, farmland around cities is disappearing beneath pavement-each year about 250,000 hectares of prime agricultural land in the United States are "developed" into subdivisions and highways. [2] Between the early 1950s and early 1970s, some 11 million hectares were converted into airports, freeways, and suburbs--a total area larger than Ohio. [3] If less than first-class land is considered, the quantity that has been--and continues to be--lost rises to over 18 million hectares since 1945, with an annual loss of a million hectares in the early 1970s. [3a]

In recent decades, for each 1000 people added to the population of California, an average of 100 hectares of arable land has been covered by buildings and pavement. [4] Figure 7-2 graphically shows the process underway. Residents and industry also compete for freshwater

[4] K. E. F. Watt, *personal communication*.

supplies, which are becoming increasingly scarce in many regions. (See Chapter 6 for more on conversion of land to urban uses and dwindling untapped water supplies.) Moreover, smog can reduce yields and even kill crops.

If farmland continued to be converted to urban use at the rates prevailing in the 1960s, California eventually would not be able to feed itself, let alone export food to other states and abroad as it does today. In dollar volume, California is the most important agricultural state. Fortunately, since 1970 immigration into California has slowed to a trickle, and rising farmland values, new protective tax laws, and actions of environmental groups have substantially reduced the rate of farmland conversion.

In general, it is important to remember that the agricultural system of a nation is an integral part of its socio-economic system, and that this often places constraints on how much food is produced. [5] For example, it is often overlooked in discussions of the world food problem that farmers, like plumbers, corporate executives, and university professors, expect economic rewards for their labors. They will not grow food to sell for less than it costs to grow it. Thus the economics of agroecosystems inevitably pervades realistic discussions of how much food can be grown in various places and how much can be stored and distributed in various patterns.

Major Food Crops

Some 80 species of food plants have been domesticated, as opposed to only about two dozen kinds of animals. Over the centuries, most of them have been improved by selective breeding and/or by hybridization. Virtually all the original domestication of both plants and animals took place in prehistoric times. [6] But, in spite of the diversity of available food plants, a relatively small array of crops supplies the great bulk of the world's food. If one had to pick the three most important food plants in the world, the almost inevitable choice would be three species of grasses: rice, wheat, and corn. So important are these cereal grains that slightly more than one-half of the

TABLE 7-1 Sources of Humanity's Food Energy

harvested land of the world is used to grow them. Wheat and rice together supply roughly 40 percent of humanity's food energy (Table 7-1). Altogether, cereal grains provide well over half of the calories consumed by the human population and nearly half of the protein. [7]

Rice is the most important crop of all; it is the staple food for over two billion people. As is shown in Figure 7-3, the People's Republic of China grows about 35 percent of the world's rice; India, Bangladesh, Indonesia, Japan, and Thailand account for another 43 percent. Most of the remaining 22 percent is grown in Southeast Asia and Latin America. [8] Total world production of rice (before milling) in 1974 was an estimated 323 million metric tons.

Wheat almost equals rice in importance to the diet of human beings. (Sometimes wheat production in tonnage exceeds that of rice, but some of it is used as feed for livestock.) In 1974 some 360 million metric tons of wheat were produced. Unlike rice, wheat does not grow well in the tropics, in part because one of its major diseases, wheat-rust fungus, thrives in warm, humid climates. Wheat is grown mostly where winters are cold and wet,

[8]United Nations Food and Agriculture Organization, *Production yearbook, 1974* (FAO, Rome, 1975); J. Janick et al., *Plant science*. These two are the main sources for what follows.

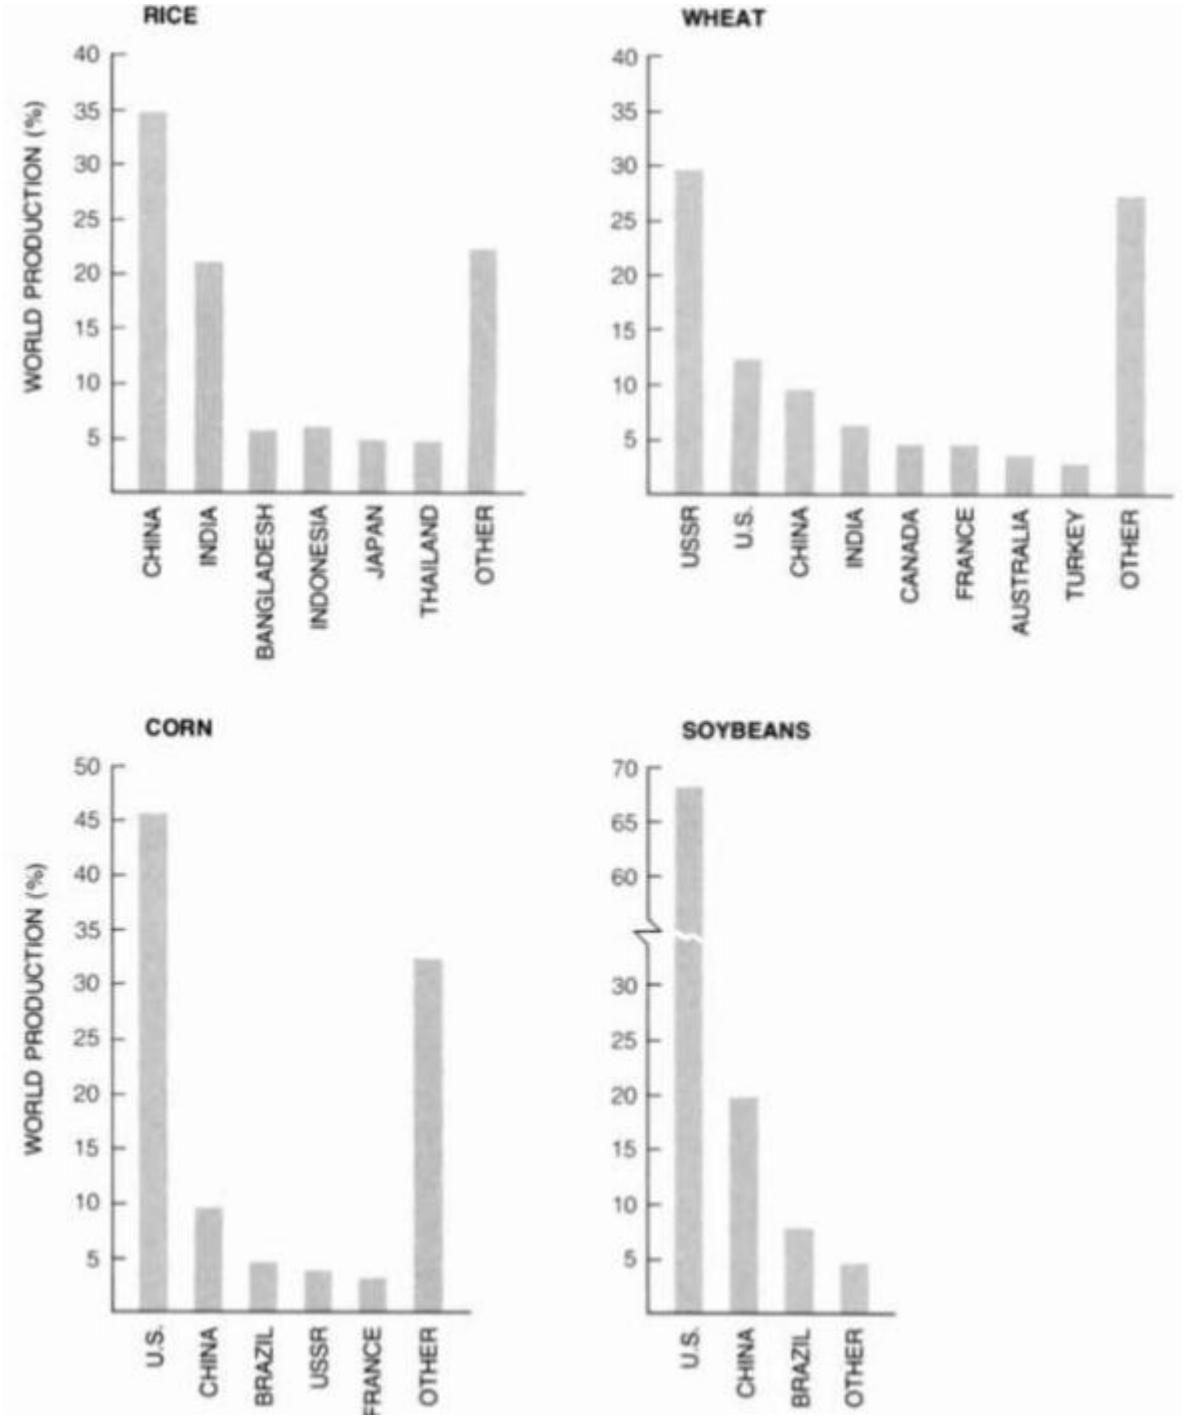

FIGURE 7-3
Where major crops are grown. (Data from FAO, *Production yearbook*, 1973.)

and summers hot and rather dry (although in the U.S. wheat belt most of the precipitation occurs in the summer). The Soviet Union produces nearly 30 percent of the world's wheat. Most of the rest is grown in such temperate areas as China, northern India, North America, Europe, and Australia.

Corn, or maize, is the third great cereal crop, with 1974 production being about 293 million metric tons. The long, warm, moist summers of the eastern half of the United States are ideal for corn production, and more than 45 percent of the world supply is grown there. It should be noted, though, that the bulk of American corn production is fed to livestock; human consumption of corn as a principal staple is mainly confined to Latin America and tropical Africa.

Rice, wheat, and corn together accounted for nearly one billion metric tons of grain in 1974. The rest of the world's cereal grain crop of about 1.2 billion metric tons was made up by other grains: barley, oats, rye, millet, and sorghum. Somewhat more than half the world's production of these grains come from the United States, the USSR, and Western Europe. These grains, together with corn, are commonly referred to as "coarse grains" (as contrasted with wheat and rice, the "small grains").

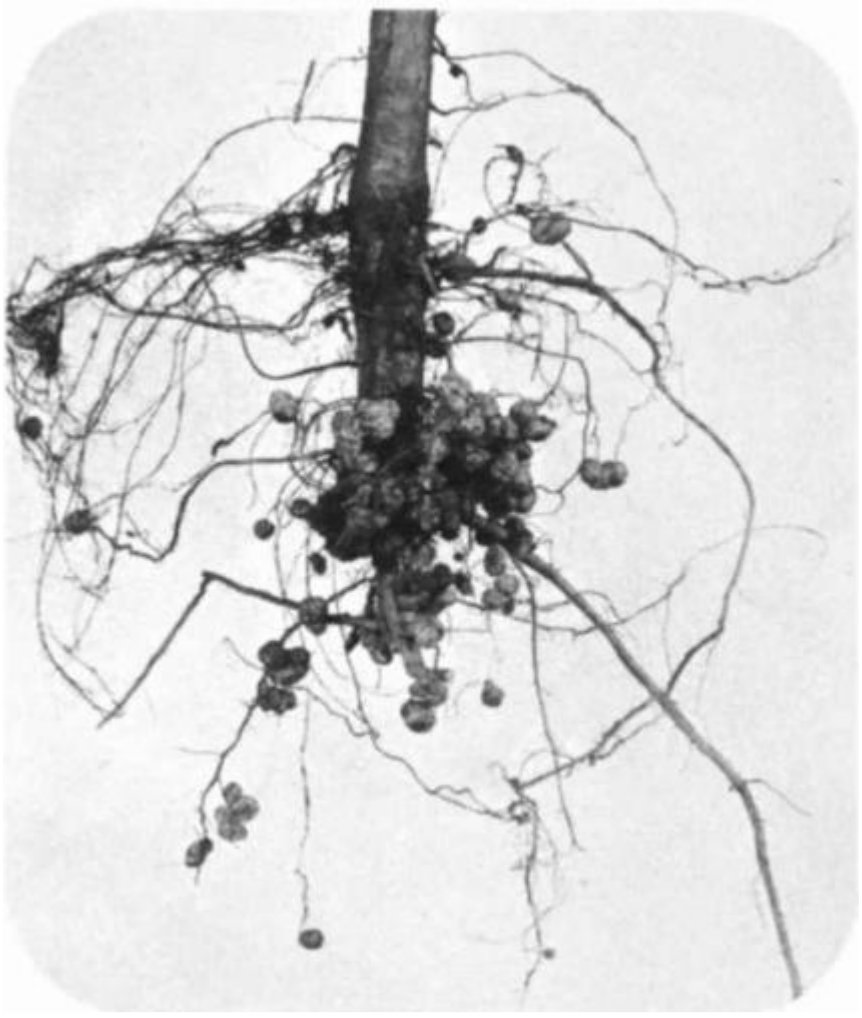

FIGURE 7-4
Nitrogen-fixing bacteria inhabit the nodules of soybean roots in a mutualistic relationship. (Photo by J. C. Allen and Son.)

Roughly 300 million metric tons of potatoes are also grown annually, but the water content of the potato is so high (75 percent) that the food value of the total harvest is considerably less than that of any of the "big three" grains. (On a per-acre basis, however, the potato may be superior.) The potato is particularly well-adapted to cool climates. Fully one-third of the world's potato production comes from the Soviet Union, 16 percent comes from Poland, and over 11 percent from China. The United States and East and West Germany are also important producers. The rest of the world accounts for less than 30 percent, mostly European and Latin American countries.

The protein content of most modern grains ranges between 5 and 15 percent and is not complete protein (that is, it does not have an ideal balance of amino acids for human nutrition). In most grains the protein is too low in content of some essential amino acids, especially tryptophan and lysine. Grains and potatoes are all rich in protein, however, in comparison with some of the starchier staple crops commonly consumed in humid tropical countries: taro, cassava, yarns, and plaintains.

Legumes (a family of plants that includes peas, beans, peanuts, soybeans and several forage crops) cannot compete in volume with grains in world food production. They have two to four times the protein content of grains, however, and thus are critically important in human nutrition and for domestic animals as well. For the human population, legumes provide about 20 percent of the protein supply worldwide. [9] Bacteria associated with the roots of legumes have the ability to fix gaseous nitrogen from the atmosphere and convert it into a form that can be directly used by plants (See Figure 74). As a result, legumes also serve as fertilizer ("green manure") when planted in rotation or intercropped with other crops, and thereby also can contribute indirectly to the protein derived from other plants.

Two legumes, soybeans and peanuts (groundnuts), are grown mainly for use as oil sources and livestock feed. These two crops account for about two-thirds of the world's legume production of some 124 million metric tons; soybeans alone reached 63 mmt in 1973. [10] Both are excellent sources of protein, especially soybeans. The protein content of soybeans is some three times as high as that of wheat, for instance. Both soybean oil and peanut oil are used for making margarine, salad dressings, and shortenings, and are also used in various industrial processes. The high-protein material remaining after the oils are pressed out (presscake) is usually sold for livestock feed. Except in the Far East, relatively little of the soybean crop is directly consumed by people, although this is changing as inflation induces people in DCs to substitute cheaper foods for meat. Soy products are becoming increasingly popular with Americans. A significant portion of the peanut crop has long been eaten in the nut form or in candy or peanut butter around the world. Production of soybeans is concentrated in the United States and China, although production in Brazil was increasing rapidly in the 1970s. Peanuts are grown mainly in India and Africa.

The remaining legumes--beans and peas--are known collectively as pulses. There is a wide variety of these, including lima beans, string beans, white beans, kidney beans, scotch beans, peas, cow peas, garbanzos, and

---

[10]Folke Dovring, *Soybeans*. This is an interesting account of the growth in importance of soybeans as a major food crop.
[9]Pimentel, et al., *Energy and land constraints*.

lentils. Because they are among the richest plant sources of protein, pulses provide a significant element in the human diet, especially in poor countries. Moreover, the proteins of pulses, although also incomplete, complement those of grains to furnish a complete protein meal when they are eaten together.

Unfortunately, annual world production of pulses has not increased significantly since 1962. In developed countries, they may have been replaced in part by increased consumption of meat and dairy products. But in rapidly growing less developed countries, the lack of increase in pulse production for more than a decade indicates a considerable reduction in per-capita supplies. Since the gap has mainly been filled by grains, the probable result is a deterioration of protein levels in diets, both in quantity and quality. In some countries, acreage planted to pulses has actually been *reduced* in favor of more profitable high-yield grains. [11]

Cereals and legumes are the worldwide mainstays of the human diet, but a vast variety of other plants is cultivated and consumed. Cassava, taro, sweet potatoes, and yams (all root crops) supply food energy to many people in the world, especially to the poor in humid tropical areas; people subsisting mainly on these starchy foods are relatively likely to suffer from protein deficiency. The roots of the sugar-beet plant and the stems of the cane-sugar plant (a grass) supply sugar to people around the world. The roots, stems, fruits, berries, and leaves of numerous other plants are important sources of energy, vitamins, and minerals in human diets.

Many plants are also used as forages--foods for domestic animals. Although ruminants (cattle, sheep, and goats) are often just turned loose on rangeland to graze and fend for themselves, many forage crops are grown in pastures or harvested and used for hay or silage (fermented fodder) specifically to feed them. In the United States, which consumes large quantities of meat per capita, the forage crop fed to animals in 1973 was only slightly less (as measured by nutritional equivalent) than the entire U.S. grain harvest for that year (and much of that was also fed to animals). Some 60 million acres of the world are planted in the legume *alfalfa* (called "lucerne" in Europe), which is among the most nutritious of all forage crops and is especially rich in protein. Some other legumes--for instance, clovers--are also grown as forage, as are a great variety of grasses. [12]

Food from Animals

The primary nutritional importance of domesticated animals in many cultures is as a source of high-quality protein. They are, of course, valued for other roles as well, especially in less developed countries where traditional techniques of agriculture still prevail. There the larger farm animals--cattle, horses, and water buffalo-are highly valued as draft animals and as transport. The dung of all livestock is valued everywhere as an important source of fertilizer and in some regions as fuel and building plaster. In some societies, the value of animals for food is almost incidental to their other uses.

The variety of animals that have been domesticated for food is considerably more limited than that of plants. Only nine species-cattle, pigs, sheep, goats, water buffalo, chickens, ducks, geese, and turkeys--account for nearly 100 percent of the world's production of protein from domesticated animals. Beef and pork together, in roughly equal amounts, account for some 90 percent of meat production (excluding poultry). Cows produce more than 90 percent of the milk consumed, water buffalo about 4 percent, and goats and sheep the remainder (ignoring tiny amounts from reindeer and some other minor domestic mammals). [13]

Although certain breeds of domestic animals are adapted to the tropics, animal husbandry is generally easier and more productive in temperate areas than in the tropics. It is primarily in the temperate zones that geneticists have produced animals capable of extraordinary yields of meat, milk, and eggs, given special care and intensive feeding of high-protein feedstuffs. The yearround high temperatures and possibly the high humidity of the tropics tend to slow growth and, in milk-producing animals, lower the production of milk and milk solids. Unfortunately, although forage may grow luxuriantly in many tropical areas, the native varieties are commonly

[11]J. D. Gavan and J. A. Dixon, *India: A perspective on the food situation*.
[12]H. J. Hodgson, *Forage crops*.
[13]IH. H. Cole, ed., *Introduction to livestock production*; H. H. Cole and M. Ronning, eds., *Animal agriculture*.

low in nutrient value. High temperature and humidity also often provide ideal conditions for parasites and carriers of disease. For instance, in a large portion of Africa where rainfall and other conditions are suitable (about 37 percent of the continent) tsetse flies carry a serious disease, nagana (caused by single-celled organisms called trypanosomes), which makes cattle herding impossible. [14]

Domestic animals, especially cattle, are often more than mere meat or milk producers in LDCS. In the semiarid zones of East and West Africa, cattle are the basis of entire cultures. They are regularly tapped for blood as well as milk, and are intimately related to the social and economic life of certain groups. Cattle provide their owners with wealth and prestige, are used ceremonially, and have aesthetic value.

In India there is a large population of "sacred cattle," so called because of the Hindu taboo against slaughter. Visitors to India rather commonly conclude that the Indian food situtation could be ameliorated by slaughtering these "useless" animals. This judgment is based on a fundamental misunderstanding of the situation. Like so many folkways and taboos, the Indian taboo has a vital influence on the local ecology. Most of the cattle feed on forage and waste vegetation that are not human foods: they do not compete with people for food. The cattle *do* supply milk, and above all they supply power. Bullocks (castrated bulls) are the tractors of India; they are absolutely essential to her agricultural economy. Finally, the cattle also supply dung, which serves as the main cooking fuel of India, and which is also used as fertilizer and as plaster in houses. Of an estimated 800 million tons of dung produced each year, some 300 million were

used as fuel in the 1960s. This fuel produced heat equivalent to that obtained from burning 35 million tons of coal (about half of India's coal production). [15]

The consumption of meat and poultry has grown very rapidly since World War II, especially in developed countries. World production in 1974 amounted to just under 116 million metric tons, of which the developed regions produced about 79 million metric tons and the less developed regions produced the remaining 37 million metric tons. [16] Meat clearly occupies a far less important position in the diets of people in LDCS, with the notable exception of herding societies such as the Masai, the people of the Sahel, and nomads in the Middle East and Central Asia.

THE DIMENSIONS OF WORLD HUNGER

In 1967 the President's Science Advisory Committee Panel on the World Food Supply [17] estimated that 20 percent of the people in the less developed countries (which include two-thirds of the world's population) were undernourished (that is, were not receiving enough calories per day) and that perhaps 60 percent were malnourished (seriously lacking in one or more essential nutrients, most commonly protein). As many as a billion and a half people thus were described as either undernourished or malnourished. This may have been a conservative estimate; others have placed the number of "hungry" people during the mid-1960s at two billion or more. [18] The President's Panel further estimated that perhaps a half billion people were either chronically hungry or starving. (These numbers did not include the hungry and malnourished millions in the lower economic strata of developed countries such as the United States, or the numbers of people who could afford to eat well but were malnourished because of their ignorance of elementary nutrition.) Nor did this situation suddenly develop in the 1960s; chronic hunger had long existed among the poor around the world.

Recent History of Food Production

Between World War II and 1972, there was a steady, worldwide, upward trend in the amount of food produced for each person on Earth. This trend generally continued uninterrupted in the developed countries, with a few exceptions and setbacks, until the 1970s. In the less developed regions, however, the steady increase

Africa	0.28	25	67
World (excluding Asian centrally planned economies)	2.83	16	462

Source: UN, *Assessment*.

in per-capita food production was halted sometime between 1956 and 1960, depending on the country. Because population growth in LDCs more or less equalled the growth in total food production, the available supply per person has fluctuated around the same level ever since. In 1970 the average country in Africa was producing less food per person than it had in the mid-1950s, while the average country in Latin America and the Far East had slightly improved its condition. Among less developed regions, only China and the near East significantly increased their food supplies per person between 1955 and 1970. This situation obtained in spite of substantial increases (roughly 30-35 percent) in *absolute food supplies* in all these areas during that period; population growth offset the gains.

There was widespread optimism in the late 1960s and early 1970s that improvements in agricultural techniques, especially in less developed nations (the Green Revolution), would allow food-production increases--at least for a few decades--to exceed the 2 percent annual growth of the world's population, which was then adding about 75 million hungry mouths every year. Between 1967 and 1972, food production did indeed rise more rapidly than population growth, most encouragingly in some of the hungriest nations in Asia. Even so, a large segment of the human population was not receiving sufficient daily bread.

The United Nations has very conservatively estimated that some 460 million people were "seriously undernourished" during those relatively food-abundant years just before 1972. Moreover, the UN conceded that, by less conservative criteria, the number of hungry people at that time actually might be *more than twice as great*. Because infants and young children are most likely to suffer when food supplies are inadequate, the UN further estimated that *perhaps one-half of all children underfive years old in developing countries were inadequately nourished to some degree*. [19]

Table 7-2 shows the UN estimates of the distribution of undernourished people in the world by region in 1970. It should be noted that even in the generally well-fed developed regions, 3 percent, or 28 million people, were considered undernourished. Not a few of those were in the United States. Figure 7-5 shows where the hungry nations are located.

Since 1971, the prospects for raising nutritional levels in the poor countries have dimmed. The early 1970s, particularly 1972 and 1974, were marked by unusually adverse weather for agriculture in a broad array of regions, including densely populated Southern Asia, agriculturally important North America, much of tropical Africa, and parts of Southeast Asia, Brazil, the Soviet

[19]United Nations, *Assessment of the world food situation, present and future*. The estimate excluded China and other centrally planned countries in Asia because of insufficient data; China was not admitted to the United Nations until late 1971. It is worth noting, however, that the accumulating evidence, though not at all conclusive, indicates that the people of China and the other centrally planned Asian countries (North Vietnam and North Korea) have been fairly adequately fed in recent years. China responded to a poor harvest in 1972 by buying wheat from the United States. So far as anyone can tell, the Chinese people suffered no significant ill-effects from food shortage then.

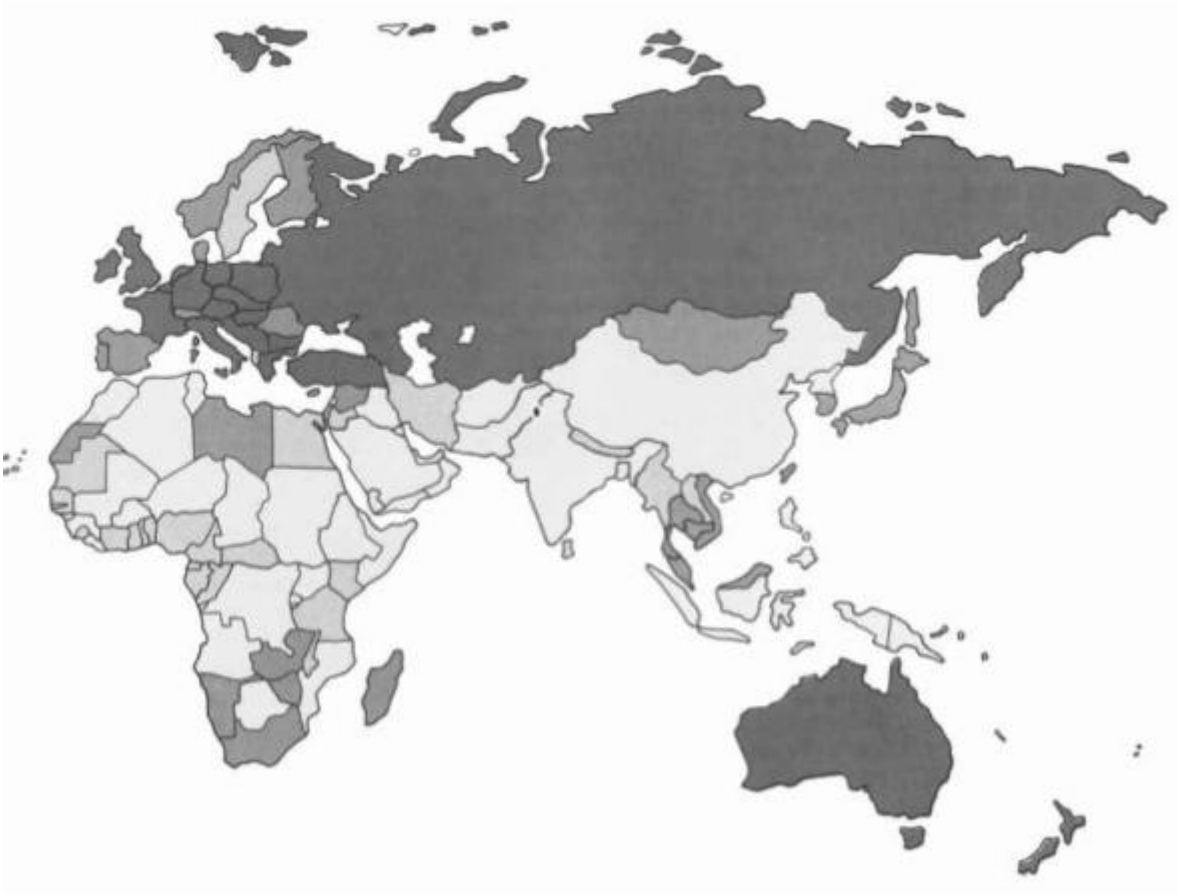

FIGURE 7-5
The geography of hunger, 1969-1971. (Data from *Assessment of the world food situation, present and future*, UN World Food Conference, 1974.)

Union, and China. These widespread weather changes, unanticipated by the agricultural community, manifested themselves mainly as floods, droughts, and sometimes both, at different times. The consequence of this series of weather changes, exacerbated in 1974 by the fourfold increase in oil prices and a severe shortfall in fertilizer production, was an unprecedented worldwide shortage of food by the end of that year.

In 1972, after a strong upward trend for 20 years, world food production declined. Production of grains-wheat, rice, and coarse grains--on which people in poor countries primarily depend for sustenance, fell 33 million metric tons below 1971 harvests, about 3 percent. To meet the growing demand, 25 million metric tons *more* than the 1971 total were needed. At that time adequate reserves existed; so most countries were able to obtain enough grain on the world market or from food aid to meet their needs, at least at prevailing inadequate standards.

The primary consequence of the 1972 shortfall in production was a worldwide steep rise in prices of basic foods, especially of grains. Higher food prices inevitably most affect the poorest people in every nation. The blame for the price-rise in grains has been attributed to speculation on the world market and to unusually large grain purchases in 1972 and 1973 by the USSR and China--some 30 million metric tons--mostly from the United States at low, government-subsidized prices. The basic cause, of course, was the production shortfall (and subsequently diminishing reserves), but this has often

been overlooked, at least in the popular press. Between 1972 and 1974, world market prices for wheat, rice, corn (maize), and soybeans tripled or quadrupled. Later they declined somewhat, but generally have remained at about twice their 1972 levels. [20]

There was a partial recovery of food production in 1973, mainly in DCs, and per-capita grain production returned to "normal" levels on a worldwide average. Grain reserves continued to decline, however, as they were drawn down to compensate for the 1972 deficit.

Widespread bad weather struck again in 1974, coinciding with the energy crisis and a severe fertilizer shortage. This time the decline over the 1973 grain production amounted to some 50 million metric tons -even more than the decline of 1972, a drop of more than 4 percent. Per capita, of course, the decline was even greater: about 6 percent.

The world food picture in late 1974 was considerably gloomier than the unattractive situation described in detail by the President's Panel on the World Food Supply in 1967. World grain reserves (stored grain, mostly U.S. surplus, plus the potential production of idled land) in 1967 were equal to 55 days' supply, the low point for that decade. In 1974 reserves were down to a 33-day supply -- essentially what exists in the "pipeline" of supply channels. [21]

[21]Lester R. Brown, *The politics and responsibility of the North American breadbasket*.

Large-scale famine was then occurring in the Sahel (the southern fringe of the Sahara desert, including parts of the nations of Chad, Gambia, Mali, Mauritania, Senegal, Upper Volta, and Niger), where drought had prevailed for six consecutive years. [22] Famine was also threatening India [23] and Bangladesh, [24] both of which had been struck by floods and at least partial monsoon failures in two of the previous three years. Other regions threatened with severe food shortages included some thirteen additional African countries, comprising virtually all of tropical Africa; four Central American and Caribbean nations; Pakistan, Sri Lanka, Laos, and Cambodia in Asia; and Yemen and South Yemen in the Middle East.

In October 1974, the United Nations' Food and Agriculture Organization (generally known as FAO) announced that no less than 32 nations, within which nearly three-quarters of a billion people were already marginally or inadequately nourished, were threatened with starvation and bankruptcy unless developed nations provided them with food and economic assistance.

On top of the widespread adverse weather in 1974, the oil embargo of fall 1973, followed by the quadrupling of oil prices by OPEC nations, caused serious problems for agriculture. Apart from the need for gasoline to operate farm machinery, petroleum and (especially) natural gas are needed for the manufacture of fertilizers. Manufactured fertilizers were already in short supply; the effect of the oil crisis was to worsen the shortage of fertilizers worldwide. And less developed countries, which have become increasingly dependent on fertilizers to raise their food production, were most hard hit. The UN estimated that the fertilizer shortage might have reduced grain production in LDCs in 1974 by 12 million metric tons. [25]

Almost simultaneously with the drops in world agricultural production, fisheries harvests, which had also risen steadily since World War II, began to decline. The peak, over 70 million metric

tons of fish, was reached in 1971. In 1972 and 1973, the fish catch fell below 66 million metric tons. [26] Although fisheries production contributes only a small percentage of the calories in the world food budget, it is a vital source of protein, especially to protein-short LDCS.

Hopes were high that 1975 harvests would brighten the world food picture and allow some rebuilding of grain reserves. But total production barely exceeded the disastrous 1974 level. This time the poor harvests were centered mainly in the developed countries, especially the USSR. Because of bad weather again, the 1975 Soviet grain harvest fell some 55 million metric tons below that of the previous year. Meanwhile, the less developed nations enjoyed an average 5 percent increase in food production in 1975 after three consecutive poor years. [27]

The total world cereal crop for 1975/ 1976 was estimated by the U.S. Department of Agriculture at 1220 million metric tons, only 20 mmt above the previous year and still 34 mmt below the record of 1973/ 1974. Since most of the 1975/ 1976 shortfall occurred in DCs (especially the USSR), those countries absorbed it, largely through reduced meat consumption. Nevertheless, averaged worldwide, production of grain per capita, at 309 kilograms of grain per person, reached a ten-year low, and there was no improvement in the carryover supply.

The picture brightened somewhat in 1976/ 1977, when preliminary reports indicated a total grain harvest of over 1320 mmt. [27a] This increase of 100 mmt was achieved despite severe floods in Japan and parts of southeast Asia, drought in the north-central United States, and a drought in Western Europe unequalled in many centuries. Grain reserves, mostly of wheat, rose significantly

[27a]USDA, WAS-12.

in 1977 for the first time since 1972 but were still far short of goals set by the 1974 World Food Conference.

The outlook for 1977/ 1978 was not encouraging. The disastrous winter of 1976/ 1977 in the United States alone, with record cold and snowfall in the East and severe drought in the West, could not fail to reduce agricultural production in the American granary. Once again, plans to build up world grain reserves as insurance against weather-caused reductions in grain production may be defeated by that same eventuality.

Agriculture's continuing dependence on weather thus has been emphatically brought home by the events of the 1970s. Moreover, the damage has not been limited to LDCS; such supposedly secure granaries as the United States, Europe, Australia, and the USSR have also suffered. Table 7-3 shows the U.S. Department of Agriculture estimates for the world's total grain production during the 1970s. Table 74 shows the decline in annual levels of the world's grain reserves since 1961.

Figure 7-6 shows the general trends of per-capita food production in developed and less developed areas (excluding the People's Republic of China) since 1955. Note that, like total production, per-capita food production in DCs has risen steadily, but in LDCs in 1975 it had barely recovered to the peak level achieved in 1970, not far above the level of the period 1961-1965. *This, of course, indicates an enormous increase in human misery*. Well over a billion people have been added to the populations of less developed nations since the early 1950s, and a large proportion of them are both very poor and chronically undernourished. Even though the average nutritional condition of the poverty-stricken of our planet may have remained about the same during those decades, both the *absolute numbers of the poor and their proportion of the total world population have increased rapidly*.

The worldwide nutritional situation that has characterized the past generation is totally unprecedented, in part because of the absolute numbers of people involved. Famines have occurred throughout history, but they have generally been temporary, if cataclysmic, events caused by weather or human conflicts and limited to relatively small, local populations. Such famines were undeniably tragic affairs that resulted in a great deal of human suffering, and chronic hunger has also been long

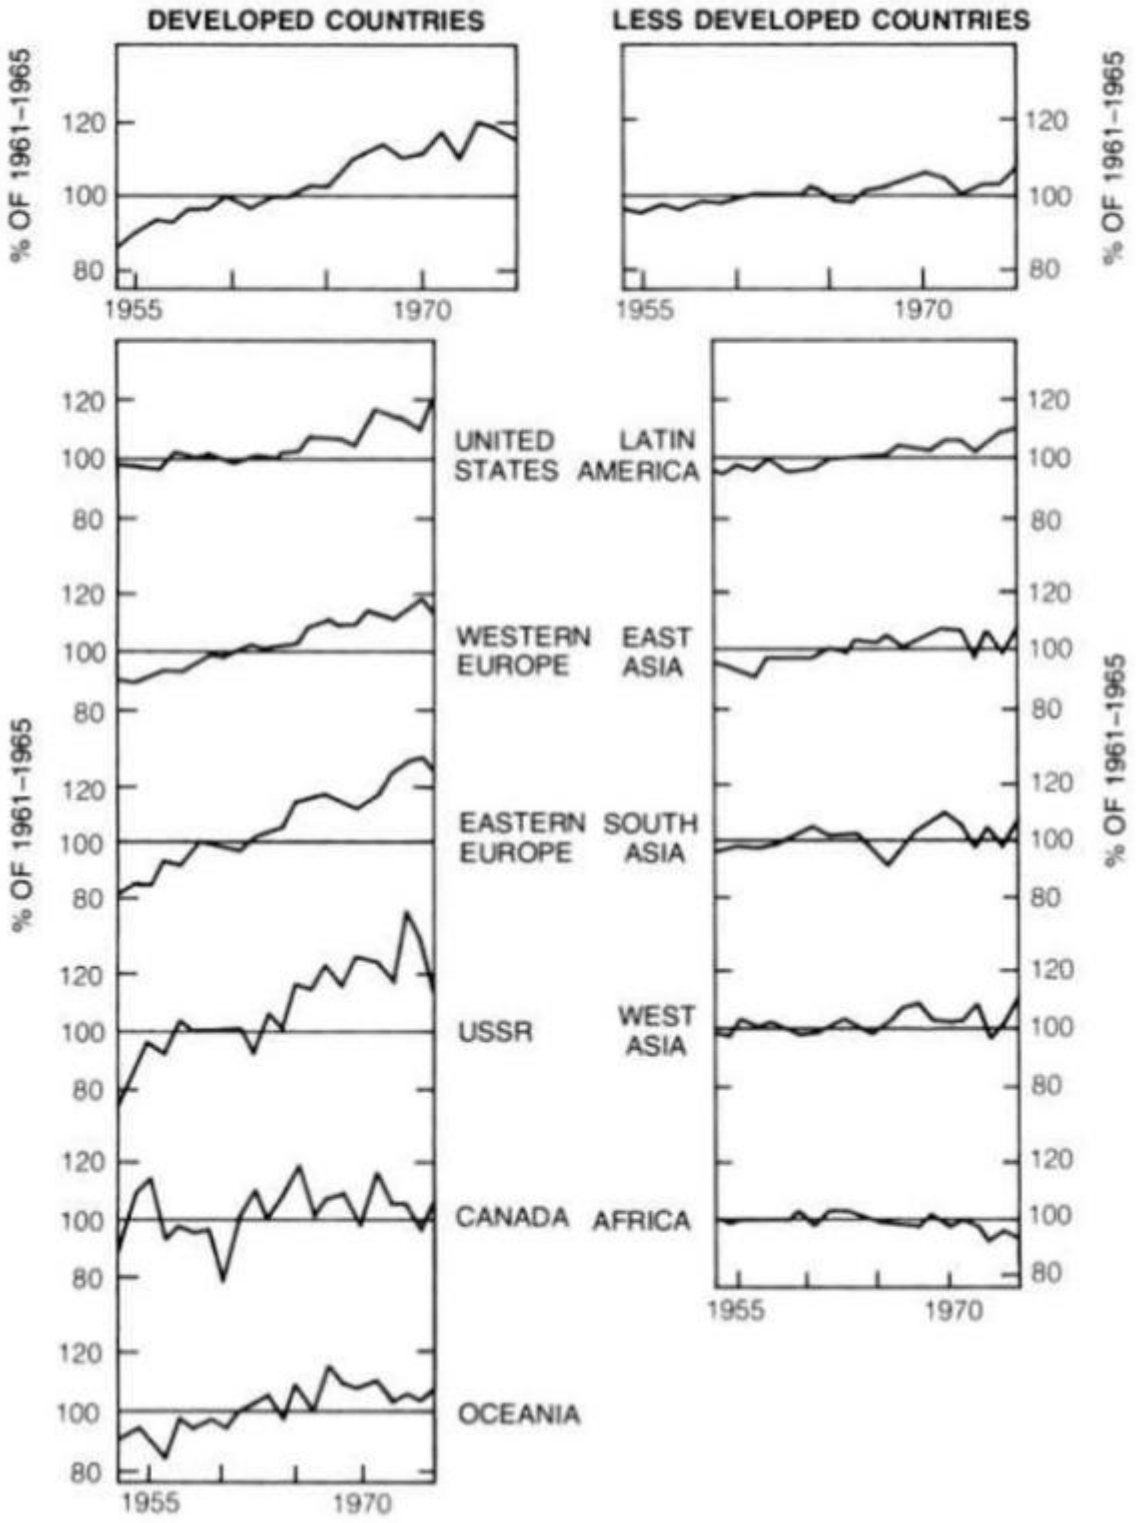

FIGURE 7-6 World food production per capita, 1954-1975. The developing countries have gained only 0.4 percent per year. In none of those regions has the index reached 110, and in Africa it has shown a downward trend since 1951. Per-capita food production trended upward 1.5 percent per year in the developed countries until the early 1970s. In each of those regions the index of per-capita food production has reached or exceeded 110 at least three times in the 22-

year period. (Adapted from U.S. Department of Agriculture, The world food situation and prospects to 1985, *Foreign Agricultural Economic Report No. 98*, 1974; recent data from WAS-12.)

endemic in many areas. But the scale and ubiquity of hunger today is an entirely new phenomenon. Unceasing poverty-related privation, including hunger and malnutrition, is now endured by more than one billion people around the globe, and perhaps 400 million live on the brink of starvation. [28] This chronic hunger is also unprecedented because the multitudinous hungry have become increasingly aware of the dietary condition of the affluent few and have high hopes of emulating them, a situation that has grave political implications for the future.

This, then, is the fundamental reason that the human population reached such a precarious position with regard to its most basic resource -- food -- so suddenly in the mid-1970s: an already marginal situation was precipitated into a crisis by a series of weather-related bad harvests. The roots of the crisis lie: (1) in rapid population growth, which has necessitated an increase in food production of about 2 percent per year for the past generation just to maintain existing nutritional levels; (2) in the finite amounts of arable land, fresh water, and fertilizer available; (3) in the low productivity of traditional farming methods, especially in LDCS; (4) in environmental constraints; (5) in the lack of world investment (either monetary, social, or political) in increasing food production; and (6) in a political decision in the U.S. to eliminate government-held grain reserves. Underlying all the other factors, the world's economic system has created and perpetuates gross inequities in the distribution of food, as of other commodities. Thus a quarter of the human population have access to abundant food, while nearly half subsist on inadequate supplies and are tragically vulnerable to any disruption in that meager allotment.

Following the Rome Food Conference in November 1974, efforts were made to establish a worldwide foodinformation network, and to organize national and international food-reserve stockpiles to meet future deficits and to avert famine in the hungriest nations. A World Food Council, responsible to the UN Secretariat, was established to foster agricultural development in LDCs and to coordinate famine-relief efforts. A Consultative

[28] Jean Mayer, *The dimensions of human hunger*.

FIGURE 7-7 Major international organizations in the food field. 1Members of the World Food Council: Argentina, Australia, Bangladesh, Canada, Chad, Colombia, Cuba, Egypt, Federal Republic of Germany, France, Gabon, Guatemala, Guinea, Hungary, India, Indonesia ,Iran, Iraq, Italy, Japan, Kenya, Libyan Arab Republic, Mali, Mexico, Pakistan, Rumania, Sri Lanka (Ceylon), Sweden, Togo, Trinidad and Tobago, United Kingdom, United States, USSR, Venezuela, Yugoslavia, and Zambia. 2This loosely organized but important London-based consultative mechanism -- which is outside the UN system of organizations and therefore has no official responsibility for implementing the recommendations of the World Food Conference -- now involves some sixty countries, including the Soviet Union. It is the body within which international wheat agreements have been negotiated since the late 1940s. 3The Soviet Union is not a member of the FAO. 4Established by the FAO council in late November 1975 as a successor to the FAO Ad Hoc Working Party on World Food Security. (From McLaughlin, 1975, Overseas Development Council.)

Group on Food Production and Investment, connected with the World Bank, was set up to channel assistance funds into useful agricultural projects. Figure 7-7 shows the major international agencies involved with food, inside and outside the United Nations.

Thanks to a decline in demand for food in the rich countries, especially for feed grains, enough food was made available on the world food market and as food aid to head off large-scale famine in 1975. Some 36 million tons of grain were imported in 1973/ 1974 by LDCs (not including China), and 8.6 million tons were given to the neediest countries during 1974/ 1975. [29] The World Food Council has sought 10 million tons of food aid per year, but only about 9 million tons were donated in 1975/ 1976. [30] Importations of food by DCs declined to about 25 mmt in 1976/ 1977, the lowest in six years, thanks to good harvests that year. [30a] Nonetheless, while grain reserves remain at critically low levels, any significant problems in food production in 1977 and subsequent years are bound to have serious social, economic, and political repercussions. The possibility of a major famine that could bring population growth to a sudden, catastrophic halt has never been more real. [31]

THE DISTRIBUTION OF FOOD

Per-capita production figures are at best crude indicators of the food situation. They conceal gross differences that exist between countries, especially between the developed nations and the less developed nations. It is impossible to judge directly from per-capita foodproduction figures exactly what is happening to the average diet of individuals within each country, because the averaging process also conceals a great range of dietary differences between regions and income levels. The wealthiest urban classes in many LDCs eat very well, whereas the poorest -- landless farm workers or urban shanty dwellers -- live from hand to mouth. The prevailing economic system encourages production of food for the rich at the expense of food for the poor. [32]

[30a]USDA, WAS-12.
[31]Lester R. Brown, *The world food prospect*.

[32]Michael Lipton, *Urban bias and food policy in poor countries*.

Regional differences in diet may reflect different economic conditions or they may be the temporary result of good or bad harvests. For instance, in some areas of northern India, following the famine of the mid-1960s, which had necessitated the importation of nine million tons of grain from the U.S., wheat and rice were superabundant, and prices were dropping steadily. Yet, in spite of this surplus of food, seven million people were in danger of starvation in one province alone, and in northern India as a whole some 20 million people were described as being in "acute distress." This situation was due largely to local droughts in areas adjacent to those producing surpluses. The people were so poor that they could not create effective "demand" for food, producing the spectacle of surpluses and dropping prices in close proximity to starvation.

Even for an entire country, figures on food production may be unrevealing, since consumption equals production plus or minus trade. The trade positions of many less developed countries changed markedly between 1956 and 1975; many former grain exporters became heavy grain importers. At the same time, many of these hungry nations export food -- including such high-protein foodstuffs as oilseed cakes and fishmeal -- to the rich countries. [33]

The present failures of food distribution are the result of a host of interacting factors, including poverty, ignorance, cultural and economic patterns, and lack of transport systems. Although worldwide supplies of food today might theoretically be adequate to feed every human being if fairly distributed, the average diet within more than half of the less developed countries is below minimum standards of nutrition in calories alone. Distribution of specific nutrients, especially protein, is equally, if not more, inequitable, although less well documented.

Between the early 1950s and 1970s, food production in both developed and undeveloped regions increased at approximately the same average rate: around 3 percent per year. The difference is in the rates of population growth: less than 1.5 percent per year for DCs; 2 percent or more for most LDCS. Table 7-5 compares rates of population growth with growth in food production between 1952 and 1972. In LDCS, food production in 1952 was inadequate to feed the populations then existing. Since then, there has been a slight improvement overall, but in 34 out of 86 LDCs for which the United Nations had sufficient information, food production actually fell behind. If rising demand for food, which would be expected to accompany rising incomes, is considered, some 53 of these countries were failing to meet their food needs in 1972. [34] In the developed world, by contrast, most populations were reasonably well-fed in 1952. Since population growth was much slower, increased affluence accounted for more than half the growth in food consumption between 1952 and 1972. Thus, whereas people in most non-communist poor countries were not significantly better-fed after twenty years of efforts to raise food production -- indeed, many had lost ground -- those in rich countries generally were enjoying much more sumptuous diets. [34a]

Levels of Nutrition

Some appreciation of the nutritional gap between rich and poor nations can be gained by comparing the availability of food energy and protein per capita. According to the United

Nations Food and Agriculture Organization, some 3100 kilocalories (kcal) per day on the average were available to each person in developed countries in 1969-1971, some 23 percent above estimated needs. And an average of over 96 grams of protein were available per capita in DCs, also well above requirements. By contrast, in LDCs on the average only about 2200 kcal and less than 58 grams of protein per capita were available, about two-thirds of the amounts available in DCs and 5 percent below estimated needs. [35] Table 7-6 shows the estimated average food energy and protein supplies in 1969-1971 in different regions. A more detailed table comparing population growth rates and per-capita food supplies for individual countries in 1969-1971 can be found in Appendix 2.

Although individual needs for calories vary according to age, sex, body size, and activity, the FAO has

established standard "reference" body weights and standard daily per-capita kilocalorie requirements for estimating a population's caloric food needs. Children's needs, which are higher than those of adults in proportion to their body weights, are standardized according to age groups. For adults, allowances are also made for pregnancies and differences in age and sex. Calculations, using these standardized average requirements, are then made for an entire population based on its age composition and vital rates. Recommended average daily allowances for calories and several other important nutrients for men, women, and children can also be found in Appendix 2. [36]

Individual protein requirements also vary with body

[36] See N. S. Scrimshaw and V. R. Young, *The requirements of human nutrition, for a good summary of nutritional needs*. For a useful discussion of how nutrients needed in human nutrition are derived from plants and from soil-air-water nutrient cycles, see J. Janick, C. H. Noller, and C. L. Rhykerd, *The cycles of plant and animal nutrition*.

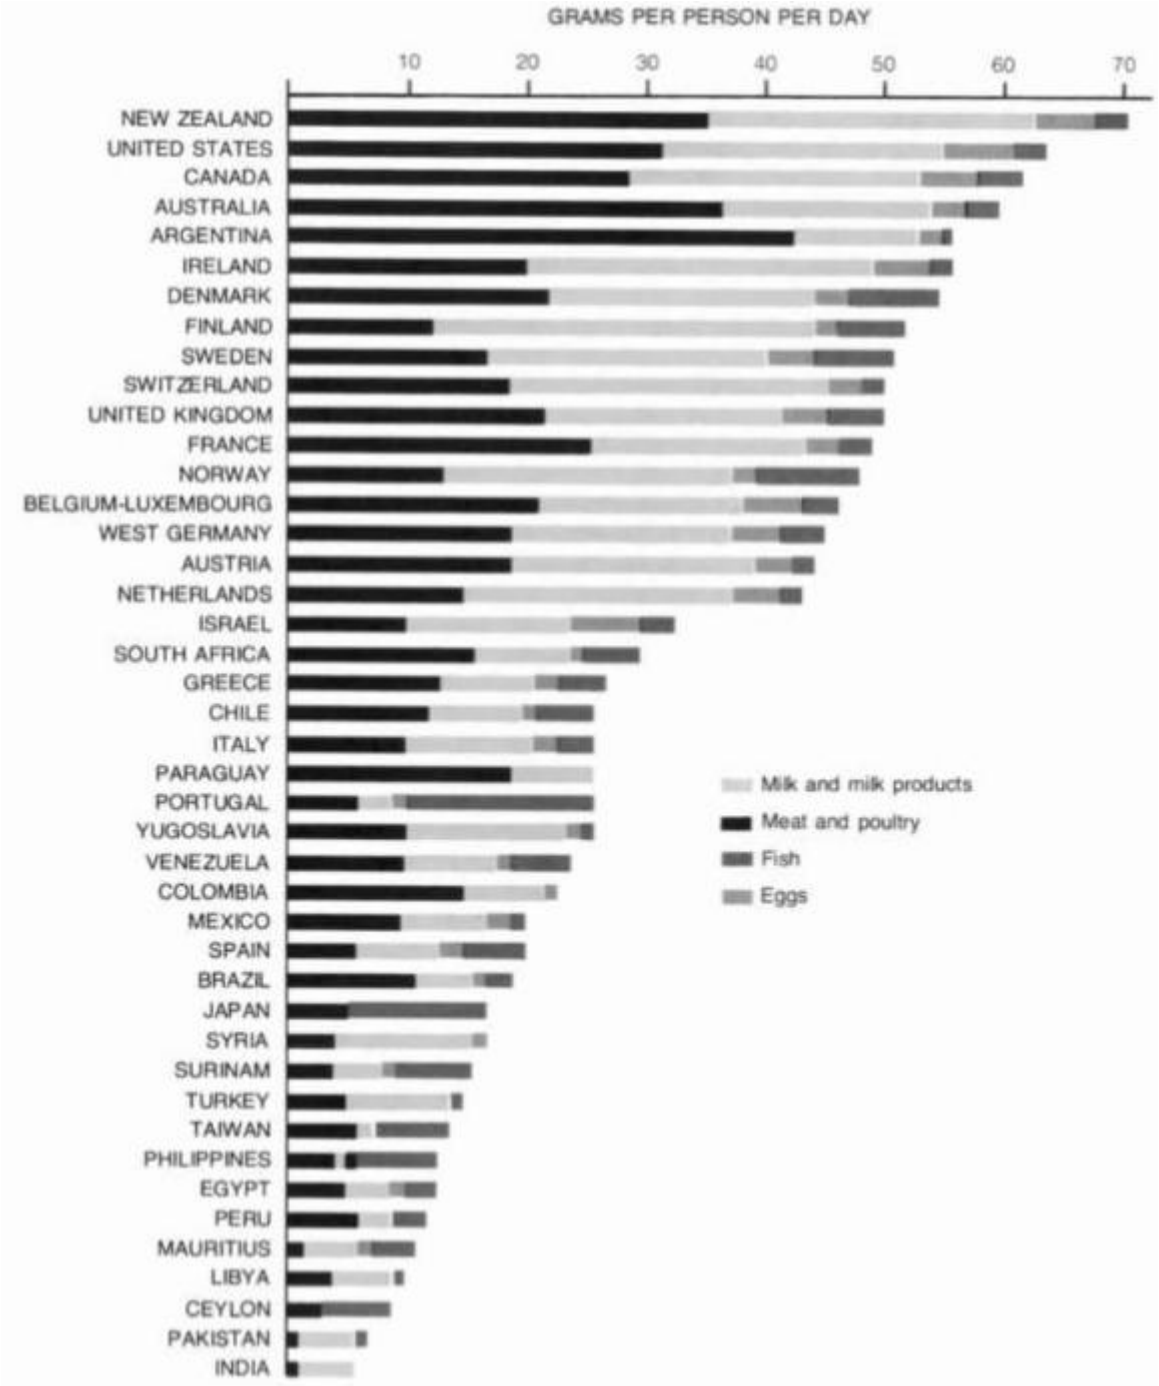

FIGURE 7-9 Daily per-capita animal protein supplies in forty-three countries. (After Cole, 1966.)

size and age, and are increased by pregnancy and lactation. Protein needs must also be calculated according to the quality of the sources; where animal foods are a rare element in the diet, more protein is needed to compensate for the generally lower quality of the protein in vegetable sources. Figures 7-8 and 7-9 show *per-capita* protein supplies for different countries in the 1960s. Since then, protein supplies, especially from animal sources, have increased in many DCs. In Japan, for instance, per-capita daily protein supplies from animal sources have risen

from less than 20 to over 30 grams. Among developed regions, only Japan, the USSR, and Eastern Europe still obtain less than half their protein from animals, but the proportion is rising fast. Total protein supplies and plant/animal ratios have changed relatively little in most LDCS, however.

There has been a growing controversy in recent years about how much protein people actually need in their

TABLE 7-7 Recommended Daily Protein Allowances

diets and whether a real protein shortage separate from simple food shortage exists in poor countries. [37] Standards for protein requirements have been steadily reduced since the 1950s as more precise measurements of needs have become possible. [38] The FAO's most recent calculations of protein needs were based on physiological tests of well-nourished individuals. Their calculations indicated that, for healthy people, a traditional, grainbased diet can provide sufficient protein if energy needs are met.

Some recent studies have cast doubt on the adequacy of these low standards, especially for people subsisting on diets that are only marginally adequate in other respects as well. When calories are insufficient, protein is utilized for energy rather than for growth or repair of body tissues. Protein needs also are considerably increased by infectious disease and parasitism, both of which are very common among impoverished, inadequately fed people. Finally, a tuber-based or grain-based diet is often too bulky for young children, who may not be able to eat enough to satisfy either their energy or protein needs. [39] Thus protein needs may often be higher for the hungry poor than for the well-fed, healthy rich. Moreover, the minimal standards set by the FAO may be inadequate even for otherwise well-nourished individuals. To ensure optimum health, protein intake probably should be considerably higher than the FAO minimum, even when calories are amply provided.

Appendix 2 contains more information on human nutritional requirements, and compares recommended nutrient allowances for people of different ages as set by: (1) FAO/ WHO, (2) the U.S. National Academy of Sciences/ National Research Council, and (3) the Canadian Bureau of Nutritional Sciences. The U.S. recommendations for protein, as well as for most other nutrients, are substantially higher than FAO'S; Canada's recommended intakes are slightly lower than those of the U.S. Table 7-7 summarizes the different recommended protein-intake levels.

Conflicting accounts of the actual food situation sometimes result from different ways of comparing figures. Food-production figures in the past have often been quoted only in calories, taking no account of whether adequate protein or other nutrients were available. In addition, there is a vast difference between what is produced and what reaches the marketplace, and there are also losses between the market and the family table. Estimates of losses to insect and rodent pests and to spoilage before food reaches the market range from 10 percent to as high as 50 percent in some areas. These losses have not always been taken into account in official statistics. The FAO allowed for some losses of food before it reached the market in making the estimates of food supplies shown in Table 7-6, but not for losses between market and consumption. To allow for these and for differences in distribution between areas and income groups within countries, the UN noted that food energy supplies "should be at least 10 percent above aggregate requirements."

As the table shows, the recommended level of food supply (with its 10-percent safety margin) was not reached in any developing region; and several regions-including some 57 nations--failed even to achieve the minimum requirement (100 percent of basic needs, with no safety margin). The UN concluded: "In view of the inevitable inequitable distribution in supplies, it is clear that all developing regions faced a serious energy-deficit problem in certain sections of the community." Although supplies of protein seemed adequate (by the low FAO standards) in virtually all countries, some of it doubtless was being used as energy to compensate for the calorie deficit. Therefore, the UN concluded that "the surplus of protein availability is more apparent than real." [40]

Given inadequate food supplies at the national level for 57 out of 97 less developed countries in 1970, and marginal supplies (less than a 10 percent margin of safety) in another 22, it can be assumed that the poorest segments of these populations were seriously undernourished. Very little direct research has been done on the subject, but a few limited surveys strongly support this conclusion. Table 7-8 shows two examples; similar results in some other LDCs are shown in tables in Appendix 2. In one province of India (Maharastra) in 1971, availability of food energy per person per day ranged from a grossly inadequate 940 kcal in the poorest 1 percent of households, to over 3000 kcal for the highest income groups. [41] Chronically undernourished people, who commonly also suffer from parasitism and disease, are typically apathetic, listless, and unproductive. In the

past, well-fed Europeans and North Americans, seeing these symptoms among people in LDCS, but not understanding their cause, often concluded that natives of these areas were "lazy."

Maldistribution of food supplies within households may be at least as serious as that between income levels. Children and pregnant and nursing women, who have the greatest nutritional needs in proportion to their sizes, are often left the smallest portions of food. Table 7-9 compares the caloric and protein intakes of children in high and low income groups in Hyderabad, India. After weaning, small children in poor countries are often fed starchy, bulky foods that fill them up without supplying enough calories, protein, and other nutrients to maintain health. Poor nutrition can lead to loss of appetite, further reducing their food intakes.

In many poor agricultural communities, when food supplies are insufficient, the men, who must be well-enough nourished to work and grow more food for

[40]UN, *Assessment*.
[41]UN, *Assessment*.

their families, are deliberately fed first and best. Landless laborers are often fed by their employers, but their families are not. Many young children die of starvation as a result of such practices; others survive but may be permanently handicapped by extreme deprivation in the crucial early months of life (see next section). The health of women, who as mothers need extra protein and energy, may also suffer greatly.

Food shortages consequently show up in widespread malnutrition and hunger to an obvious degree among infants, preschool children (ages 1-4), and pregnant and nursing women. Deaths from starvation and malnutrition among young children in LDCs are commonplace. Of the 55 million deaths that occur worldwide each year, between 10 and 20 million have been estimated by French agronomists René Dumont and Bernard Rosier to be the result of starvation or malnutrition. [42] Most of these deaths are among children; nutritionist Alan Berg has estimated that some 15 million children die each year of malnutrition and associated diseases. [43] Box 7-1 describes some of the more prevalent nutritional-deficiency diseases.

In these cases, the cause of death usually is officially attributed to some infectious or parasitic disease, which only dealt the final blow. Diseases that ordinarily are only minor nuisances in well-nourished individuals are devastating to the malnourished, whose resistance is seriously impaired. [44] Even if the disease does not kill, it is likely to intensify the malnourishment by draining the individual's reserves. Diseases normally considered minor can precipitate a severe, previously unsuspected deficiency disorder; thus malnutrition encourages disease and in turn is exacerbated by it. Extremely poor sanitary conditions further complicate the picture; dysentery and infestations of various kinds of worms are commonplace among the poor in LDCS. Diarrhea, dangerous even in a well-fed baby, is disastrous to an ill-fed one. *For our purposes, any death that would not have occurred if the individual had been properly nourished may be considered as due to starvation, regardless of the ultimate agent*.

Research on nutrition and the poor in Latin America has begun to reveal a syndrome in which undernourished mothers, babies of low birth weights, high rates of infection in both mother and child, high infant mortality rates, and retarded psychomotor development in children are all

associated. Supplemental feeding of pregnant women appears to be effective in reducing the incidence of low birth-weight babies and of infant mortality. [45] The interacting factors of malnutrition and disease are major causes of the high infant-mortality rates in the LDCs compared with those of the DCs (Table 7-10). In some countries infant mortality is eight or nine times as high as that in the United States (by no means the world's lowest).

Infants are significantly protected against both disease and severe nutritional deficiencies if they are breastfed. Mother's milk is extremely nourishing, does not transmit parasites, and indeed provides positive protection against infection, especially diarrheal disease. [46] Poor people in the LDCs (particularly those who migrate to cities and fill up the shantytowns) have begun to adopt from the wealthier urban classes (and from developed countries) the habits of bottle-feeding and early weaning. Consequently, in some areas, malnutrition and mortality rates among infants are on the increase. Unlike their affluent neighbors, low-income mothers can at best offer poor substitutes for their milk. The luckier infants receive formulas based on powdered or condensed milk. But powdered milk is expensive, so it is often "stretched" with extra water. Moreover, the water available for formulas and for washing the bottle is far from sterile, and without refrigeration the formulas may spoil rapidly. Thus the baby is exposed to dangerous infections. Even worse, out of combined ignorance and poverty, mothers may feed their babies barley flour, cornstarch, sago, or arrowroot gruels, perhaps with a tiny bit of milk added "for color." [47]

The weaning situation has been extensively studied in Chile, where it was found that the prevalence of breastfeeding for at least a year declined from 95 percent in the 1950s to 6 percent by 1969. By then only 20 percent of Chilean infants were nursed for even two months. Less

extreme but significant declines have been observed in several other LDCs, including Mexico, the Philippines, Singapore, Kenya, and Nigeria.

Berg has calculated a conservative "cost" to LDCs of the switch to bottle-feeding, based on the value of the cow's milk that would be required to replace the mother's milk. Assuming that only 20 percent of the mothers who live in LDC cities do not nurse their children, the loss is $365 million. If half of the other 80 percent of urban babies are weaned by six months, the total loss is $780 million. [48] The real cost, of course, is far greater and probably cannot be measured in dollars. The greatest cost is the increased malnutrition and disease suffered by the children.

Chile has an excellent national health service, but it also has an embarrassingly high infant mortality rate, which seems to be associated with the recent shift in infant feeding practices. In Chilean villages, deaths among bottle-fed infants were found to be three times more frequent than among breast-fed babies. Interestingly, infant mortality has been found to be rising among families with incomes somewhat above poverty levels, evidently because more and more such families are weaning early. [49]

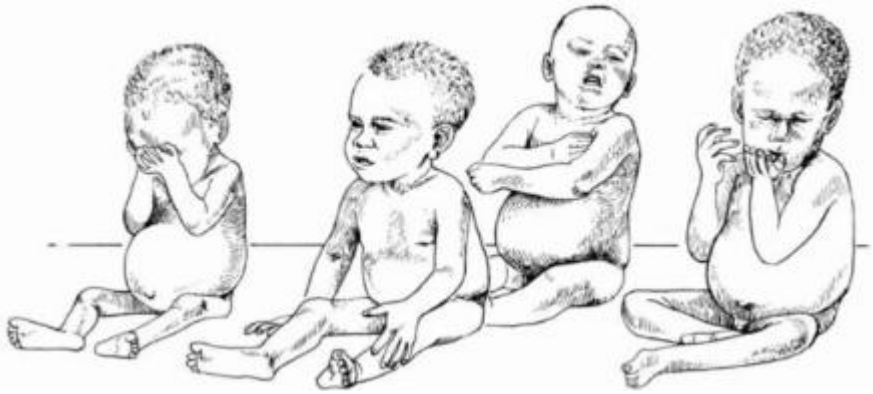
[48] Berg, *Nutrition*.

[49] Ibid.

BOX 7-1 Common Deficiency Diseases

The most commonly encountered deficiency diseases in LDCs are marasmus and kwashiorkor (Figure 7-10), both of which affect young children and have similar causes. Marasmus is probably indicative of overall undernourishment, but it is often referred to as a "proteincalorie deficiency." It seems to be related to early weaning or to a failure in breast-feeding, when inadequate substitutes for the mother's milk are provided, and it often appears following a bout of diarrhea or some other disease. Most victims are babies less than a year old. The child with marasmus is very thin and wasted, with wrinkled skin and enormous eyes.

Kwashiorkor is a West African word that means "the sickness the child develops when another baby is born." *Kwashiorkor* seems to be another form of protein-calorie starvation, resulting from inadequate supplementation for mother's milk after the age of six months or so. Sometimes it is precipitated by weaning, when the child of one or two years is offered only starchy, bulky foods to eat. In mild cases the child's physical growth is retarded, the hair and skin are discolored, and a pot-belly develops. There is also a loss of appetite. When the disease is more acute, the discoloration is more pronounced, hair is loosely rooted and pulls out in tufts, legs and feet swell with fluids, digestive problems arise, and the child becomes markedly apathetic. After this stage is reached, death will follow unless medical care can be quickly provided.



Vitamin-A deficiency often accompanies protein malnutrition and shows up in a drying of eye membranes (xerophthalmia) or softening of the cornea (kerotomalacia), which soon leads to blindness if not treated. Supplementing proteindeficient diets with high-protein foods without adding vitamin A may cause a previously unsuspected deficiency to appear in an acute form. This happened in early food-aid programs that distributed nonfat dry milk. Since 1965 American nonfat dry milk shipped overseas has been fortified with vitamin A. Vitamin-A deficiency is widespread in much of the less developed world, especially in South and Southeast Asia and

parts of Latin America. Like many other nutritional problems, this one most often afflicts preschool children. The United Nations has estimated that as many as 100,000 children go blind each year in the Far East alone as a result of vitamin-A deficiency. *

Another prevalent form of malnutrition in LDCs, particularly among women and small children, is anemia, usually iron-deficiency anemia. Lack of protein, vitamin B12, or folic acid can also play a part in anemia. During pregnancy, a fetus absorbs from the mother's stored reserves a large supply of iron, which it needs during the months after birth (mother's milk contains very little iron). Successive pregnancies can very quickly lead to exhaustion of a mother's reserve supply; if her diet does not replenish it, the result is anemia for both mother and child. This not only produces a lack of energy and low productiveness in the mother, but can also increase the likelihood of stillbirth and premature birth. The incidence of death from anemia ranges from 6 to 16 times higher in LDCs than in the United States. In Latin America, surveys have shown that between 5 and 15 percent of men have anemia and 10 to 30 percent of women do. Up to half the children in some areas are anemic. **It is common wherever poverty and poor sanitation prevail, and in these circumstances it is often aggravated by such parasitic infections as hookworm, which consume large amounts of blood.

Rickets and osteomalacia (softening of the bones) are due to lack of Vitamin D or calcium, or both. Vitamin D is synthesized in the skin when it is exposed to sunlight. Rickets first became a health problem for Europeans in smoky, congested cities during the Industrial Revolution, where children had only dim, narrow alleys for playgrounds and often were kept

*UN, *Assessment of the world food situation*, 1974.
**Ibid.

IGURE 7-10 Symptoms of kwashiorkor (protein-calorie deficiency) in African children. (Drawn from a photograph by Eva D. Wilson.)

indoors to work. † Like many other deficiencies, this syndrome also affects both mother and child, for the calcium deprivation may begin in the prenatal period. During pregnancy, the fetus draws from the mother's body minerals and vitamins that may not be replenished by her food. Breast-feeding draws still greater amounts of calcium. Successive cycles of pregnancy and lactation may leave the mother virtually crippled by the drain on her bone structure, enforcing

confinement to her house. Thus she is denied both the sunlight that would replenish her Vitamin D and the possibility of working to obtain better food.

Rickets, the childhood form of calcium deficiency, is not very common in tropical countries, where sunshine is abundant. Nevertheless, it does exist, more commonly in the cities and towns. It is found also in India, Pakistan, and parts of the Middle East. Customs of keeping children indoors and of keeping women secluded or heavily veiled undoubtedly contribute to the incidence of both diseases.

Lack of dietary iodine causes goiter, from which the UN estimates some 200 million people around the world suffer. Iodine is available from seafood and food grown in iodine-containing soils. Many regions of the world far inland from the sea have soils deficient in iodine. Iodine deficiency in mothers can cause cretinism--a form of dwarfing and severe mental retardation--in their children. But this can be entirely prevented simply by the use of iodized salt.

[†]W. F. Loomis, *Rickets, Scientific American*, December 1970.

Prolonged nursing, on the other hand, if accompanied by insufficient supplementary feeding, also can result in malnutrition for both child and mother. Mother's milk alone is adequate nourishment for a child for only the first four to six months after birth. Lactation can drain a woman's nutritional reserves if she is not adequately fed. Nevertheless, the extra food a nursing mother needs--as well as solid supplements for the baby after six months--can usually be supplied far more cheaply, easily, and safely than can safe and adequate substitutes for her milk.

It must also be mentioned that breast-feeding has an important demographic effect: it significantly delays the return of the woman's fertility after parturition and thus lengthens the period between births when birth control is not practiced. [50] The length of delay of the next pregnancy varies widely among income levels and countries, and is influenced by such factors as when and how much supplementary food is offered to the child and sexual customs associated with lactation. Conservatively, it can be said that the delay averages six months or more. Such increased birth spacing obviously benefits the health of mothers and children, and contributes as well to lower birth rates (Chapters 5 and 13).

Since breast-feeding is cheaper, more convenient, safer, and healthier for the child, and provides wellknown emotional and psychological benefits for both mother and child, why is the vogue for bottle-feeding sweeping the cities of the less developed world? Various reasons have been proposed, including medical and health workers who encourage bottle-feeding, largely for reasons of convenience in health facilities. These people generally are unaware of the nutritional and health hazards of bottle-feeding for the poor. Often free powdered milk is distributed through health services, ostensibly for use as a supplement, but its availability encourages bottle-feeding. The baby-food and processed-milk industries have also been blamed for promoting their products among low-income groups who cannot afford them and who lack the facilities (safe water, refrigeration) to use them safely. An additional problem, especially for working mothers, is lack of privacy for nursing in public areas or workplaces. (That the nursing of a baby is a

shocking sight is another peculiar Western notion that has been exported.) Underlying all these pressures is the prevalent idea among the poor that bottle-feeding must be superior because the rich do it. Because they know essentially nothing about nutrition or sanitation, illiterate poor mothers cannot understand that their adaptations of formula-feeding are vastly inferior to the traditional method, potentially fatally so.

Fortunately, the switch to the bottle is still largely limited to urban areas in LDCs; perhaps two-thirds of the infants in those countries are still breast-fed and thereby protected to a large extent against both malnutrition and disease. As awareness of the problem spreads among leaders in less developed nations, the trend may be reversed through the institution of educational programs to encourage breast-feeding, curbs on promotion of commercial baby foods, and provision of facilities for nursing in public places.

Because preschool-age children (1 to 5 years old) are no longer protected by breast-feeding against disease and malnutrition, it has been proposed that the mortality rate of this age-class is the best indicator of the nutritional level of a population (Table 7-11). In many parts of Latin America, Asia, and Africa, child mortality rates range from three to forty times higher than in the United States. Well over half the deaths among Latin American children under five in some countries have been attributed either directly or indirectly to malnutrition. [51] Although dependable statistics are hard to obtain, the mortality rate for children under four (including infants) in parts of India has been estimated to be as high as 250 per thousand. There is little question that most of these deaths also are basically due to malnutrition.

The President's Science Advisory Committee reported in 1967 that the high mortality rates of children 1 to 4 years old in LDCs "suggest that moderate protein-calorie malnutrition affects at least 50 percent of these children." [52] In 1974, the United Nations reached similar conclusions. Altogether, the UN cautiously estimated that, around 1970, perhaps ten million children under 5 years old in LDCs were severely malnourished, 80

million were moderately malnourished, and 120 million more suffered from milder forms of malnutrition. [53] How many millions more have been added to their ranks since 1972 can, as yet, only be guessed.

Implications of Severe Malnutrition in Children

The serious malnutrition prevalent in our overpopulated world causes incalculable suffering, waste of human life, and loss of human productivity. Malnourishment, especially protein

deficiency, inhibits the development of protective antibodies and lowers resistance to diseases, thus contributing to higher death rates and loss of productivity in less developed countries. But even more alarming is the growing body of evidence that malnutrition in infants and young children may have essentially permanent effects. It has been known for a long time that severe undernourishment during the years of growth and development will result in a certain amount of dwarfing and delayed physical maturity, even if the deficiency is temporary and a normal diet is later restored. What is far more ominous is the evidence that malnourishment before birth and during the first two or three years afterwards may result in permanent impairment of the brain.

A child's body grows from 5 to 20 percent of its adult size in the first three years, but meanwhile the brain grows from 25 to 80 percent of its adult size. Recent

[53]UN, *Assessment*, p. 64.

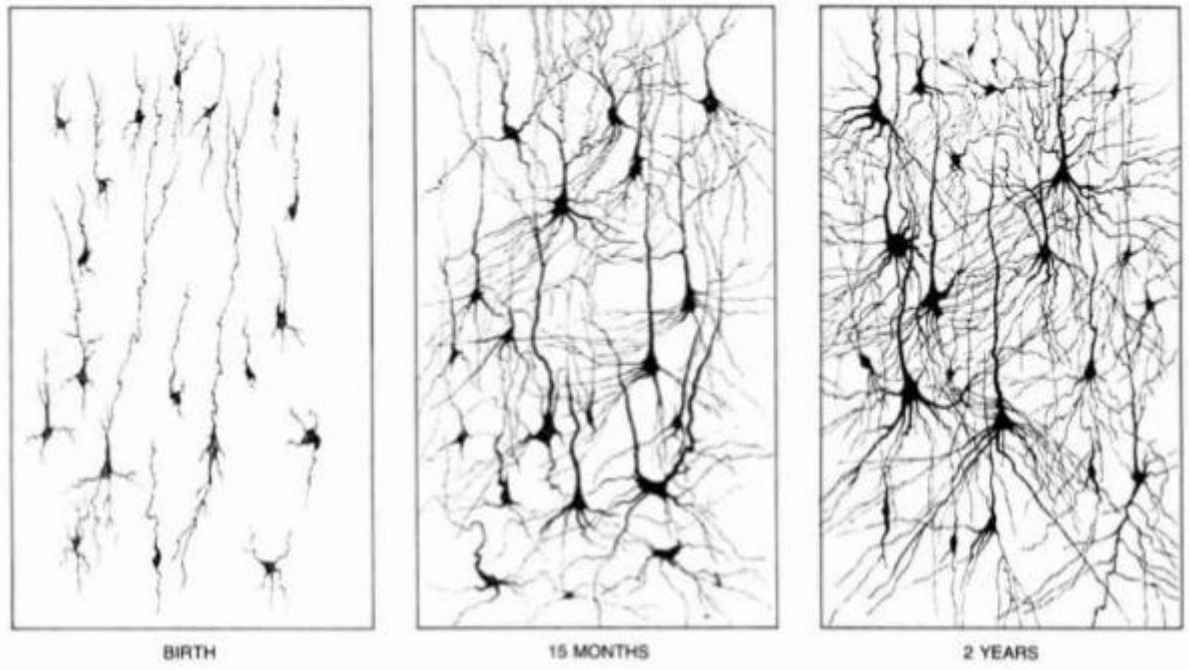

FIGURE 7-11 Development of neurons in the cerebral cortex of a young child. At birth all neurons are present but are immature. The drawings show stages of normal development of axons at birth, 15 months, and 2 years of age. (From Lewin, 1974.)

research has elucidated the normal growth pattern of the nervous system and the brain in human beings. [54] While the majority of *neurons* (nerve cells) are present in the brain of a developing fetus by 18 weeks after conception, they mature and establish their multiple interconnections much later. A second set of cells, known as glia, of which there are eight times as many as there are neurons, continue to multiply until the child is about two years old. The precise role of glia is not yet known, except that certain types of glial cells are responsible for the process of myelination--the creation of the insulating myelin sheath--around the axons, long fibers that extend from neurons and transmit messages from one neuron to another. Figure 7-11 shows the

stages of normal development at birth, 15 months, and two years of age in the cerebral cortex. The myelin sheath is essential for the proper function of nervous tissue. Myelination goes on for at least four years after birth, but it is concentrated in the first two years. In addition, most of the development of the cerebellum, the part of the brain that, among other functions, controls coordination of the arms and legs, takes place between birth and age two.

Thus some 80 percent of human brain development takes place before birth and in the first two years afterwards. This extremely rapid brain growth must be supported with adequate food. If it is not, the brain essentially stops growing. Apparently, it may never regain the lost time if the deprivation is severe and prolonged. The sizes of both the head and the brain itself are reduced in individuals who were severely undernourished during those crucial early years.

Studies on rats have provided information on just what happens to a nutrient-deprived brain during its period of rapid growth. Of course, human implications must be inferred with care from research on laboratory animals. But the brain of a rat develops in essentially the same way as a human brain; only the timing is significantly

---

[54]Roger Lewin, *The poverty of undernourished brains, and Starved brains*. The second of these two articles is less technical and includes more recent studies.

different. It is now believed that hunger in human beings does not influence the number of neurons in the brain, which develop early in prenatal life, but practically everything else is affected. In malnourished animals, there are many fewer glial cells, and this doubtless is the primary reason for smaller brain-sizes in undernourished children. Myelination and axon development are reduced, and there are far fewer interconnections. One study of underfed young rats showed a reduction in connections of 38 percent, plus indications of damage to those that developed. [55] Such underdevelopment seems bound to have serious effects on reasoning ability, memory, and other functions in human beings. Finally, undernourishment results in underdevelopment of the cerebellum--an exception to the belief that neurons are generally protected from the effects of deprivation, as those of the cerebellum develop later than those in the rest of the brain. The consequence of impairment of the cerebellum is retarded development of motor coordination. Poor manual dexterity and clumsiness have long been observed as characteristic of undernourished children. Furthermore, these physical defects of the brain were produced in the laboratory animals not by extreme starvation, but by *moderate* levels of malnutrition.

Studies on rats also suggest that, when mothers are malnourished during pregnancy, their children and even grandchildren may suffer impairment of both brain development and the ability to form antibodies normally. [56] The mechanism affecting the second generation is unknown, although the cause for the first generation is fairly obvious. Whether or not this "second-generation effect" also applies to human beings is not known, although some of the findings of Guatemalan studies of maternal malnutrition are suggestive. [57] These studies indicate that mothers of small stature, who themselves exhibit signs of having suffered early malnourishment, are more likely to have babies of low birth weight. Such infants in LDCs (but

not in developed countries, where other factors, such as cigarette smoking by mothers, seem to play larger roles in determining birth weights) are consistently more prone to disease, death, and retarded development.

An accumulating number of studies in various less developed countries have established a strong correlation between nutritional levels and physical and mental development in preschool and school-age children of poor families. Among impoverished youngsters in rural Guatemala and Mexico, height and mental achievement were positively correlated; all these children were near the lower end of both the height and mental-achievement scales for their ages, indicating that their development was affected by their nutrition. Among well-fed, middle-class children in the same societies, height and mental development showed no relationship. [58]

The development of a particular group of 22 children who had been virtually starved as infants was compared with that of other children in the same Mexican village, who were "normally" undernourished. The severely malnourished children showed signs of retarded language development by six months of age; at age three they were still below normal development for two-yearolds. Some catching up appeared by three and a half, as they showed signs of physical recovery from their early deprivation. But the trend suggests they will never fully catch up with their luckier peers. [59]

A study in Jamaica compared school-age children who had been severely malnourished before age two both with siblings who had no history of acute malnutrition and with neighbors or classmates of nearly the same age. The malnourished children scored significantly lower on IQ tests than the others did, although the sibs (who may also have been chronically malnourished early in life) performed slightly less well than did the unrelated controls. This failure to catch up occurred even though the acutely malnourished children had recovered in a hospital and had received special follow-up care for two years afterwards. [60]

In Chile, comparisons were made among Santiago slum children on adequate diets, other slum children receiving supplemented diets and medical care, and

middle-class children. The slum children on supplemented diets more closely resembled the middle-class youngsters in physical and mental development than they did their neighbors with poor diets, although the two groups of slum children came from otherwise very similar

environments. Of the malnourished children, only 51 percent reached the normal range of development, compared with 95 percent of the middle-class group. Another group of children, who had marasmus as infants and were subsequently given medical care and supplemental food, were all found to have intelligence considerably below normal three to six years later. [61]

Similar results have been obtained in studies conducted in the United States on severely malnourished children, comparing their later development with siblings and children of similar background who had no histories of malnutrition. [62] The malnourished children showed retarded growth and development, small head size, and poor language development.

An apparent exception to these and other findings is a study on young men who were conceived before and during an acute famine in the Netherlands during World War II. [63] Comparisons of their army-induction tests with men who were born in cities relatively unaffected by the famine revealed no significant differences in mental achievement. However, the acute phase of the famine lasted only about six months, and it occurred in a population that was quite adequately fed both before and afterward. Moreover, one can easily imagine that many adults donated some of their meager portions of food to expectant or nursing mothers and to babies.

The influence of malnutrition on mental and behavioral development is somewhat complicated by evidence that other environmental factors also play a part. A stimulating environment has been shown to have a direct role in the development of rat brains, [64] and recent research has shown that such effects can be found in human beings too. Since children who are deprived of food are very likely also to live in an impoverished environment in terms of social interaction and mental stimulation, it is not always easy or possible to separate these two causes of mental impairment. This is especially true when malnutrition begins in pregnancy or before, threatening the mother's ability even to feed and care for the child. Playing with the baby or otherwise providing the mental stimulation it needs may be quite beyond her capability, particularly if there are several other children. When the separate influences of environmental and nutritional deprivation have been studied, it was clear that the *combination* resulted in the greatest damage, but each had measurable effects. [65]

To what degree are early nutritional and/or environmental deprivation reversible? These matters are still being debated, but in general it can be said that at least some compensation is possible, but not easily achieved. In both rats and human children, environmental enrichment (in the form of varied, stimulating surroundings and plenty of social interaction) apparently can overcome the results of early deprivation if the deprivation was not too prolonged, and if the enrichment program is carried on for sufficient time. [66] The experience of the American Head Start Program for underprivileged children showed the consequences of giving up too soon. When the program was abandoned, children who had made substantial progress in educational achievement lost much of the ground they had gained.

It appears that nutritional enrichment likewise can eventually compensate to a large extent for early deprivation. A recent study of Korean orphans who had been adopted before the age of three by American middleclass families compared one subgroup that had been malnourished in infancy with "moderately nourished" and "well-nourished" subgroups and with Americanborn peers. Years later, when the adopted orphans were in grade school, their mean heights and

weights had all exceeded those of Korean children of the same ages, although they were still below those of their Americanborn contemporaries. The mean IQs of all three sub-

groups were comparable to those of American children. Differences persisted between the groups, however. The "malnourished" children on the average were smaller, lighter, and had significantly lower IQ scores than the well-fed children, and the "moderately nourished" group fell in between. [67]

This is a situation, of course, in which both nutritional and environmental enrichment have been amply provided and sustained. In other studies in which nutritional rehabilitation was provided temporarily and then the children returned to their impoverished homes, retardation of growth and development persisted. Such initially deprived youngsters never seem to catch up with adequately fed siblings or neighbors in the same environment in the absence of sustained special "enrichment" efforts. [68]

What does this mean in practical terms for the less developed regions? In a typical LDC, according to the UN, half of all children under five suffer some degree of undernutrition. Many die, but another fraction may survive with significant developmental retardation. Even though such handicaps might *eventually* be largely overcome through intensive, sustained rehabilitation, no poor country could afford such a program for a substantial portion of its child population.

At the very least, governments in all countries must be made aware of nutritional levels in their populations and what these levels can reasonably allow them to expect and demand of their people. The prevalence of hunger, especially among children in a large portion of the population, has grave implications for the future development plans of LDCs, including proposals for increasing food production. A government that expects elaborate development efforts to be carried out by a weakened, undernourished populace, a significant fraction of whom may be physically and mentally disadvantaged, is likely to be disappointed.

The exact mechanisms whereby undernutrition, infection, and an impoverished environment interact to produce high infant and child mortality, morbidity, and impaired development are not

known. But more than enough is known to undertake a program of *prevention*. The goal would be simple: to ensure that every mother and her children are adequately fed during pregnancy and those crucial early years, and to provide them with basic medical care and sanitary living conditions. Such a program would be far easier and cheaper to institute than massive rehabilitation after the damage is done, and it would have broad benefits for the entire society. Unfortunately, achieving even such a relatively simple goal would require an enormous restructuring of priorities and reallocation of resources for most LDCs, and there is little sign of such change in most countries. [69]

The Other Side of the Coin

In stark contrast to the widespread hunger that prevails in many less developed areas, increased affluence has allowed a steady increase in nutritional levels in developed areas in past decades. Less than half of the growth in food consumption in DCs between 1952 and 1972 was due to population growth; the remainder was accounted for by affluence. This does not mean that people in rich countries directly consumed more kilocalories per person than they did twenty years earlier. Rather, they were eating far more meat, poultry, and dairy products, which today are produced in large part by feeding grains, oilseed cakes, and fishmeal to livestock.

Figure 7-12 shows the trend in per-capita beef and poultry consumption in the United States. Poultry consumption more than doubled, and that of beef nearly did between 1950 and 1972. Similar increases have taken place elsewhere, although people in most other DCs still consume less meat than Americans. This rising demand for meat has led to a rapidly growing demand for feedgrains and other feedstuffs in developed countries. By 1974, livestock were being fed *one-third* of the world's total production of grain. [70]

By 1972, people in DCs on the average consumed, directly and indirectly, four times as much food per

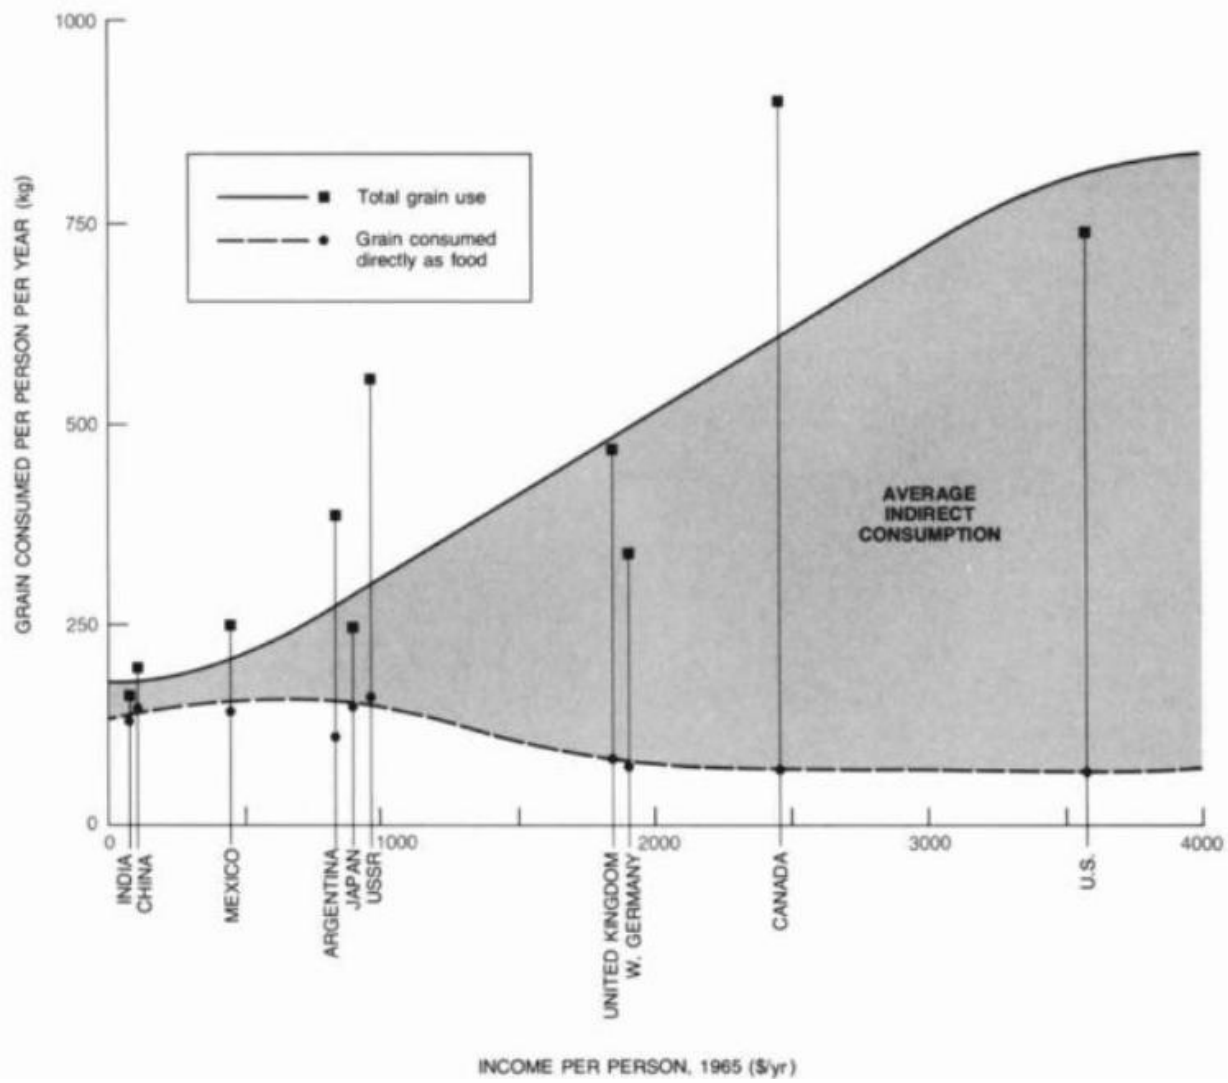

FIGURE 7-13

The relationship of direct and indirect grain consumption to per-capita income in selected countries. (From L. R. Brown, "Population and affluence: Growing pressures on world food resources", *Population Bulletin*, vol. 29, no. 2. Courtesy of Population Reference Bureau, Inc., Washington, D.C.) INCOME PER PERSON, 1965 ($/yr)

person as people in the LDCs. [71] A comparison among countries of grain consumption graphically shows the difference in diets between the rich and the poor (Figure 7-13). Three-fourths or more of the food energy in an Asian's diet comes directly from grain -- 135 to 180 kilograms (roughly 300 to 400 pounds) per year. An affluent American accounts for the consumption of nearly a *ton* of grain per year, but 80 percent of it is first fed to animals. Because Americans are thus feeding higher on the food chain (Chapter 4), most of the food value is lost to human nutrition. With American livestock-feeding methods, producing one kilogram of poultry requires two or three kilograms of grain, and producing one kilogram of beef on the feed lot requires ten or more kilograms of grain. [72] Other meats fall between these extremes of efficiency in conversion.

Cattle and sheep can be raised very successfully, if perhaps not so rapidly and abundantly, on forage grown on soils unsuitable for crops, [73] perhaps supplemented with agricultural by-products such as cornstalks. A relatively small grain supplement would result in quite satisfactory beef, especially if different cattle varieties were used that had been bred for efficient production of lean, tender meat. Present methods of beef production result in an animal with an excessive amount of fat.

Moreover, the fat in grainfed cattle appears to be of a different *quality* from that in range-fed animals. The latter contain abundant long-chain polyunsaturated fatty acids, needed nutritionally by human beings, particularly for building nervous tissue. Grain-fed animals, on the other hand, seem to be deficient in the long-chain polyunsaturates, but contain great amounts of nonessential saturated fat. Consumption of large amounts of saturated fat has been implicated as a contributing factor in cardiovascular disease, the leading cause of death in the United States and many other DCs. [74] The diets of citizens of affluent nations have been shown to have other adverse effects on health, also. Among the first of these is obesity, a contributing factor in several diseases. High protein, high fat diets have also been associated with some kinds of cancer that are relatively common in DCs. [74a]

Questions about the morality of feeding to livestock grains that could nourish hungry people have been raised in various quarters, especially since 1972. [75] Unfortunately, today's economic system once again is to blame. The poor and hungry people in other countries cannot afford the cereals and soybeans produced abundantly in the United States. The only "demand" for them is generated by livestock producers in the U.S. and other developed countries. Since 1973, rising costs of feedgrains--corn, sorghum, rye, barley, oats, etc. -- due to increasing export demand, have led American farmers to reduce their grain-feeding of cattle and sheep. But the higher costs also put these grains even further out of reach of the poor in LDCs. Clearly, the only way to make the surplus grain produced in North America available to hungry people is to separate some of it from the commercial market and make it directly available to the LDCs either free or on special concessional terms. This, of course has been the aim of food aid programs; but as commercial demand grows, the temptation to reduce food aid programs also grows.

At least one developed country-- Norway--has undertaken a national nutrition program aimed at improving diets and making the most efficient use of food resources. [76] Both by public education and by economic incentives and disincentives, people have been encouraged to demand, and farmers to produce, leaner meats, more grains and vegetables, and less sugar and livestock products. The result has reportedly been not only improved diets and health, but reductions in resources (land, water, energy, and fertilizer) used to produce the nation's food, and reductions in imports of feedgrains. The potential benefits of a nutrition policy are, it seems, not limited to LDCs. [77]

Hunger in America. It must be remembered, however, that not all Americans are overfed. Some 10 to 15 percent of the U.S. population have incomes too low to meet the most basic needs. People were shocked in 1968 when the extent of hunger, malnutrition, and clinical deficiency diseases in the U.S. was first widely publicized. As in LDCs, this hunger and malnutrition appeared to be related to poverty and an accompanying syndrome of unemployment, displacement from the land, and appalling sanitary conditions, often accompanied by a high incidence of parasitism. Testimony before a Senate committee indicated that the nutritional level of a segment of the population examined in a Public Health Service survey in 1969 was as low as those found in many less developed countries. Investigation revealed that between *10 and 15 million* Americans were constantly and chronically hungry, including a large proportion of children. Another 10 to 15 million had incomes too low to provide a well-balanced diet. [78]

Among a random sample of 12,000 American men, women, and children from low-income areas in Texas, New York, Louisiana, and Kentucky, the survey found seven extremely severe cases of marasmus and kwashiorkor and eighteen cases of rickets, as well as many milder cases of malnutrition. There was also evidence of widespread goiter (caused by iodine deficiency), 17 percent of the 12,000 people had serious protein deficiencies, and a similar number were described nutritionally as "real risks." Most of the children were below average size for their ages, and 3.5 percent were definitely stunted. One-third of those under six were anemic, and nearly as many showed signs of being Vitamin-A deficient, many seriously so. Altogether, from 35 to 55 percent of all the people surveyed exhibited signs of serious nutritional deficiencies of various kinds.

The high incidence of deficiencies of Vitamins A and D and iodine found by the Public Health Survey is embarrassing, since they are all easily preventable. The need for the use of iodized salt may be forgotten or unknown among some of the poor; yet the government survey found that it was not even available in the markets in parts of Texas, a known goiter area.

The underlying causes of malnutrition and hunger in a country as rich as the United States resemble, in some respects, those in LDCs; they include inadequate food distribution, poverty, and ignorance. But in the United States they have existed mainly because of the lack of will on the part of the well-fed to do anything about them. U.S. government food-aid programs have clearly failed to achieve their supposed aims. Free surplus foods were distributed to the poor until the early 1970s by the U.S. Department of Agriculture. But that department's primary interest, unfortunately, seems to have been in the expeditious elimination of farm surpluses, rather than in the nutritional needs of the recipients. By the mid-1970s, the food-stamp program

was the primary means of providing nutritional assistance to the poor, allowing them to buy food at reduced prices. But for the lowestincome groups, families with less than $1000 per year, even the stamps were too expensive. For a time many local governments declined to participate in the programs even when they had large eligible populations. Poor administration probably accounted for some of the failure as well. Free and low-cost school lunch programs have also had a long history of mismanagement of funds, and have been hampered by food-industry lobbying at the legislative level. But by 1975, they were reaching nearly 80 percent of the American school population.

In early 1969 Senator Ernest F. Hollings of South Carolina testified to the Senate Select Committee on Nutrition that, when he was governor of South Carolina from 1959 to 1963, he and other state officials deliberately concealed their state's hunger problem in an attempt to boost industrial development. They feared that knowledge of South Carolina's difficulties would discourage industry from locating there.

Public pressure has removed some of these problems, but they have been replaced by others. By 1975 some 19.5 million people were receiving food stamps at an annual cost to the federal government of five billion dollars. [79] The program has become a nightmare of overregulation and built-in inequity, but both Congress and the administration seem helplessly unable to improve it substantially. A better solution might be a comprehensive income-supplement system that would elminate the need for separate food programs.

---

[78] Ernest F. Hollings, *The case against hunger*; Robert Sherrill, *Why can't we just give them food?*

[79] Kenneth Schlossberg, *Funny money is serious*.

Meanwhile the poor are not much better off than they were in 1968, despite the huge expansion of food programs. It has been estimated that perhaps 20 million additional people are eligible for food stamps but are not enrolled in the program. Inflation has effectively wiped out much of the benefit, especially for people living on small fixed incomes, as many elderly persons do. Rises in food prices between 1972 and 1975 disproportionately penalized the poor, because the cheapest foods (cheap cuts of meat, sugar, beans, etc.) escalated the most in price. At the height of some inflationary surges, the rumor circulated that millions of low-income Americans were subsisting on pet food. [80] This was hotly denied in many quarters, including some pet-food makers, but the rumor persisted.

In Spring 1974 the early results of a new national nutritional survey were released. This survey covered the entire population rather than concentrating on lowincome areas. [81] Among the preliminary findings: about 95 percent of all preschool children and women of childbearing age had substandard intakes of iron, and 10 percent of the children were anemic; calcium-intake levels were low in black women; Vitamin A intake was low in poor white women; and many people seemed to be getting insufficient Vitamin C.

The overt starvation that was found in 1968 in the United States may since have been greatly reduced, but poor nutritional habits continue to exist at all income levels, and people in the lowest income levels still must struggle just to meet their minimum needs.

The World Trade System

Major elements in the distribution of food (and its inequities) around the world are the world trade system and the economic system of which it is a part. Unfortunately, food (like other commodities) goes to those who can pay for it, not necessarily to those who need it most, especially within and between capitalist economies. Distribution may be somewhat more equitable within communist and socialist countries, but on the world market capitalist rules prevail for them as well. Fortunately, there are programs that bypass this system and distribute donated food to the neediest or allow it to be purchased at lower cost, and there are indications that these programs may be expanded in the future.

The total volume of food that crosses national boundaries has always been a relatively small fraction of total production, but it has been growing even faster, at about 3.5 to 4 percent per year, than total food production and consumption. In 1973/ 1974, net exports of major grains traded amounted to an estimated 151 million metric tons, about 16 percent of world production of those grains for that year. (Rice is excluded from these figures, but only a small fraction of the rice crop is exported.) Among exported commodities, wheat is decidedly the leader; it accounts for more than a quarter of all food trade. Figure 7-14 shows the relative proportions by weight of important commodities traded. As the figure shows, more than half of them are grains. The growth in exports of grain worldwide is shown in Appendix 2.

There has been a substantial change in recent decades in the origin and destination of exported foods. Before World War II, many countries in Asia, Africa, and Latin America were important grain exporters. By the mid1960s, those regions were importing grain in far greater quantities than they had ever exported it (Table 7-12). By 1970 the only net grain exporters of any significance among LDCs were Thailand, Burma, Mexico, and Argentina. [82] (Mexico has since reverted to being an importer.) While several LDCs were exporting rice in the early 1970s (notably the Philippines and China), they were simultaneously importing wheat, which was cheaper, and using the foreign exchange thus gained for other needed imports.

To picture the LDCs simply as net food importers would be a mistake, however. Although the DCs annually delivered some 2.5 million tons of gross protein to the LDCs during the 1960s, the LDCs sent the DCs about 3.5 million tons of higher quality protein in the form of fishmeal, soybeans, and presscakes of oilseeds. The DCs use nearly all of this to feed poultry, livestock, and pets. More than sixty countries, including Mexico, Panama, Surinam, Hong Kong, and India, supply the United States with shrimp, which could otherwise be a

life-saver for the protein-starved children of those countries. Peru has been exporting to the DCs most of its anchoveta catches, which potentially could relieve protein deficiencies in Latin America. Georg Borgstrom has described the advantage held by the rich countries of the world in the present pattern of protein flow as "an almost treacherous exchange." [83]

Many of these foods are beyond the means of the poor, so they are exported to earn needed foreign exchange. Some, such as anchoveta fishmeal and oilseed cakes, are not considered suitable for human consumption, and so are exported as feed, again for foreign exchange. Although political and commercial leaders in LDCs have willingly cooperated in promoting production of these commodities for export, their intentions were not necessarily evil. Some undoubtedly hoped to use the foreign exchange to purchase food and goods that might improve the prospects of their people, and some is spent that way. Unfortunately, the proceeds have often been squandered on luxuries for the wealthy urban elite or used for development projects that have no effect on the welfare of people outside the cities.

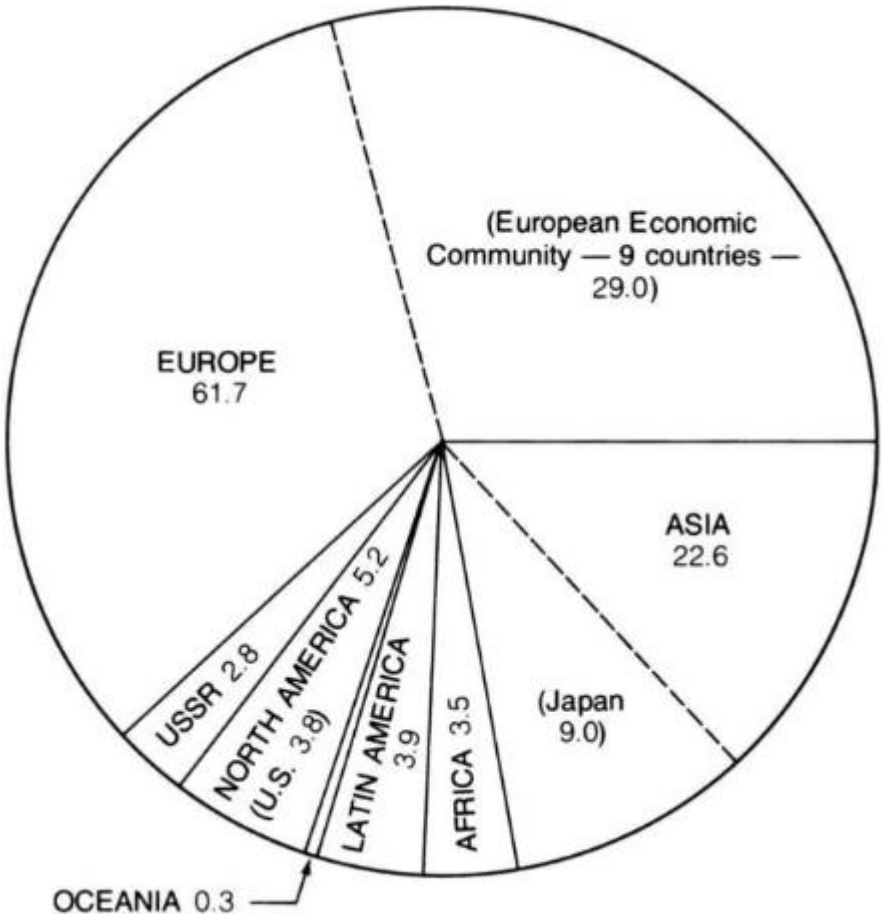

FIGURE 7-15 A. The distribution of world food exports by region, 1970 (percentages of total metric tons). B. The distribution of world food imports by region, 1970 (percentages of total metric tons). (From University of California Food Task Force, *A hungry world: The challenge to agriculture*, 1974.)

Although most Americans are far more conscious of U.S. food exported to LDCs, the vast majority of our exports go to DCs-indeed the overwhelming bulk of food trade occurs between developed countries. Figure 7-15 shows origins and destinations of food exports in 1970. All the less developed countries imported barely 21 percent of all imported food; indeed, they exported more than they imported in 1970. As the figure shows, Europe dominates both the export and especially the import scene; together with the USSR, in 1970 Europe took in nearly 65 percent of all imported food. (In several of the years since then, the Soviet share has been much larger.) Europe exports manufactured goods and high-quality protein foods in exchange for grain, feedstuffs, and other commodities. Most European countries are far more dependent on imports for their food than are the poor countries.

Japan is even more dependent on imports to feed its population than is Europe (Table 7-13). In 1970, Japan's 106 million people imported more than two-thirds as much food as did the nearly two billion people in the rest of Asia. Note that Japan's huge harvest from oceanic fisheries (labeled domestic production) is projected in the table to continue.

The United States and world trade. The United States is by far the world's leading exporter of food today, accounting for nearly half of all grain traded on the world market. Like other DCs, however, the U.S. is also a major importer of foods, especially oilseeds and fishmeal for livestock feed, seafood, meats, tropical fruits, sugar, coffee, and dairy products. These products come from all over the world, but our largest suppliers are Latin America (especially Brazil and Mexico), Asia (especially the Philippines), Europe, and Australia.

The biggest customers for U.S. exports in 1974, more or less in order of importance, were: Japan, several western European nations, Canada, the Soviet Union, and the People's Republic of China. [84] The last named two are by no means regular, longstanding buyers. In

1975 the USSR, after suffering a severe setback in its wheat harvest, negotiated a purchase of some 20 million metric tons of American grain. [85]

Partly because much of the Soviet Union's productive land is relatively far north, and therefore more than usually susceptible to adverse weather such as early frost, and partly for other reasons, Soviet harvests can vary by as much as 30 percent from one year to the next.

The negotiations for the Soviet purchases in 1975 were accompanied by an uproar of protest by U.S. labor unions who anticipated a repetition of the grain-price escalation that followed the Soviet purchases in 1972. [86] The United States government then imposed a temporary embargo on grain exports to the USSR, which incensed wheat farmers [87] (and alarmed trading partners). Because the U.S. normally exports around twothirds of its annual wheat crop and large portions of other grain crops (Figure 7-16), even very large Soviet purchases were unlikely to cause a domestic shortage or significant price changes unless the U.S. harvest had been well below normal levels or there were unusually great demand from other countries. Neither proved to be a problem in 1975. In order to avoid future crises caused by unanticipated purchases by the USSR, a special agreement was negotiated, whereby the USSR agreed to buy 6 million metric tons of grain from the U.S. each year from 1976 to 1981, with options to buy another 2 million metric tons as long as the American supply (stocks plus estimated production) was above 225 million metric tons. [88] Further purchases in any given year were also negotiable.

Probably the greatest cause of the unstable, wildly fluctuating grain prices on both the domestic and the world markets (Figure 7-17) since 1972 has been the

[88]USDA, WAS-9.

calculated elimination of U.S. grain reserves (which accounted for most of the world reserves) by the U.S. Department of Agriculture. Former Secretary of Agriculture Earl Butz and others in the USDA viewed recent worldwide food shortages as a bonanza for using up the surpluses of former years and meeting the nation's foreign-exchange balance of payments. In hot pursuit of a "free grain market," which supposedly would reward the productive American farmer, these individuals pursued policies that benefited neither American consumers nor the hungry abroad, but which made large amounts of money for their friends in big agribusiness corporations. As *Lester Brown* observed, Secretary Butz was opposed to the price-stabilization effect of sizable governmentheld grain reserves, "because he comes from an agribusiness background, and the more uncertainty there is, the more prices of grains fluctuate, the more money the traders who know what's happening [that is, the big grain traders] can make." [89]

Early indications from the Carter Administration were that the previous "agribusiness first" policy of the U.S. Department of Agriculture would be reversed. Indeed, even during the election campaign, President Carter had declared his support for reestablishment of grain reserves in the United States and also for establishment of a worldwide food reserve system as proposed by the U.N. World Food Conference in 1974 (see below).

The declines in worldwide grain harvests in 1972 and 1974 were not anticipated, nor were their effects on grain supplies and food prices. As a result of the unexpected shortages and the disappearance of reserves, far from being consistently rewarded for their efforts, American farmers have been subjected to various cost squeezes and unpredictable prices for their products. [90]

In recent years, the food-export business in the U.S. has boomed. Unfortunately, the boom was accompanied by a scandalous amount of cheating and corruption. [91] Some of this came to light when several LDCs, formerly recipients of free food, felt they had the right to complain

when their paid-for shipments arrived short-weighted and so contaminated that they were unfit for consumption. By 1976 some 26 nations, including the Soviet Union, had officially complained of contaminated, misgraded, and short-weighted shipments. [92] On investigation, the corruption proved to be very pervasive, and dozens of individuals--including grain inspectors, shippers, and grain dealers--were indicted in 1975.

Foreign aid: food. Just as the need for imported grains has grown in less developed countries since the 1950s, so for a while did food-aid programs. Between 30 and 45 percent of the food imported by LDCs between 1954 and 1969 was from one or another food-aid program. Most of this was U.S. surplus grain sold on concessional terms. During the 1960s United Nations multilateral programs also developed. Food-aid shipments reached a peak total of 18 million tons in 1964/ 1965. But they were scarcely half that volume in 1972/ 1973 and were even lower in the food-short period of 1973/ 1974. Table 7-14 shows the trend in international food aid from 1964 to 1973.

The decline in food aid was largely due to the disappearance of American surplus grain stocks, which until the early 1970s accounted for some 83 percent of the donated food. As grain prices rose, the U.S. government made no effort to increase the dollar commitment to Title II of Public Law 480 (the Food for Peace Act), the program that provided free food to poor nations, and the grain commitment shrank accordingly. In 1973 and 1974, the U.S. Administration even cut the program back. In those years, the poorest and neediest countries were receiving less than a fifth as much food as they had six to eight years earlier. In 1974, roughly half of all American food aid went to two countries, South Vietnam and Cambodia, neither of which was in acute distress. [93]

Table 7-15 shows the proportion of U.S. food exports that was devoted to aid programs over the years. Title I provided food under concessional terms: long-term, low-interest loans and publicly subsidized prices. Public and international pressures induced the U.S. government to increase shipments under both programs following the Rome World Food Conference. That it was not done sooner is no tribute to the leadership or sensitivity of the Nixon and Ford Administrations at a time when an unprecedented situation demanded new initiatives.

---

[92]United Press International, "Massive grain-export scandal stains U.S. integrity worldwide", *San Francisco Chronicle*, February 8, 1976.

[93]Brown and Eckholm, *Next step*; Emma Rothschild, *Food politics*.

One reason for the decline in the volume of food aid in the early 1970s was the apparently rising per-capita production in many regions just before 1972. Several former recipients of free food had also become commercial buyers. This was especially true of India, whose government had deeply resented the strings attached by the U.S. to food donations in the 1960s. Among other demands, the U.S. had insisted on expansion of the Indian Family Planning Program.

In addition, public support for food aid (and foreign aid in general) seemed to be dwindling. Reports of widespread waste, corruption, and misappropriation of funds and materials in various famine and disaster-relief programs have undoubtedly contributed to this sentiment. In Bangladesh, following independence, much donated food was diverted to the black market, and some was smuggled into India where prices were higher. [94] Food was sent to the Sahel countries long after people began starving. When it finally arrived, much of it spoiled in storage before it could be moved by the region's inadequate transportation system to the needy, far inland. Even then, politics prevented most of it from reaching those most in need. [95]

In 1974/ 1975, Ethiopia quadrupled its exports of grain to other Red Sea nations. Meanwhile, perhaps a half million Ethiopians were starving, and the government had applied for free food from the U.S. Much of the food aid was resold, some was put in storage. When some of the food was released for the hungry, no airplanes were available to transport it to the hinterland; all aircraft were engaged in bombing the rebellious province of Eritrea. [96] For months the Ethiopian government had attempted to conceal the existence and extent of famine within the country. Officials of FAO and UNICEF were aware of the situation but apparently did not intervene. [97] Tales of failure in distributing donated food to victims of famine and other disasters are legion. Not all relief efforts are such dismal failures, however, and usually even in the worst cases, some of the food eventually finds its destination. Relief of the famine in the Indian province of Bihar in 1965-1966 is sometimes cited as one of the rare unqualified successes in averting disaster.

Although there have been direct transfers of food from DCs to LDCS, there have been very few programs for development assistance aimed at increasing LDC food production. Of the perhaps $20 billion of development assistance that was provided annually around 1972 from DCs to LDCs (mostly as loans, with some grants), only about $1 billion (5 percent) was earmarked for agriculture. [98] This is largely because until 1969, DC governments (especially food-exporting DCs such as the United States and Canada) were reluctant to encourage food production in LDCS, which might then compete on the world food market. [99] The slighting of agricultural development also may reflect the degree of commitment felt by the governments of hungry countries toward increasing food production to feed their people.

Since 1972, this long-neglected area has been somewhat revitalized, and United Nations agencies and the World Bank have belatedly concentrated far more effort on the agricultural sector. By 1974, commitments for agricultural development had increased to $3.6 billion. Among the proliferating agencies involved in food, in 1976 the newly created International Fund for Agricultural Development (IFAD) alone was pledged a starting fund of $1.2 billion in special drawing rights, mainly from DCs and OPEC nations. The fund will provide soft loans (long-term, low-interest) for agricultural development and nutritional improvement in LDCS, and recipient countries will have a majority vote in decisions about distribution. The fund is planned to expand to $5 billion annually by 1980. [100]

Agricultural research programs. The enormous increases in food production that will be required to feed the growing human population during the coming decades will also necessitate a substantial acceleration in agricultural research. [101] Unfortunately, for decades agriculture has been a neglected stepsister of the other sciences, even in developed countries. In most less

developed nations it has been virtually ignored. [102] Since the early 1960s, however, an international agricultural research structure has slowly evolved.

Leadership of the international effort is now centered in a consortium of governments and foundations called the Consultative Group on International Agricultural Research (CGIAR), which coordinates the efforts of the international research centers. The first two centers, established by the Ford and Rockefeller Foundations in 1959 and 1964, were the International Rice Research Institute (IRRI) in the Philippines and the International Maize and Wheat Improvement Center (CIMMYT) in Mexico. In addition to these, the consultative group is sponsoring six newer research centers and an International Board for Plant Genetic Resources. [103] These research units employed some 200 professional workers in 1975, and have been set up to cover most important crops and all major geographic areas. The group's budget was increased from $34 million in 1974 to $64 million in 1976. Table 7-16 shows locations and missions of the consultative group's research centers in the mid-1970s. In addition to this system, there are several other international agricultural research efforts sponsored outside of the CGIAR.

[102] A. Mayer and J. Mayer, *Agriculture, the island empire*.

[103] For a detailed description of the new centers for research, see Nicolas Wade , *International agricultural research*.

A major international effort is badly needed if the technical and biological problems attending new agricultural technology (discussed below) are to be solved. It must be realized, however, that instant solutions are not likely to materialize; the "miracle" that Norman Borlaug achieved in developing high-yield varieties (HYVs) of wheat followed decades of hard work and an intimate

familiarity with the needs of farmers. Fancy facilities and high pay at these institutes cannot substitute for hard work, hard thinking, and knowledge of field conditions.

Perhaps the major research challenge now lies in the less developed countries themselves. In some LDCs, such as the Philippines, Taiwan, and India, impressive agricultural research is being done by national research institutions; but, overall, research in those nations has been neglected and poorly funded in comparison to that in DCs -- about $240 million annually for all LDCs -- although the amount is now increasing. [104] A serious obstacle to spreading new agricultural technology within LDCs has been the critical shortage of agricultural research workers, technicians, and extension workers. In 1960, a typical LDC had fewer than 15 agricultural workers per 100,000 population, whereas most DCs had as many as 150. There has been improvement since then, but there is still a long way to go.

Until recently, most agricultural assistance, whether composed of research methods, technologies, or donated foods themselves, has been Western-oriented. The result is that it has not always been suited to the recipients' social, economic, and cultural backgrounds. Locally grown, traditional foods of potential value, for instance, may be overlooked or neglected in favor of Western crops because they cannot be processed with Western technology. Unfamiliar donated foods also may be wasted because they are not widely accepted. Least appropriate of all is training LDC food specialists in sophisticated packaging and processing techniques that are economically useless for their home countries. Such problems can be avoided if research is conducted in the same regions where the results are needed, so that the technology can be adapted to local conditions and customs. Food specialists Brown and Pariser put it well: "The time is past when 'West is best' can be taken for granted; 'adapt and adopt' is surely less offensively arrogant and much more to the point." [105]

A final problem with agricultural research in both DCs and LDCs is that agriculturalists have long tended to do their work with little consideration of the crucial ecological and coevolutionary dimensions of the problems they were investigating (see Chapters 4 and 11). Growing awareness of the environmental side-effects of modern agricultural technology and of the inescapable ecological problems of agriculture in the tropics are changing this attitude in some quarters. But, in general, agricultural research is still paying a penalty for its long isolation from other life sciences.

There have been signs of renewed interest in agricultural research at national as well as international levels, including in the United States. In late 1975, the U.S. Congress passed a new International Development and Food Assistance Act, which authorized funds for agricultural development and research, including those pledged to IFAD; strengthened the Food for Peace Act (P.L. 480); and called on the President to push for establishment of a world food-reserve system.

In late 1975, the National Academy of Sciences published a recommended reorganization of the American agricultural-research establishment. [106] Among their recommendations were: (1) to make research one of the USDA's major missions; (2) to increase funding of research related to productivity; (3) to allocate funds to several specific areas of basic and applied research, including work on "photosynthesis, nitrogen fixation, genetic manipulation by DNA

recombination and other techniques, alternatives to chemical pesticides, and alternative technologies which reduce consumption of energy;" (4) to establish a program of competitive grants; (5) to revitalize the Cooperative State Research Service, which channels funds to agricultural research stations; and (6) to establish a policy council for determining goals and policies, which would also coordinate activities with other agencies. Such a program, if implemented, might do much to revitalize the overbureaucratized

agricultural-research organizations and encourage development of more environmentally beneficial approaches to food production in the United States. Many of the research objectives, if realized, obviously would be equally helpful to other countries, especially LDCs.

The Future Outlook

Now that we have examined the unmet needs and demands for food today, it is necessary to consider those of the future. There are, of course, many potential and some unavoidable limitations on further increases in food production. These will be examined in later sections of this chapter. First, it would be wise to establish what the goals should be.

Because the world's population is still growing at close to 2 percent per year and can be expected to continue growing rapidly for at least the next several decades (barring a major catastrophe that raises the death rate), substantial increases in food production will be required merely to meet demand at the present per-capita level of consumption. Even if food distribution were made much more equitable at the same time, raising food production so that the undernourished billion or so people could be adequately fed represents an even greater challenge. Projections by the United Nations of increased food needs under these conditions just for the period between 1970 and 1985 are staggering. [107]

Table 7-17 shows projections of food demand, assuming population growth according to the United Nations "medium variant" projections, and compares three assumptions of change in demand. "Zero income" assumes no change in per-capita gross domestic product (GDP), hence no change in per-capita demand. "Trend income" assumes that per-capita GDP will continue past trends in growth. "High income" assumes an acceleration over past trends in per-capita GDP growth. Thus the world must raise total food production at least a third above 1970 levels by 1985 just to meet needs at the same per-capita level. If there is continued growth in affluence, demand for food in 1985 will be for nearly 50 percent more than was consumed in 1970.

Several other groups besides the United Nations have made projections of food needs to 1985. Among these are Iowa State University, The U.S. Department of Agriculture, [108] and the University of California Food Task Force. [109] Although each group used slightly different assumptions in making their projections, their conclusions as to expected needs are basically similar.

[107] UN, *Assessment*; FAO, *The state of food and agriculture*, 1974.
[108] The world food situation and prospects to 1985.
[109] A hungry world: The challenge to agriculture.

When the projections are broken down by region, the expected needs in 1985 of the chronically food-short developing countries range from 48 percent to 86 percent above 1970 consumption, depending upon changes in per-capita demand. Even with a continuation of past trends in demand, less developed regions will need food increases ranging from 70 to 80 percent. Nearly doubling food production in those countries in fifteen short years would call for a virtual miracle. And some countries (Nigeria, Iran, Iraq, Saudi Arabia, and Thailand, for instance) will require *more than twice* as much food. China and other communist Asian countries have somewhat better prospects, largely because of their slower population growth. The developed countries, on

the other hand, could get by with relatively modest increases (15 to 30 percent), although rising demand, especially in the Soviet Union, is likely to push "needs" considerably higher.

It should be noted, of course, that rising demand -- at least that component due to greater affluence -- will not apply equally to all kinds of food. Demand for some foods is expected to increase much more rapidly than for others. Production of protein and oil sources, such as meat, fish, dairy products (and, by implication, feedgrains), nuts, and pulses (beans and peas), must be increased at a much greater rate than production of starchy tubers, for example. The United Nations projections of increased demand for various commodities can be seen in Appendix 2. These projections, of course, do not take into account the effect that possible price changes would have in changing demand.

The projections are made by extrapolating the likely course of food-production increases for various regions, based on recent performance. Obviously, a great many factors can affect food production, from weather and climate changes to alterations in government policies and agricultural economics, including world trade. Such events are not taken into account, since they cannot be predicted.

Although the various groups who have made projections of future demand for food agree fairly closely on the expected demand, they part company on the subject of whether the increased demand can be successfully met. The U.S. Department of Agriculture report is relatively complacent about humanity's ability to feed itself in 1985. The USDA estimates, however, have been strongly attacked by knowledgeable critics. USDA scientists have claimed that their estimates indicate that it would be possible not only to keep food production ahead of population growth, but even to increase world grain production per capita. [110] Agronomist Louis Thompson, dean of agriculture at Iowa State University has declared that the optimism of the USDA "is not widely shared because their projections are based on coefficients developed from a period when weather was generally favorable, when there was a significant improvement in varieties of wheat and rice, and there was a significant uptrend in the use of nitrogen fertilizers on all cereal grains throughout the world." [111]

The United Nations in 1974 also estimated the ability of nations to increase food production fast enough to meet demand in 1985. When the UN extrapolated trend is compared with projected demand, a disturbing picture emerges: throughout the less developed world, demand substantially outstrips production (see Table 7-18). The trend of past decades, in which less developed countries switched from being food exporters to importers, appears to be accelerating. Indeed, except in the communist Asian countries, projected production increases largely fail even to keep pace with population growth. If demand for food worldwide can be met in 1985 (assuming the projections are borne out by events), it will therefore only be because of surplus production in developed countries -- primarily North America.

The UN 1974 projections showed the total annual deficit of cereal grains in non-communist less developed nations increasing to 85 million metric tons in 1985. [112] If grain-exporters Argentina and Thailand were left out of the calculations, the deficit climbed to 100 mmt. If 1985 turned out to be another 1972, 1974, or 1975 in terms of reduced harvests, the estimated grain deficit could

reach 120 million metric tons or higher. This shortfall in grain production in LDCs compares strikingly with average

annual deficits in 1969-1971 of only 16 mmt, and even with that of 43 million metric tons in 1973/ 1974. [113]

In 1976 newer projections became available, and these were even more ominous. The World Food Council and FAO then estimated the probable 1985 food deficit in LDCs (if the weather is "normal" that year) to be 120 million metric tons. [114] The International Food Policy Research

Institute has estimated the 1985/ 1986 deficit to be 100 million metric tons if average yearly food production increases can match the rate of the period 1960-1975. However, if the rate of increase is as slow as it has been since 1969, the deficit could reach a staggering 200 million metric tons. [115]

It is clearly expected that this anticipated huge deficit in food production -- unless it can somehow be made up by greater-than-anticipated production increases within the LDCs -- will be filled by the grain-exporting countries: the United States, Canada, Australia, Thailand, and Argentina. But there are some serious problems in the way of producing so much grain to help LDCs in addition to meeting increased demand both on the domestic market and from traditional trading partners. Nor is the assignment of transporting and properly distributing the grain in recipient nations an easy one. Transport facilities have been strained by the large grain transfers of the early 1970s; unless grain shipping facilities are expanded, the problem will be far worse in the early 1980s. Similarly, the problems that have plagued food-aid programs in the past will also worsen unless measures are taken to counteract them.

Finally, there will be some very tough decisions confronting both the importers and exporters if production should falter and the import needs fail to be met. These essentially political problems are explored more fully in Chapter 15.

EXPANDING THE HARVEST

Given the present precarious world food situation and the alarming outlook forecast by various groups, the important questions for the future are: can a continued expansion of food supplies be sustained? If so, for how long? And what are the best means of doing so that are consistent with improved human well-being?

Within the framework of any system of technology or any economic system, the environment imposes limits on agricultural production. As noted earlier, for the foreseeable future food production will depend on the availability of sunlight, fertile soil, water, and a growing season long enough for crops to mature. Unfortunately, these conditions are unevenly distributed over the Earth. For example, although many tropical forest areas have a

[114] Jon McLin, *Remember the world food conference?*
[115] Sterling Wortman, *Food and agriculture*.

year-round growing season and abundant rainfall, their soils are often extremely poor, making large-scale agriculture virtually impossible. [116] Vast portions of subtropical land lack adequate rainfall or nearby freshwater sources for irrigation. Most of the world's land that is suitable for growing crops is already being cultivated (Chapter 6). The best prospect of increasing food production therefore lies in raising yields (production per hectare) on that already cultivated land.

The Green Revolution

A great deal of publicity has been given to the so-called Green Revolution, a modernization of agricultural practices that some enthusiasts hoped would enable the less developed countries to keep agricultural production well ahead of population growth for several decades. Most of the Green Revolution's elements are already an integral part of agricultural systems in developed countries, where cereal yields have been consistently much higher than in LDCs (Figure 7-18). There are two general components to the Green Revolution: increased use of recently developed high-yield varieties of grain (primarily wheat and rice), and increased use of "inputs" (especially fertilizers and irrigation water, but also often pesticides), which are required to realize the potentially high yields of those crops.

Since the mid- 1960s there has been a rapid expansion of acreage planted to high-yield crops in many LDCs. The area planted to new varieties of wheat and rice in Asia, Latin America, and Africa increased from about 59,000 hectares to over 32 million hectares between 1965 and 1975. [117] By 1975 it had reached 43 million hectares. Figure 7-19 shows the percentages of wheat and rice acreage planted in high-yield varieties in those years in several Asian countries. By 1972 HYVs occupied more than half the acreage planted to wheat in India and Pakistan, and half the acreage planted to rice in the Philippines. Since 1972, however, the rate of expansion of acreage planted to new crop varieties has slowed in several countries for reasons that are examined in the following sections.

Miracle varieties. The new high-yield varieties of wheat and rice are capable of producing yields considerably greater than those of traditional strains. For instance, the first rice variety developed by the International Rice Research Institute in the Philippines, IR-8, can produce two or more times the harvest of traditional rice plants from a given area, if handled correctly. Some newer strains perform even better than IR-8 and have other improved qualities.

All the new grain varieties are extremely responsive to fertilizers. If conditions are suitable, and if a crop is fertilized at several times the level ordinarily used for traditional varieties, HYVs can use that fertilizer input much more efficiently in producing grain. If planted in good soil, given the large amounts of water that are a necessary accompaniment of heavy fertilizer inputs, and given protection from pests, the strong, short stalks of the new dwarf varieties can carry a truly miraculous load of grain. [118]

These new varieties also mature faster and are less sensitive to seasonal variations in day length than are traditional strains. Both characteristics increase the possibility of multiple cropping -- that is, growing and harvesting more than one crop per year -- when adequate water is available. In Mysore State in India, for example, farmers are growing three corn crops every fourteen months. Where there is a dry season with inadequate water available for growing rice, some farmers are growing new high-yielding grain sorghums (which require less water) in alternation with rice. In some areas of China, northern India, and Pakistan, farmers are planting rice in the summer and wheat in the winter.

It must be emphasized, however, that the *full potential* yields of the miracle grains can be realized only if an *entire complex of conditions is met*, especially the proper input of fertilizers, water, and pesticides. Without these, yields may be little higher than those of traditional varieties, and in some cases they may be less.

That the Green Revolution has considerable potential for increasing yields in many LDCs is beyond question. Early results of introducing the new seeds in several countries were very impressive. India's wheat harvest

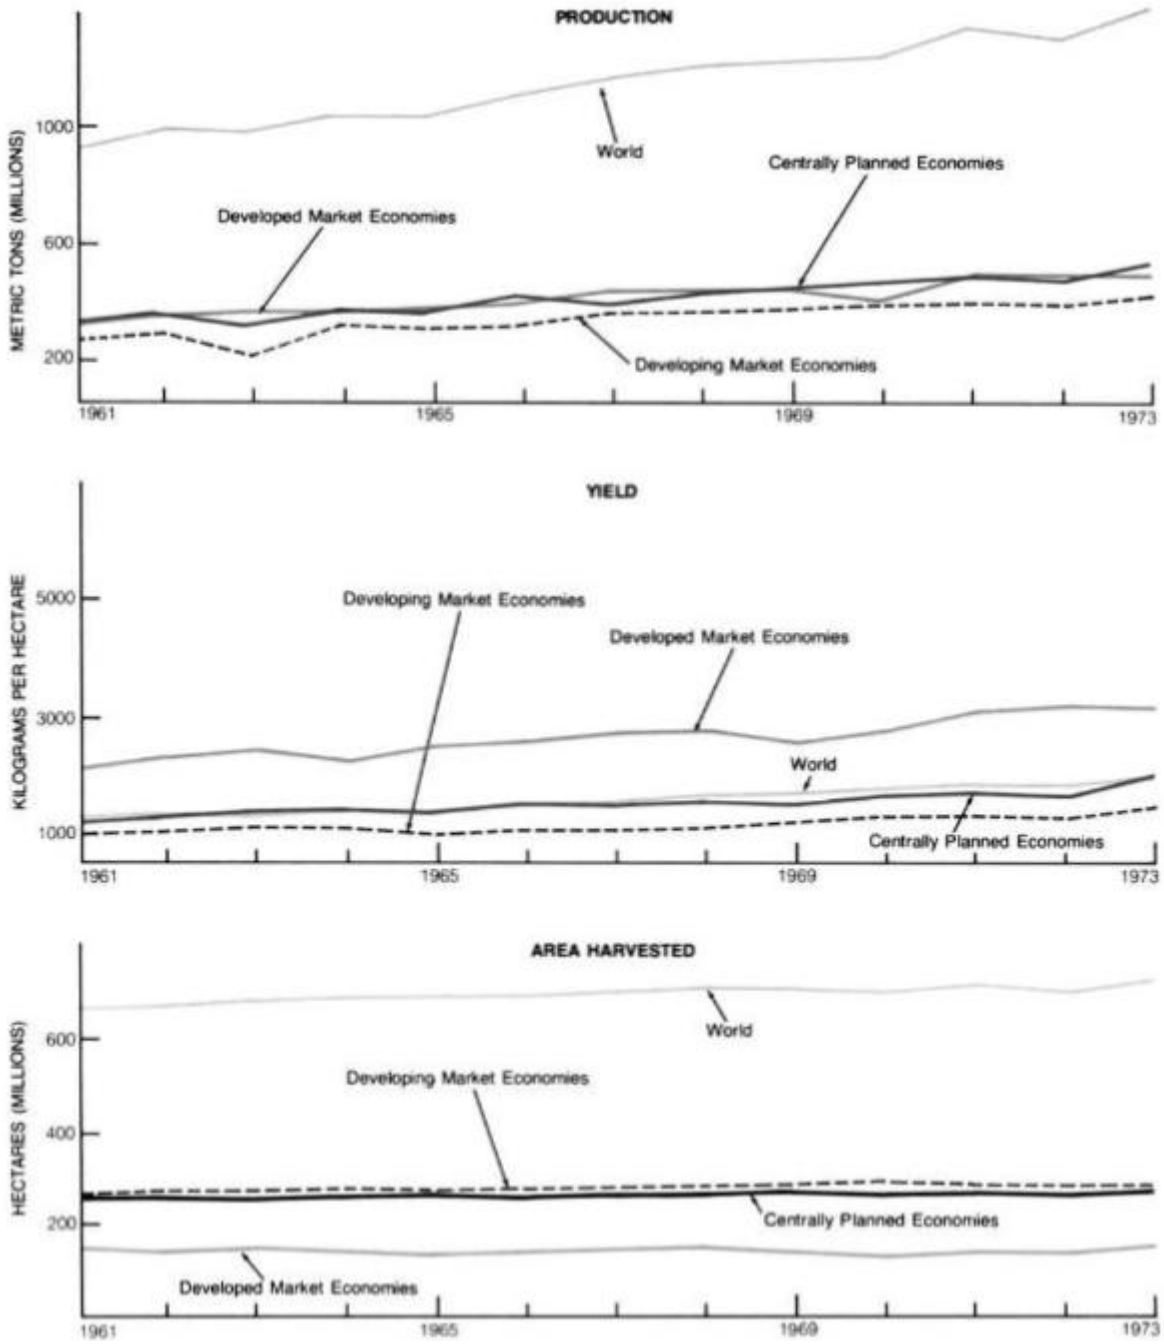

FIGURE 7-18 World grain production, yields, and areas, 1961-1973. Includes wheat, maize, rice (as paddy), minor and mixed grains. (Adapted from U.S. Department of Agriculture, *The world food situation and prospects to 1985*,. Foreign Agricultural Economic Report No. 98, 1974.)

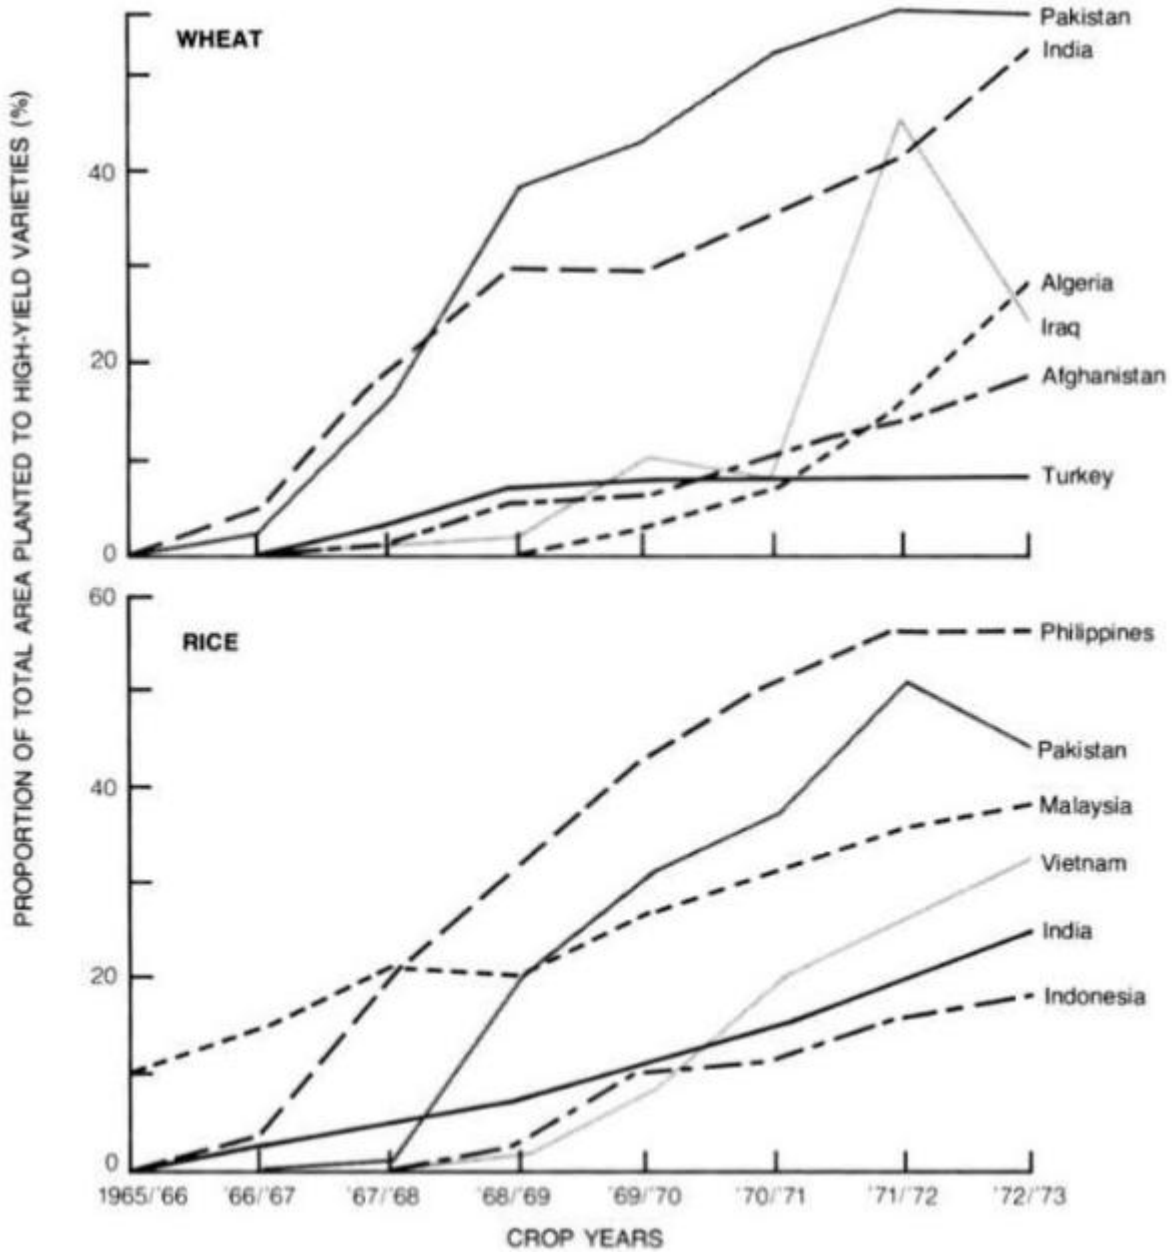

FIGURE 7-19 The proportion of total area planted to high-yielding varieties in Asia. (Adapted from U.S. Department of Agriculture, *Measuring the green revolution*, Foreign Agricultural Economic Report No. 106, 1975.)

more than doubled within six years (1965-1972), and the Pakistani crop in 1968 was 37 percent higher than in any previous year. There were also large gains in rice production in the Philippines and Ceylon between 1966 and 1968. All these gains were largely due to the new grain varieties.

According to Dana G. Dalrymple of the USDA, HYV and traditional strains could be directly compared by growing both on the same quality of irrigated land and adding equal amounts of fertilizer. In such a comparison, high-yield wheat might generally outperform traditional

varieties by 50 to 100 percent in yield, and HYV rice might outperform the traditional varieties by 10 to 25 percent. [119] Significantly increased grain production is thus still possible in many LDCs where the HYVs have not yet replaced traditional varieties to any great extent. But those increases nevertheless would be modest in comparison with projected needs for just the next two decades. There are, in addition, many unanswered ques-

[119] Dana Dalrymple, *Measuring the Green Revolution: The impact of research on wheat and rice production*, pp. 25, 26, 35.

tions about various aspects of the Green Revolution -social, economic, environmental, and biological -- that inevitably will influence its ultimate scale and duration. [120]

Economic and Social Factors

The Green Revolution extends far beyond the planting of new kinds of seeds, and it is beset by myriad economic headaches. Many of these problems are associated with the inputs required by the HYVs: the extra fertilizer, water, and in many cases farm machinery and pesticides needed to realize the full potential of the new seeds. The dependence of HYVs on heavy use of fertilizer, for example, made the fertilizer shortages and price inflation of 1974, aggravated by the energy crisis, a particularly serious problem for LDC agriculture. [121]

Fertilizers and other inputs. Natural fertilizers (manure, crop residues, etc.) could be used in place of manufactured ones, of course. In many ways they are preferable, especially for tropical soils. [122] The FAO has estimated that seven to eight times more nutrient elements were available in natural fertilizers that were not used in 1970-1971 in less developed regions than there were in the artificial fertilizers that were used. [123] Unfortunately, natural fertilizers are not always available at the right place and right time, and they are not easily collected. Moreover, there is often competition for them for other uses (for example in India where cow dung is widely used for fuel). So chemical fertilizers, even in very poor countries, are generally preferred and used.

The production of chemical fertilizers is straightforward, and a good deal is known about their effective application. Three principal elements, nitrogen, phosphorus, and potassium (in chemical shorthand, N, P, and K, respectively), are the basis of most fertilizer compounds. Supplies of some of the resources to make these fertilizers are limited (fossil fuels for nitrogen; phosphate deposits for phosphorus), and the problems associated with these limitations are discussed in Chapter 8 and Chapter 9. The HYVs now being deployed in many LDCs require 70-90 kilograms of fertilizer per hectare for optimum performance, but the average level of application in most LDCs is a fraction of that, ranging in 1973-1974 from 14 kilograms per hectare in Africa to 33 kilograms per hectare in South America. [124] Moreover, much of the fertilizer used in LDCs had to be imported.

There are staggering difficulties barring the implementation of fertilizer technology on the scale required to raise LDC grain yields to match those of DCs. The agricultural accomplishments of Japan and the Netherlands are often cited as offering hope to the LDCs, but, if India were to

apply fertilizer as intensively as the Netherlands, India's fertilizer needs would amount to one third the present world output. Per-capita use in the Netherlands is more than ten times that of India. (But the Netherlands is nonetheless unable to feed itself). [125] Table 7-19 shows production and consumption of fertilizers in different regions of the world in 1973/ 1974.

If an LDC is to convert to fertilizer-intensive agriculture, the fertilizer must either be produced within the LDC or purchased from outside; and then it must he transported to the fields. Capital is required for fertilizer plants or for fertilizer purchases, and for transportation facilities. India, for example, had hoped to attain a fertilizer production of 2.4 million metric tons by 1971. But by 1974/ 1975, its production was only 1.3 million metric tons, only some 60 percent of the small amount used. [126] The difference had to be made up by imports. The energy crisis played a major role in the shortfall, as it did in other LDCs. [127] But that was not the sole cause of India's 1974 fertilizer shortfall; poor maintenance of equipment, shortages of raw materials, and problems

---

[120]For an early critique, see William C. Paddock, *How green is the Green Revolution?* A more recent summary of the problems associated with the Green Revolution is given in Wade, Green Revolution pt. 1, and Green Revolution, pt. 2.

with labor and transportation have plagued attempts to raise domestic production.

The energy crisis put a heavy burden on LDCS, many of which were short of foreign exchange and desperately needed to import both fertilizers and fossil fuels for manufacturing them. Fertilizer production within LDCs recently has been doubling about every five years, but it would have increased even faster if the cost of fertilizer (which is strongly affected by the price of oil) had not trebled between 1971 and 1974. [128] Figure 7-20 compares recent trends in fertilizer costs and consumption. Although LDC fertilizer production has been expected to continue rising rapidly, the rising capital requirements for production expansion and other problems may hold increases in production below increases in demand, especially after 1980. Chemical engineer and fertilizer specialist Raymond Ewell expects demand for fertilizers in LDCs to increase (in millions of metric tons) from 12.4 to 31 in 1980, 57 in 1990, and 92 in 2000. [129]

Whether such rapid rises in demand will indeed materialize is not clear; the price escalations of 1974 were naturally followed by a drop in demand, especially among the poorer farmers. Fertilizer prices declined

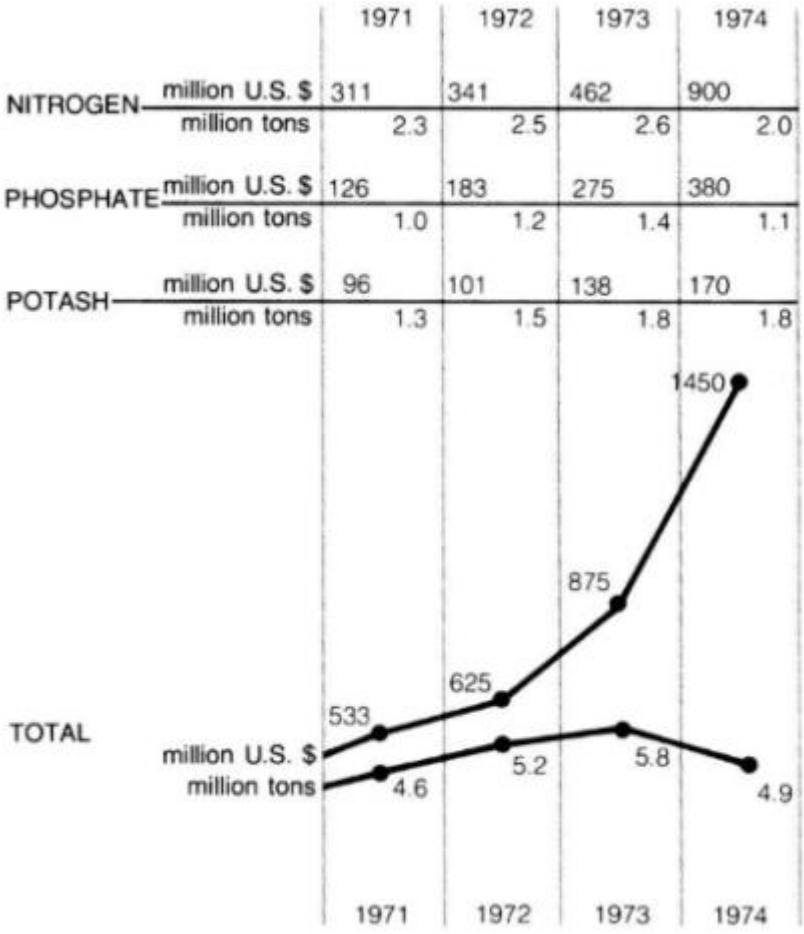

FIGURE 7-20
The cost of scarcity: The import of manufactured fertilizers by developing countries. The figures for 1972-1974 are estimates. (Adapted from *Ceres*, Food and Agriculture Organization, March-April 1975.)

[128]FAO, *State of food and agriculture, 1974*.
[129]Raymond Ewell, *Food and fertilizer and the developing countries*, 1975-2000.

dramatically in 1975 and 1976 as supplies expanded, but this apparently was not immediately translated into a resumption of rising demand in LDCS. [130] Unless the food-short countries can find the means both to expand their own production capacities and to subsidize fertilizer costs for poor farmers, the prospects of expanding the Green Revolution further will not be very bright.

In addition to fertilizers, abundant water is essential for fertilizer-responsive miracle grains; so there must be investment in large- or small-scale irrigation installations, such as dams, tube wells, pumps, and irrigation ditches. Pesticides are also necessary to get the most out of the new varieties, especially when they are planted in extensive monocultures. When timing is a problem, as for multiple-cropping, or when soil is extremely dry or heavy, mechanized planting and harvesting may be necessary. Roads, trucks, and railroads, which are required to bring inputs to the fields and take produce to markets, are often lacking in LDCs. Without access both to inputs

and market outlets, there is little incentive for small farmers to adopt the new technology and expand their output. All the inputs and supporting facilities are expensive, and capital is in chronically short supply in most LDCs.

Poverty and related problems. Beyond the need to provide materials and transportation for farmers, there are serious economic problems resulting quite simply from poverty. The majority of farmers in LDCs are subsistence farmers; their farms are tiny and barely produce enough to support the farmer and his family. In many countries, progress in agricultural development is hindered by a lack of farm credit, which is simply unavailable or offered at usuriously high rates to small farmers.

New grains are typically introduced by "progressive" farmers, usually those with the largest, richest farms. They are in the best position to pay for the inputs of fertilizer, pesticides, irrigation water, and equipment. This advantage of large landholders over small farmers is intensified when the higher yields bring in more money, which can be further invested in more land and more fertilizer. [131] The result of this is to increase the income gap between rich and poor farmers, creating a two-tiered society. The rich farmers prosper, participate in, and benefit from some modernization of their country. The poor, on the other hand, are mostly left out of the development process; they remain stranded in destitution, their lives untouched, with little hope for a better life (see Chapter 15 for more on this subject). [132]

Moreover, when the larger farmers adopt the new technology, they often opt for a mechanized version of it. As a result, even though HYVs generally require considerably more work to produce their high yields, hired labor is displaced. In some areas this has significantly contributed to the flood of landless poor farm workers who are migrating to LDC cities (see Chapter 5).

If the small farmers are to participate in the Green Revolution, then, they must be provided with credit on reasonable terms and access to the seeds, fertilizer, water, and pest-control inputs. Then, when their crops have been harvested, they must be able to sell them for enough cash to pay their creditors and to invest in the inputs for the next crop. But in LDCs, even though local people may be hungry, they may not be able to buy food.

It is not unusual for agricultural economists to speak of helping hungry people by "increasing the demand for food." In some areas and in some years, farmers' yields may be increased by the new grains to the point where their marketable surplus is significantly expanded. This can produce a grain-glut that the local marketing system cannot immediately handle. Storage and transport facilities are inadequate for distribution, and there may not be sufficient "demand" for the food. There is virtually always a potential demand for increased food production, of course; but to become *effective demand*, desire must be matched with purchasing power. Destitute people, even though they may be starving, have essentially no purchasing power.

Increased grain production all too often means lower

Bureau for Program and Policy Coordination, AID, Washington, D.C., December 23, 1975; USDA, WAS-12.

[131] Some of these problems were discussed early by W. Ladejinsky (Ironies of India's Green Revolution), whose warnings have proven at least in part to be justified (Wade, International). For a vivid description of social problems associated with the Green Revolution in another country, see R. W. Franks, *Miracle seeds and shattered dreams in Java*.

[132] James E. Kocher, *Rural development, income distribution, and fertility decline*, an occasional paper of the Population Council, 1973.

grain prices. When this happens, the poor can afford to buy more food, but the farmer's incentive is reduced. If the low prices persist, they might result in less food being available. Governments in LDCs thus sometimes are forced into grain-price support programs they can ill afford. Striking a balance on food-price policy that puts food within the means of the urban poor without damaging the farmers' incentive is no easy task; not many LDC governments have wholly succeeded, although many have tried.

On the other hand, one problem with the Green Revolution appears to have been overestimated. Many observers, at the beginning, felt that small farmers in the LDCs could not be easily or quickly educated to use the new techniques. Experience in the late 1960s and early 1970s showed that in most cases, when incentives, supporting facilities, and credit were provided, acceptance was rapid: "Poor farmers, even those tens of millions who are either illiterate or barely literate, do indeed respond to new and profitable opportunities and can quickly adopt highly complicated production technologies with which they have had no prior experience." [133]

A final difficulty must be mentioned in connection with any change in food crops. In general, the hungriest people in the world are also those with the most conservative food habits. In South China, a local vitamin-B deficiency was caused because people refused to eat their rice unmilled. They objected to the additional cooking time required, they did not like the flavor, and it gave them upset stomachs. New varieties of grain often exhibit milling or cooking characteristics different from traditional ones. Even rather minor changes, such as going from a rice variety in which the cooked grains stick together to one in which the grains fall apart, may make a food unacceptable. It seems to be an unhappy problem of human nutrition that people would sometimes rather go hungry than eat a nutritious substance that they do not recognize or accept as food. [134]

Following the early successes of introducing the new technology in many less developed countries, various of these social and economic obstacles to its spread began to be felt. Once the better-off farmers with suitable land and access to irrigation water and other inputs had adopted the new technology, it proved relatively difficult to sustain the early rate of expansion. Practically speaking, the Green Revolution is not available to the small, poor farmers -- who are the majority in most poor countries -without special supporting measures. Box 7-2 compares the quite different approaches to agricultural development taken by the two largest LDCs in the world, China and India.

In many ways the problem of revolutionizing LDC agriculture is inextricably tied up with the general problem of LDC "development." Shortages of capital, resources, and trained technicians exist along with lack of effective planning, the absence of adequate storage, transport, and marketing systems, and ineffective demand due to poor income distributions. When these are combined with high rates of population growth, malnutrition, and disease, they make any kind of development extremely difficult, and thus retard agricultural development in particular. It is a vicious cycle -- one that will take much more than a new food-production technology to break.

Reduction of food losses. One area in which technology can greatly help to improve the food supply is in the reduction of losses in the field, in transit, and in storage. A conservative estimate of worldwide losses of crops, livestock, and forests to pests, diseases, and spoilage is about 30 percent. In less developed countries the percentage lost is often considerably higher. [135]

For example, the Indian Food and Agriculture Ministry estimated that in 1968 rats alone consumed almost 10 percent of India's grain production. Others think 12 percent may be more accurate. It would take a train almost 3000 miles long to haul the grain India's rats eat in a single year. And yet in 1968 India spent $265 million on importing fertilizers, about 800 *times* as much as was spent on rat control. Rats in two Philippine provinces in 1952-1954 consumed 90 percent of the rice, 20 to 80 percent of the maize, and more than 50 percent of the sugar cane.

BOX 7-2 India and China: Two Case Histories

The two most populous nations in the world are China (800 to 900 million) and India (over 600 million). Both are underdeveloped by the usual standards: low per-capita income or gross national product, and relatively little industry compared to developed nations. But between these two giants there are far more differences than similarities, and some of the more striking differences are to be found in their food and agricultural systems.

India

The story of India's agricultural system is in part a story of misplaced priorities, mismanagement, poor organization, ecological destruction, and inadequate use of limited resources. It is also a story of abject poverty and constant hunger in a large portion of the population. Available figures indicate that in the early 1970s there was enough food in India to meet needs at a minimal level, assuming an average per-capita requirement of 1955 kilocalories. If the actual population was 631 million (a high but generally accepted estimate derived from 1971 census data), an average of 1982 kcal and 59 grams of protein were available per person in 1974. [a] Scattered studies comparing average food intakes in households of various income levels in India over the years, however, have consistently shown consumption levels among the poor to be substantially below average for the nation and well below average needs (see Appendix 2 for United Nations figures

on food). [b] The poorest 30 percent of the population has been estimated to receive 20 to 30 percent less kcal than the national average in normal times.

The urban poor are in a particularly precarious position; they are heavily dependent on food grain distributed by the government at low prices. This food is largely supplied from imports (including food aid) and surpluses in other regions. In times of shortage, farmers and grain dealers often hoard supplies, awaiting higher prices, and are especially reluctant to sell to the government. Unless imports are increased to compensate, the urban poor go hungry. Poor distribution of food supplies combined with economic problems also lead to hunger. More than once flood or drought in one province has caused a local famine while surpluses of grain piled up in the next one and governmentsupported prices held that grain beyond the reach of the poor.

India lived on the brink of starvation for decades until the Green Revolution in the late 1960s seemed to promise relief. Between 1966 and 1971, grain production, which supplies three-fourths of the calories in the Indian diet, rose an average of 4.5 percent per year, well above the population growth rate of 2.5 percent. By 1973, new high-yielding varieties (HYVs) accounted for 75 percent of India's total production of wheat and 36 percent of the rice. But after 1971, expansion of the Green Revolution lost momentum. Partly because of that and partly because of unfavorable weather, there was no increase in annual food-grain production between 1971 and 1975, although the population grew by about 54 million. Table 7-20 shows the record of India's food production since 1951, when the population was only about 363 million. It is worth noting that there has been *no* significant increase in production of pulses -- a major source of protein -- since 1951, although the population has increased by about 75 percent since then.

The problems attending the Green Revolution in India and elsewhere are described in the text. In general, however, the Green Revolution has tended to intensify existing social and economic differences between rural groups, differences that often affect a farmer's ability or incentive to increase production. These and other changes have led to a further displacement of landless farm workers, exacerbating an already enormous unemployment problem. The Green Revolution ran out of steam in India in the early 1970s partly because most of the farmers who could afford and had access to the necessary inputs (fertilizer, seed, irrigation, etc.) had already converted. An additional factor appears to have been an insufficient use of fertilizers. In the year 1973-1974, only a little more than half the amount recommended by the government (which was still below the economic optimum) was used on either HYVs or traditional varieties. This was partly due to short supplies, but there seems also to have been a lack of demand as well because of their higher prices and because small farmers were unfamiliar with their use. [c] It is estimated that increasing fertilizer application to recommended levels could alone increase grain production by 22 million tons.

In 1975, the Indian government announced a massive land-reform program, combined with reform of the usurious farm-credit system, designed to extend the Green Revolution to the poor subsistence farmer. [d] Whether the program will be carried out successfully remains to be seen, but it is a long overdue step in the right direction. After years of neglecting agriculture and rural development in favor of industry, India may finally be shifting to a more realistic set of priorities.

But much more is needed than extension of Green Revolution techniques to the poorest farmers in order to make Indian agriculture a viable enterprise. Not only must it support today's 630 million, but also it must provide for several hundred million more Indians by the end of the century, regardless of the success or failure of population-control efforts (Chapter 13). To do this, the destructive effects of centuries of poor management must be reversed. A major factor in the disastrous floods and droughts so characteristic of India's history has been the disappearance of her once-abundant forests. [e] (For a discussion of this ecological relationship, see Chapter 6.) Forests have been steadily cleared throughout India's history to expand land area for crops and pasture. The wood has mainly been used for fuel and to some extent for construction. As the forests have been reduced to remnants in remote areas, wood for any use has become scarcer, whereas rates of water runoff and soil erosion have accelerated. Increasing dependence on cattle dung for fuel as a result has in turn restricted its availability for use as badly needed fertilizer.

Indian food production, of course, is heavily dependent on the monsoon -- the seasonal rains of the summer months. Nearly all the rainfall for the most productive parts of the nation, especially the Northwest, comes with the monsoon. The winter crops of wheat and barley are indirectly dependent on monsoon rainwater brought by extensive irrigation; rice and other summer crops are directly dependent on them. Much of the monsoon water is lost through runoff, floods, and inefficient forms of irrigation, especially in years of abundant rainfall. In recent years, many thousands of tubewells have been sunk and millions of pumps installed to increase the amount and efficient use of irrigation water. This no doubt provided much of the impetus for the surge in wheat and rice production of the Green Revolution. Gavan and Dixon claim that a principal reason for the halt in production increases in the early 1970s was that the limits to

BOX 7-2 (Continued)

expanding acreage planted to HYVs under present irrigation facilities had been reached. [f] Further expansion apparently must await more fundamental development of the hydrologic system. A first priority here should be development of a flood-control and storage system of reservoirs to accumulate water in years of good monsoons for use in years of monsoon failure and for alleviation of flooding. India already has plans for further expansion and improvement of the irrigation system, including a greater use of groundwater supplied by tubewells. What longterm effect this will have on the groundwater table is unclear, although there are methods whereby recharge can be induced during the monsoon.

More efficient utilization of India's limited water resources would, among other things, permit a significant increase in double- and triple-cropping (growing two or three crops per year on the same land). India already multiplecrops about 20 percent of its cultivated land, but the potential exists for a far higher percentage if sufficient water were available and if the time needed to harvest one crop and plow for the next were shortened, perhaps through increased mechanization.

An important long-range program that the Indian government has contemplated, but apparently has been unable to carry out, is large-scale reforestation. Such a program would provide immediate benefits by employing large numbers of people, and future benefits in building an important resource, contributing to flood control, reducing soil erosion, and restoring groundwater supplies. It might even have a stabilizing influence on the erratic monsoons. Such a program might be difficult and costly, and it might involve displacing large numbers of people, but the long-run benefits would surely outweigh the costs.

India's agricultural system thus has reached a momentous turning point. Most of the available easy measures to increase production -- introduction of HYVs, increased production and use of fertilizers, and expansion of the archaic irrigation system -- have already been exploited,

although there is still some room for improvement through greater use of fertilizers and perhaps installation of more tube wells. At best, however, such extensions of past measures may buy a few more years of rapid population growth. Because they have mostly been imposed from outside, such efforts have often tended to damage, rather than strengthen, the underlying social and economic structure. Agricultural development in India since World War II has indeed been significant, and food production has certainly increased. But the average Indian is not much better off, and the lives of the poorest third of the population have remained basically untouched; they are as poor as ever, and there are many more of them.

If India is to survive even into the middle term, major investments must be made in capital, resources, and human effort to redevelop the agricultural system *from the bottom up*. This means that ways must be found to assist small farmers directly and to provide incentives for them to raise their production and become part of the national economy, and that new agricultural technology must be labor-intensive in order to provide employment for the rural poor, increase their purchasing power, and raise food production. Since most of the food would be consumed locally by the producers, this would also alleviate food-distribution problems.

Meaningful land reform, full exploitation of the potential of HYVs, achievement of control over the hydrological regime to allow full use of available water supplies without jeopardizing future supplies, improvement and conservation of arable soil, reforestation: realization of all these would permit considerable further expansion of India's agricultural production, perhaps a doubling of today's or more. India's *potential* for increased food production is thus very great; the perhaps equally great barriers to achieving it are mainly economic and political. If they can be surmounted, India's future could be relatively bright. But whether they will be overcome in time remains a matter for serious doubt. [g]

China

Judging from the limited available information, China appears to have made substantial progress since the 1949 Revolution in modernizing its agricultural and food-distribution systems and in providing adequate diets for its 1975 population of some 800-962 million. [h] The UN's estimated daily averages of 2170 kcal and 60 grams of protein available per person [i] are not much above India's, but they may be an underestimate. Moreover, supplies apparently are much more equitably distributed. Visitors to China from Western nations have uniformly commented on the absence of evident malnutrition and general deprivation among the Chinese people. Although everyone seems to live modestly, no one lacks the basic necessities of life. This, of course, is a radical change from conditions before the revolution, when extreme poverty, hardship, and starvation were commonplace. It is also very different from India today, where the existence of widespread poverty and malnutrition cannot be missed by any reasonably observant visitor.

Like the Indians, the Chinese depend mainly on cereals and pulses for their diets. But China's total food-grain production for 1971 (including potatoes and other tubers) was about 250 million metric tons, more than twice India's production that year. [j] This indicates that there was 50 to 60 percent more food available per person in China than in India. Furthermore, this food was produced on substantially *less* land; China has only about 107 million hectares of arable land -- about 15 percent of its total land area -- whereas India has over 140 million hectares. China's remarkable productivity is the result of using HYVs (many of them independently developed in China, especially rice) [k] and fertilizers, both natural and chemical, and of extensive multiplecropping, intercropping (growing different crops together simultaneously), relay cropping (overlapping in time), and irrigation. (Table 7-21 shows comparisons of these factors among India China, and several other countries.) There have

the primary sources for this section. Both articles are based on a visit to China by a group of American agronomists under the auspices of the National Academy of Sciences in 1974.

[k]For details of China's rice HYV program, see Dana G. Dalrymple , *Development and spread of high-yielding varieties*, pp. 90-92.

BOX 7-2 (Continued)

also been impressive programs of soil and water conservation and reforestation in China.

Rice is China's principal crop, accounting for almost half (44 percent) of the total grain production; wheat is second in importance, with about 17 percent of the total. Various other cereals and pulses, such as sorghum, millet, corn, barley, and soybeans, make up the rest. Acreage planted to rice is not very much greater than that planted to wheat, but rice is often doublecropped or even triple-cropped with another grain: for instance, rice-rice-wheat or ricerice-barley.

Behind China's success in raising agricultural productivity lies its unique social and economic system, which has been designed to provide maximum incentive for production of food or factory output (and disincentive for large families; see Chapter 13). Both personal and community income are directly tied to productivity. With the exceptions of young children and the aged, everyone is expected to contribute to his or her production team's work. But rural families are also encouraged to have their own gardens and to raise a pig or two. The produce can be either consumed at home or -- more often -- sold for extra income.

Chinese agriculture is necessarily laborintensive; some 80 to 85 percent of the population is engaged in agriculture or agriculturerelated work. (By contrast, in the United States only about 2 percent of the population works in agriculture.) Therefore, although China has clearly embarked on a Green Revolution, it is quite different from the sort exported from the West, most markedly in the minimal dependence on heavy mechanization. The abundance of human labor has allowed the extensive use of intercropping, which is impractical where harvesting, weeding, and planting are all done by large machines. In order to free workers for other tasks, especially for small-scale rural industry, China is now striving to increase mechanization on the farm. But the mechanization is small to intermediate in scale, apparently resembling that of Japan and Taiwan.

Crop protection against pests and diseases is also labor-intensive. It is carried out by specialists who constantly check and survey crops in the field and spray only when an outbreak appears. Diseased plants and seeds are removed individually and destroyed. Broadcast spraying apparently is rarely done. [l] Some protection is also undoubtedly afforded indirectly by Chinese cultivation methods, especially intercropping, transplanting, and the use of fast-maturing strains of rice and wheat. Pest and disease resistance also are important goals in plantbreeding programs. [m]

Active plant-breeding programs have apparently been carried on in China since the Revolution. Chinese strains of high-yield, fastmaturing dwarf rice were being developed in the 1950s. Some work has also been done on hybrid corn, using American varieties imported before World War

II, as well as on wheat, soybeans, sorghum, and millet. Most of the work today is carried on independently in communes, with help from provincial agricultural-research centers.

Visiting American agronomists have expressed concern that basic research in China is being neglected because academic agriculturalists are involved in the practical work and are not being replaced by younger, academically trained people. In the short run, this may not be too serious a problem, as long as the research is being done elsewhere and its results can be made available to the Chinese. But in the longer run it may prove a serious impediment to improvement of agricultural productivity. A complete lack of highly trained scientists might handicap the ability of the Chinese to utilize foreign technology, as well as destroy the domestic base for new research.

An advantage of the Chinese system, on the other hand, is that breeding experiments are being carried out independently in so many different places. This seems likely to result in many different improved varieties of each crop and the maintenance of a large pool of genetic variability.

---

[l] Sprague, *Agriculture*.

[m] For an environmentalist's view of Chinese agriculture, see Kieran P. Broadbent, *The transformation of Chinese agriculture and its effects on the environment*.

Chinese farmers have for centuries been efficient users of natural fertilizers: silt, human, and livestock wastes, and crop by-products, such as grainstalks, husks, and vegetable trimmings. All these are still in use, although crop by-products are also used as livestock feed. China clearly intends to increase the use of inorganic fertilizers and is building some 13 large chemical-fertilizer plants as well as importing fertilizers. By 1978, all needed fertilizer is expected to be produced domestically. In the early 1970s the level of fertilizer application in China was well above that in India, but apparently still below optimum.

As in India, China's potential food production is largely limited by available water. Most of the arable land is confined to three major river valleys, and over a third of it is irrigated by the Largest irrigation system in the world. [n] China also has carried on for some years an extensive program of reforestation and restoration of eroded grasslands. After some early setbacks, there apparently has been steady progress for at least a decade in reforestation -- or so visitors attest. Just how successful this has been is not known, but the frequent devastating floods of pre-Revolutionary China seem to have become a thing of the past.

Today, despite some setbacks and wrong turns, China's agricultural system appears to be on the whole an extraordinary success story, especially when compared with present conditions in most other LDCs or with conditions in China a generation ago. Whether or not one approves of the political measures taken to bring about the change, one cannot ignore the obvious results. Oft-heard comparisons with political systems in developed countries are inappropriate; it is far more

pertinent to compare the lot of an average Chinese family with that of a lowincome Indian or tropical African family whose traditions and way of life are much more similar. Even apart from the obviously greater economic security of the Chinese family, it can be argued that it also has a greater degree of control over its own destiny, despite the political restrictions.

But beyond the achievements of today, what are the prospects for further increases in Chinese food production? China's stringent populationcontrol measures appear to have been more successful than India's so far, but the Chinese population is still growing by at least 1.6 percent annually, adding 14 to 18 million new mouths to feed each year. Food production hence must continue to rise at least as fast, and preferably faster, since the Chinese people have come to expect a steady increase in their standard of living. But the rapid rise in annual food production seen in the years before 1972 has apparently slackened (as in India), and Chinese agronomists reportedly are worried. Among other things, a serious food shortage might represent a threat to the present government.

It is a strange irony that the potential for further raising of food production is probably considerably less in China than in India, precisely because so much has already been accomplished. China has already gained substantial control of its hydrological system, although some further gains may yet be made there. No significant new land remains to be opened for growing crops unless huge investments were made in irrigation projects and soil improvement. The grassland-restoration program, however, may eventually result in the opening of grazing areas, and some expansion of multiple-cropping and inter-cropping may yet be possible. The greatest hope for increase probably lies in further replacement of traditional grains with HYVs, perhaps with some additional improvement of their yields through greater use of fertilizer and from results of ongoing crop-breeding programs. Maintaining momentum in the latter task, however, may require revitalization of basic scientific research.

China has a reasonable chance of winning the battle against its population explosion, but its success in raising food production to date is only half the story. The other half is population control (Chapter 13). Ultimately, success depends on winning on both fronts, especially as the remaining options for raising food production diminish.

---

[n] Mark Gayn, *For water, the Chinese move mountains*.

The FAO has estimated that in warm climates (like India's), rats may outnumber people by 3 to 1. Biologist Stephen C. Frantz studied a bandicoot rat population that subsisted on stored rice in a neighborhood of godowns (small warehouses) in Calcutta. Ordinarily, no effort was made by local people to prevent the rats from eating the grain. This one population in a small area consumed over 2 tons of grain per year and, by contamination caused a loss of 8 tons of rice per year-enough to support 30 people. [136] Such losses apparently are extremely common throughout the less developed world -- yet they are largely preventable by such simple measures as building ratproof storehouses. Sometimes the problem is cultural. In South Asia, where people are accustomed to sharing food with rats and other competitors, they lack motivation to control pests -- and this attitude is supported by religious beliefs.

Other pests besides rats also compete successfully for food produced by people. During the 1960s, birds in Africa destroyed crops worth more than $7 million annually. Insects in LDCs may destroy as much as 50 percent of a stock of grain in a year's storage period. Spoilage from molds, mildews, and bacteria also takes a heavy toll, even in DCs. [137] Since many LDCs are in the tropics and subtropics, where high temperatures and often high humidity encourage these organisms, their spoilage problems are even greater. Hence, the development of good storage and transport facilities alone might increase LDC food supplies at the market level by 20 percent or more. [138]

Problems with pests on crops in the field, like those with stored food, are also more severe in warm climates, where crops may be grown continuously year-round. Controlling populations of insect pests in fields and reducing losses due to them requires great care in order to avoid serious ecological problems. The same is true for controlling rats, birds, rusts, and other noninsect field pests. The ecological problems associated with control of pests in the field are discussed in Chapter 11.

Protection of foods once they are harvested, however, is much more straightforward and ordinarily involves much less ecological risk. Storage facilities may be refrigerated, made ratproof, and can be fumigated with nonpersistent pesticides that are not released into the environment until they have lost their toxicity. Transport systems can be improved so that more prompt movement, proper handling, refrigeration where necessary, and other measures greatly reduce spoilage en route. Perhaps the safest investment that could be made in LDCs toward improving the quantity and quality of food would be the improvement of methods of handling, shipping, and storing crops after the harvest.

Biological Problems

Perhaps even more important than the effects of the social and economic problems of agricultural development -- including possible energy constraints -- may be the potential effects of biological problems. Because biological problems usually take long periods of time to develop, early successes in the Green Revolution may have given the world a false impression of what rates of improvement in yields can be sustained.

For instance, in the 1960s the new grain varieties were rushed into production in places like Pakistan where the climate and irrigation conditions were favorable. They have sometimes been put into production without adequate field testing, which is very time-consuming, thus risking attack by insects and plant diseases. [139] Continuous breeding efforts, however, are being carried out in order to develop varieties suitable for different conditions. In general, though, when crops are selected for specific factors, such as high yield, something else may be sacrificed or overlooked, such as protein content or resistance to bacteria or insects.

The predictions [140] that pest problems would make serious inroads into the productivity of high-yield varieties have been borne out in several instances. For example, destruction of a substantial portion of the Indonesian rice crop in 1974-1975 has been blamed on the susceptibility of the IRRI strain planted to the insect

pest that carries grassy stunt virus. [141] Grassy stunt virus has also caused problems in the Philippines with a strain called IR-20. The latter had replaced IR-8 after it succumbed to another disease known as tungro. A third strain, IR-26, resisted all the local diseases and pests, but was too fragile to withstand strong winds. [142]

Simply planting extensive monocultures (a single strain of one crop) almost invites invasion by diseases and pests. [143] This practice is more common in DCs than in LDCs, but it has been increasing in LDCs as well. In addition, the new strains of rice are grown year-round in some tropical areas, providing a continuous habitat for pests and diseases, and the new short-stalked varieties with dense seed heads are vulnerable to attack by rats. [144]

Increased use of pesticides in developed countries has created a number of problems, which are discussed in detail in Chapter 11. Practicing more intensive agriculture and expanding the use of new crop varieties in LDCs almost certainly will require more input of pesticides with all of their deleterious ecological side-effects. Part of the price of agricultural development in those countries therefore may be an increase in environmental pollution and, possibly, a decrease in production of protein by fish-ponding and a decrease in food from the sea (see below). Besides the more obvious pollution problems caused by pesticides, the side-effects also include the development of resistance in pests and the extermination of their natural enemies.

Such untoward results in some areas have led to abandonment of pesticide use as farmers returned to traditional methods of pest control. In Sri Lanka, pesticides destroyed a species of ant that farmers by tradition had encouraged to control pests. Consequently, increasingly large quantities of chemicals were required to protect the crops. Unfortunately, as in this case, a failure in one element of the technological package (such as a severe pest outbreak) can lead to skepticism about the entire package. [145]

One does not have to turn to Indonesia, Sri Lanka, or the Philippines, however, to see the decimation of modern crop strains by pests, especially where the crops are planted in huge monocultures. Americans were shocked into recognition of this problem when an epidemic attacked the U.S. corn crop in 1970. An estimated 710 million bushels, roughly 17 percent of the anticipated crop, was lost to southern corn-leaf blight. A new genetic strain of a fungus, *Helminthosporium maydis*, proved to be especially damaging to corn with "T cytoplasm," a type widely used in seed production. About 80 percent of the American corn crop was potentially susceptible to the disease.

It is hoped that measures being taken to replace the susceptible corn with resistant strains will prevent a repetition of the 1970 epidemic. The chance remains, however, that the fungus will

evolve the ability to attack other strains; it has, after all, been coevolving with corn for many millennia.

L. A. Tatum of the Plant Science Research Division of the U.S. Department of Agriculture commented, "The corn blight epidemic is a dramatic demonstration that gains in crop production, especially from high yield varieties, may be short-lived unless supported by constant alertness and an aggressive research program. . . . The epidemic illustrates the vulnerability of our food crops to pests." [146] In 1972 a committee of the National Academy of Sciences found that "most major crops are impressively uniform genetically and impressively vulnerable." [147]

Genetic reserves. One of the most serious sideeffects of the Green Revolution is the accelerating loss of reserves of genetic variability in crop plants, variability that is badly needed for continuing development of new strains. [148] A multitude of traditional crop varieties, which could potentially serve as reservoirs of variability, are rapidly being replaced by a relatively few highyielding varieties throughout large areas. This process is

well advanced in developed countries where intensive plant breeding originated and modern crop strains are almost exclusively grown. Table 7-22 shows the degree to which American agriculture depends on a relatively few varieties of major crops.

Traditional varieties are now rapidly disappearing in LDCs as well, as farmers switch to new HYVs. Geneticist Reuben Olembo of the UN Environment Program expressed the problem vividly: "When farmers clear a field of primitive grain varieties, they throw away the key to our future. Eventually the new hybrid becomes so pure it cannot sustain itself." [149]

The introduction of a few new crop strains, of course, is not the only cause of the erosion of crop variability. Growing urban sprawl and extended cultivation continually wipe out populations of wild and semiwild ancestors of HYVS; famine in Biafra (and more recently in the Sahel) led to the loss of much potential crop diversity because everything that grew was consumed; the filling of Lake Nasser behind the Aswan dam drowned irreplaceable strains of feedgrains; and even the cleaning up of ruins in tourist areas of the Mediterranean basin has resulted in serious losses of plant genetic material.

Existing programs to create seed-stock reserves are woefully inadequate, both at the national and international levels. The National Seed Storage Laboratory at Fort Collins, Colorado, has been described as unevenly maintained, incomplete, and "shockingly deficient in some kinds of materials." [150]

Aside from nuclear war, there is probably no more serious environmental threat than the continued decay of the genetic variability of crops. Once the process has passed a certain point, humanity will have permanently lost the coevolutionary race with crop pests and diseases and will be no longer able to adapt crops to climatic change. The problem of genetic erosion is especially tragic because it could be solved at a cost miniscule compared to that squandered annually on weapons by DCs. The new International Board for Plant Genetic Resources of the Consultative Group on International Agricultural Research has begun to move in the right direction--establishing seed banks, and making material available for plant breeders. [151] Whether it moves rapidly enough and with the requisite safeguards remains to be seen.

Much more effort must be put into collecting and maintaining samples of traditional crop strains, and, wherever possible, into preserving crop strain diversity in the field. As noted in Chapter 4, merely saving small

[151] International Board for Plant Genetic Resources (FAO), *The conservation of crop genetic resources*.

samples of seed is not sufficient; and, because accidents have already destroyed some key collections, [152] it is important that duplicate collections be preserved in various parts of the world. Above all, programs should be under the careful supervision of plant geneticists who are knowledgeable in techniques of avoiding the decay of genetic variability.

Special problems of the tropics. Many of the poorest nations of the world, those with the most rapidly growing populations and most inadequate diets, are located in the Tropic Zone. In this region, agricultural productivity tends to be very low, but many agronomists hope that the potential for raising productivity is therefore great. Unfortunately, though, many of the biological problems that accompany the Green Revolution are intensified under the conditions of the humid tropics.

For example, it is not clear that breeding programs can keep ahead in the coevolutionary race against pests in the tropics. The life expectancy of new wheat strains in the northwestern United States is now reported to be only about five years. [153] Because, on the average, there are more generations of pests per year in the tropics, the rate at which they can penetrate strain resistance is likely to be even faster there. Hence, new crop strains need to be introduced perhaps every three years or so, unless pests can be effectively discouraged by other techniques, such as intercropping or rotation of crops.

If pesticides are employed, the heavy rains characteristic of equatorial regions may wash them quickly away, necessitating heavier or more frequent applications than are usual in temperate areas. The result, of course, would be amplification of the associated environmental consequences (see Chapter 11).

Similarly, the loss of organic matter from soils in the humid tropics, already serious because of heavy rains and thin soils, can be expected to increase as agriculture is intensified in those regions. Introduction of HYVs will necessarily be attended by increased use of fertilizers. But, if artificial fertilizers are used alone, the loss of organic matter from tropical soils may proceed even faster than it does in temperate areas. [154] There are likely to be other serious environmental problems if inorganic fertilizers are heavily used (Chapter 11). These problems, however, could

be mitigated by favoring organic fertilizers over inorganic ones as much as possible. Knowledge of local soil characteristics (such as acidity or presence or absence of particular nutrients) can be a useful guide to appropriate fertilization and choice of crops. [155]

Today, the unavoidable (given rapid population growth) intensification of agriculture in the humid tropics generally takes one of two possible forms: (1) intensification of milpa farming, in which clearings are made larger and closer together, and regeneration times are shortened; or (2) imposition of large-scale, temperate-style agriculture, after clearing the forest. Either approach can lead to more or less permanent degeneration of the soil. [156]

Massive deforestation also seems to cause changes in local climate and exposes the land to severe flooding and erosion. Such destruction has occurred repeatedly in widely dispersed areas of the tropical world, from Nigeria and Zambia to Guatemala and the Amazon basin. Unfortunately, this trend is continuing, if not accelerating.

Large-scale agriculture may, indeed, not be possible in the humid tropics. But an approach that works -- one grounded in large part in an understanding of tropical ecology -- is beginning to emerge. This new agriculture also borrows heavily from milpa traditions in such practices as planting many different crops together (a milpa farmer may plant as many as 20 different species in his small clearing) in a small-scale, labor-intensive operation. Such small, family-run farms, often more efficient even in temperate agriculture than large-scale, highly mechanized operations, are still more so in many tropical settings. [157]

Experiments in mixed cropping are currently being carried out in several tropical areas in an effort to find the best kinds of mixtures for local conditions. Often adaptations of traditional practices prove fruitful. One variation is alternating forest growth with food crops (known as *agrisilviculture*). Sometimes trees are interplanted with shade-loving crops, rubber trees with coffee or peanuts,

for example. Mixed cropping frequently results both in higher yields and in reduced pest problems. (This is true both in tropical and in temperate areas.) [158]

An important principle in tropical farming is that the soil must always be covered (especially lateritic soil) to avoid sun-baking, leaching, and erosion. For additional protection, crop residues may be used as both mulch and fertilizer. In some tropical areas at least, minimal or no tillage of soil on slopes has proven helpful in reducing erosion without lowering yields. [159]

The lessons being learned in tropical agricultural research are vitally important for the futures of many tropical poor countries. The question now is whether they can be learned by agricultural establishments in those nations and the techniques can be transmitted to the farmers before the wrong approaches have destroyed the forest ecosystem beyond reclamation.

High-yield agriculture and climate. One potential drawback to the high-yielding crop varieties is that they have been bred to respond to a relatively narrow band of weather conditions -- precipitation and temperature, particularly. Within the expected band of conditions they perform extremely well, but if rainfall or temperatures are too high or too low, yields may decline substantially. Generally, traditional varieties are less sensitive to stresses such as bad weather; under adverse conditions they may outperform HYVs.

A change in climate, if permanent and stable, can, of course, be compensated if necessary by breeding crop varieties that respond to the new set of conditions. But developing new strains in some situations might not even be necessary. For example, since the 1940s there has been a cooling trend in middle latitudes of the Northern Hemisphere, including the corn belt of the United States. If this trend continued to the year 2000, the resultant shorter growing seasons would be detrimental to corn and soybean crops at the northern edge of their range. Cooler weather would, however, be beneficial at the lower middle latitudes where the highest yields of these crops are obtained when average July and August temperatures are below normal. [160] As far as corn and soybeans are concerned, the overall effect of the continued cooling trend would probably be a gradual southward shift of the corn and soybean belts.

The most critical threat to crop yields is not a gradual change in overall climate, but an increase in its variability. For example, if the weather in the corn and soybean belts should be as variable in the last quarter of the twentieth century as it was in the first quarter, average yields of those crops would be reduced by about 3 percent. [161] If the U.S. is especially unlucky with the weather, the average could be reduced even further -hardly a cheering prospect for an era in which the world must count on constantly increasing yields of these crops.

A key point to remember is that the period of weather from 1940 to 1970, which is conventionally regarded as normal, was actually a period of *abnormally stable summer weather* for many of the world's granaries. The notion that good weather is normal weather is one important factor that has misled the U.S. Department of Agriculture to conclude, "Through the use of better varieties and improved cultivation and fertilization practices, man has reduced variation in [corn] yields in both good and bad weather." [162]

In recent years, the leadership of the USDA has persisted in the erroneous belief that modern technology has largely freed high-yield agriculture from the influence of weather. They have clung to this belief despite repeated warnings from many scientists concerned with the interactions between climate and agriculture, among whom are Reid Bryson, James McQuigg, Stephen H. Schneider, and Louis M. Thompson. [163] Thompson, an agronomist, and McQuigg, a climatologist, issued an important warning to the government in 1973. [164]

[162]Report on the influence of weather and climate on United States grain production, U.S. Department of Agriculture, quoted in Thompson, *Weather variability*.
[163]By far the best presentation of the problem of climatic variability and its political implications can be found in S. H. Schneider and L. Mesirow , *The Genesis strategy*.
[164]Report to the National Oceanographic and Atmospheric Administration, "The influence of weather and climate on United States grain yields: Bumper crops or drought", U.S. Department of Commerce, Washington, D.C., 1973.

Thompson had statistically analyzed yields of wheat, corn, and soybeans, and had shown that about half the variability in yields since 1900 could be explained by variability in the weather. [165] For example, in Missouri average corn yields increased from about 40 to about 80 bushels per acre between 1955 and 1973, and the variability of the yields decreased. Thompson's analysis showed that it was the abnormally favorable weather conditions for that period that reduced the absolute amount of yield variability, not *improved technology*, which appears to have reduced the percentage variability by increasing the total yield. McQuigg and Thompson argue strongly in their report that the consistently high grain yields of recent decades were basically caused by good luck with the weather and that it is "imperative that we not be lulled into a dangerous and unjustified expectation that such fortunate circumstances will continue." Their warning was prophetic in light of weatherrelated yield reductions in key United States crops in 1974, 1976 and 1977.

In fact, agriculturalists seem to be moving in directions that will reduce the chances of having good luck. One of the main elements of the technology of high-yield agriculture may make yields more vulnerable to variation than they were in traditional agroecosystems. Climatologist Stephen H. Schneider and his collaborator Lynne E. Mesirow argue in their fine book, The Genesis strategy, that HYVs, while producing higher absolute yields, tend to give *more variability* in absolute yield. [166] The essence of their argument is illustrated in Figure 7-21, which shows that HYVs, whether relatively sensitive or insensitive to environmental stresses, still are more variable in absolute yield than traditional varieties.

Climatic change therefore can have negative effects on agricultural yields in two different ways. One is through rapid directional change. Even if the change is toward "better" weather, there may be a depression of yields during the transition while farmers and the agroecosystems adjust. More important, increased variability in the weather could greatly enlarge the absolute difference between good and bad harvests. If humanity had superabundant food, this might make little difference, but even

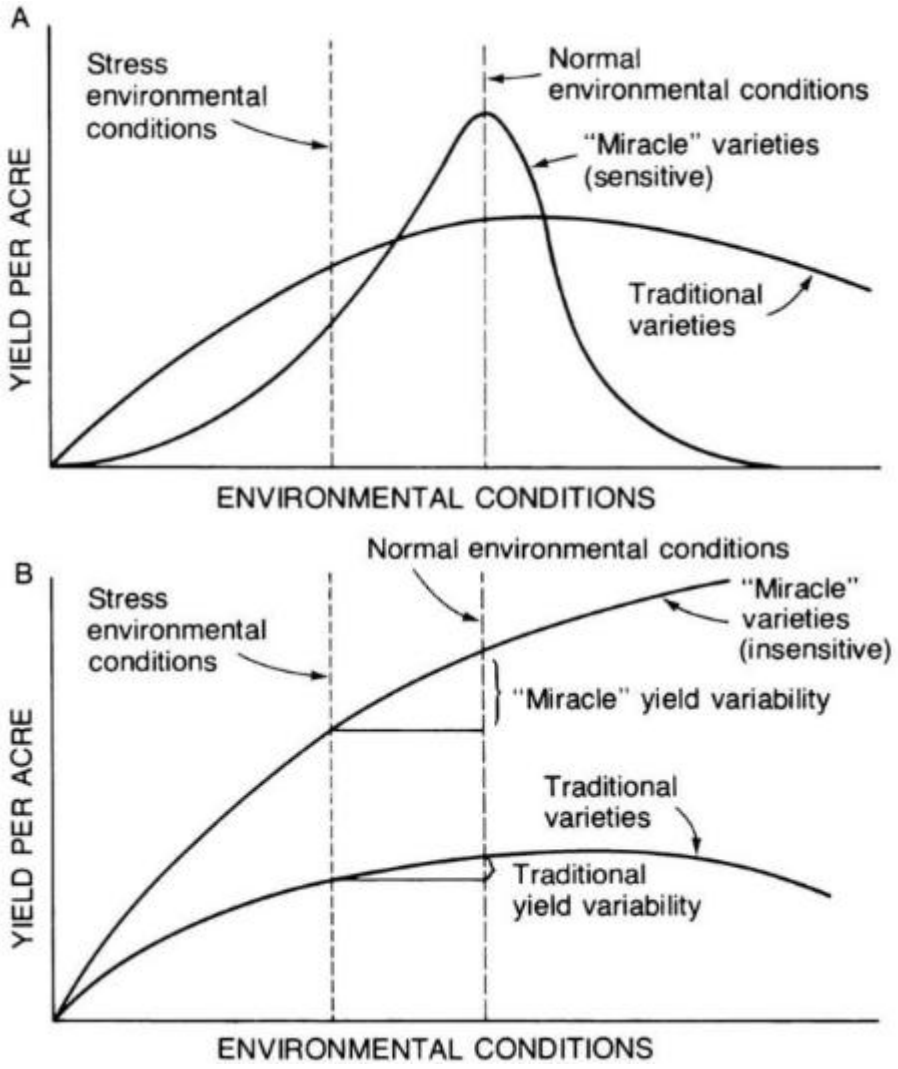

FIGURE 7-21 Part A shows how yield varies with environmental conditions for traditional varieties and for high-yield ("miracle") varieties that are particularly sensitive to such conditions. (Environmental conditions means some generalized aggregate of rainfall, humidity, fertilizer inp mean and extreme temperatures, etc.) Part B shows the same compar between traditional varieties and a "better" set of high-yield varieties which are relatively insensitive to environmental conditions and yield more than the traditional varieties no matter what the conditions. In cases, *variability* in crop yield as a function of environmental factors seen to be greater for miracle crops than conventional varieties. (Fro Schneider and Mesirow, *The genesis strategy*.)

now "world grain reserves are . . . roughly equivalent to (or smaller than) the difference between production in a favorable weather year worldwide and an unfavorable year." [167] When a few percentage points in global yield are all that stand between humanity and massive famines, it would seem prudent indeed to adopt Schneider's "Genesis strategy" and "store food in the fat years as a hedge against the lean." [168] Unhappily, the U.S. Department of Agriculture, largely for economic reasons, has preferred so far to keep its head in the sand. [169]

High-Yield Agriculture and Resource Constraints

Modern, high-yield agriculture, as practiced in developed countries, can reasonably be described as a system that turns calories of fossil fuel into calories of food. Fossil fuels, of course, are used extensively in both the manufacture and the operation of farm machinery, in the production of pesticides and other materials used by farmers, and as both fuel and raw materials in the mining and manufacture of fertilizers. [170] Fossil fuels are also essential to the construction and operation of the systems that transport materials to the farm and carry farm produce to market. A significant portion of this energy must be used to stabilize otherwise unstable agricultural ecosystems; that is, to protect them from insect pests, plant diseases, winds, drought, floods, or the like.

As the use of manpower in North American and European agriculture has declined since 1900, fossil-fuel inputs have steadily increased. By 1970, less than 5 percent of the U.S. population lived on farms, compared to more than 23 percent in 1940. The reduction is less dramatic in most of Europe, where the small family farm is still the norm. Such reductions in human labor while food production increased substantially would have been impossible, of course, without great inputs of energy.

A study conducted in the 1960s indicated that, on the average, for each kilocalorie of food produced in the United States in 1960, some 1.5 kilocalories of fossil fuels were consumed directly by agriculture, and even more were consumed in related activities. [171] More detailed analyses of both American and British energy consumption in their food systems have since appeared. Biologist David Pimentel and his colleagues at Cornell University analyzed the energetics of producing corn, which was chosen as a typical crop. [172] They calculated that about 2.8 kilocalories of corn were obtained for each kilocalorie of energy input on U.S. farms in 1970. About half of the input replaced human labor, and the rest supported high productivity. This study covered only energy expended on the farm, although it did include the energy cost of manufacturing farm machinery, fertilizers, and pesticides. (In fact, corn, rather than being a "typical" crop, is among the more energetically efficient products in the U.S. food system.) [173]

Some other studies have been extended to include energy consumption by all elements of the food system: the farm and its inputs, food processing, packaging, distribution, storage, selling, and cooking. Steinhart and Steinhart estimated that the energy subsidy of the entire U.S. food system in 1970 amounted to an average of nearly 9 kilocalories for each kilocalorie obtained as

food -- and the subsidy has continued to rise in the 1970s. [174] Eric Hirst calculated that the U.S. food system accounted for about 12 percent of the national energy budget. About 40 percent of the energy in the food system was devoted to producing the food, and the rest was used in processing, distributing, and handling the food at home.

There are great variations, of course, in energy demand among crops. Corn, soybeans, sorghum, sugar cane, and wheat require relatively small inputs compared to caloric yields, for instance, whereas tomatoes, melons, and green vegetables rank high, and fruits, potatoes, rice, and peanuts fall in the middle. (These measurements can be somewhat misleading, however, because the energyintensive crops are generally low in calories and are grown for other values such as vitamins, minerals, and fiber.) [175] The most energy-intensive of all foods are grain-fed animal products, when the energy subsidy of the feed crops is included. [176]

There are also very large variations in energy consumption among farming methods. Fossil-fuel inputs, for instance, are very low in LDCs compared to those in most industrialized nations. Figure 7-22 shows the energy subsidies, both for different crops and for different ways of obtaining food, from hunting and gathering and milpa (shifting) cultivation to intensive, high-yield crops and livestock production. It should be pointed out, however, that LDC agriculture is nonetheless quite energy-intensive -- the difference is in the

sources of energy and the efficiency of their utilization. [177] The main sources of energy for food production in most LDCs are wood, dung, crop wastes, draft animals, and human labor. In general, these sources are used very inefficiently.

What has all this to do with the Green Revolution? Most plans for modernizing agriculture in lessdeveloped nations call for introducing energy-intensive practices similar to those used in North America and western Europe -- greatly increased use of fertilizers and other farm chemicals, tractors and other machinery, irrigation, and supporting transportation networks -- all of which require large inputs of fossil fuels. If systems of food production, processing, and distribution worldwide were "modernized" to the same degree as in the U.S. and the U.K., *the equivalent of 40 percent of the world's commercial fuel consumption in 1972 would be required to feed Earth's 4 billion people today*. [178] The likelihood that such high levels of energy use in the food system can or will be attained seems extremely remote, even though increased energy use in that system should have a high priority in the competition for resources.

It is becoming increasingly obvious that resource constraints -- the limited amounts of arable land, fresh water (see Chapter 6), fossil-fuel energy and fossil-fuelderived agricultural materials -- are likely to circumscribe future agricultural development in LDCs. There are, however, many opportunities for increasing efficiency in the use of available energy sources [179] and for exploiting presently neglected potential resources, such as solar and wind energy, in both DCs and LDCs. (Such possibilities are discussed further in Chapter 8.)

It should be noted, moreover, that alternative farming methods that use far less fossil fuel than American-style agriculture requires, with no loss of productivity, are available. Both Japan and Taiwan, for example, attain yields similar to those of American farmers with lower fossil-fuel inputs. China has rapidly and successfully increased its food production in the past two decades with only a fraction of the energy cost typical of developed countries. The secret (and the price), of course, is much greater use of human labor and relatively less dependence on heavy machinery and manufactured fertilizers and pesticides. [180] Further increases in Chinese yields will undoubtedly require more energy, as fertilizer use increases and small-scale mechanization is introduced, but inputs seem likely to remain well below typical DC levels, at least for the foreseeable future. The approach that China has used is open to other LDCs, of course, and they would be wise to adopt those Chinese methods that suit their own situations.

Besides being less consumptive of diminishing energy resources, a more labor-intensive, less chemicaldependent agriculture causes far less environmental damage than does energy-intensive Western agriculture (see Chapter 11). [181] Western agricultural science may revolutionize food production in LDCs, but they in turn may be able to teach the West some techniques that will allow high yields to be maintained over the long term.

David Pimentel and his group have shown that, because of the limited supplies of arable land and energy, even today's human population of 4 billion could not be supported by a high-protein, American-style diet, in which 69 percent of the protein is derived from animals. [182] The outlook for feeding adequately (let alone bounteously) the 7 billion people expected in the year 2000, and still greater numbers after that, is decidedly gloomy. The Cornell group nevertheless has proposed a scenario in which adequate diets could be provided for the population of 2000 and beyond. In their scenario, people in rich countries would stop consuming grain-fed animals, depend more on vegetable sources of protein, and restrict their milk- and meat-eating to pasture- and range-fed animals. At the same time, people in poor countries could make greater use of animal protein by increasing and improving their flocks, herds, pastures, and rangeland.

Such a changeover could release enormous amounts of food resources and relieve pressures on energy supplies, even as diets for the poorer half of humanity were substantially improved. Without such a change, the

[182]Energy and land constraints.

Cornell group estimated that, to feed the population of 2000 at the same per-capita calorie and protein levels as in 1975, worldwide cereal production would have to be raised by 75 percent, legumes by 66 percent, and other vegetables by 100 percent. This assumes an increase of 30 percent in animal protein production also. If feedstuffs suitable for human consumption were diverted to the human supply and worldwide production of animal protein were reduced about 24 percent, however, it would be necessary to increase cereal production by the year 2000 by only 41 percent, legumes by 20 percent, and other vegetables by 50 percent. Obviously, if population growth slowed significantly in the next quarter-century, or if food production could be increased more rapidly, there would be an opportunity to improve the average human diet -- preferably by providing an adequate one for the hungriest billion.

Declining Yields and Proliferating Problems

One ominous element in the record of faltering grain production of the early 1970s was an overall decline in average yield (production per hectare) worldwide (Figure 7-23). This drop applied to all major cereals except rice, and reversed a long-estabished trend of steadily rising yields. Lester Brown, president of Worldwatch Institute, attributed the downturn primarily to five major factors, besides the weather:

(1) the release for production of the 50 million acres of idled, below-average-fertility cropland in the United States that, added to the global cropland base, almost certainly reduced the average crop yield; (2) the high cost and tight supply of energy; (3) the high cost and tight supply of fertilizer; (4) the build-up of population pressures that reduce the fallow cycles of shifting [milpa] cultivators in large areas of West and East Africa, Central America, the Andean countries, and Southeast Asia to the point where fallow periods are now too short to allow soil fertility to regenerate; and (5) the growth of the demand for firewood in developing countries to such an extent that local forests could not keep pace and that more and more animal dung was used as fuel and less and less as an essential source of soil nutrients. [183]

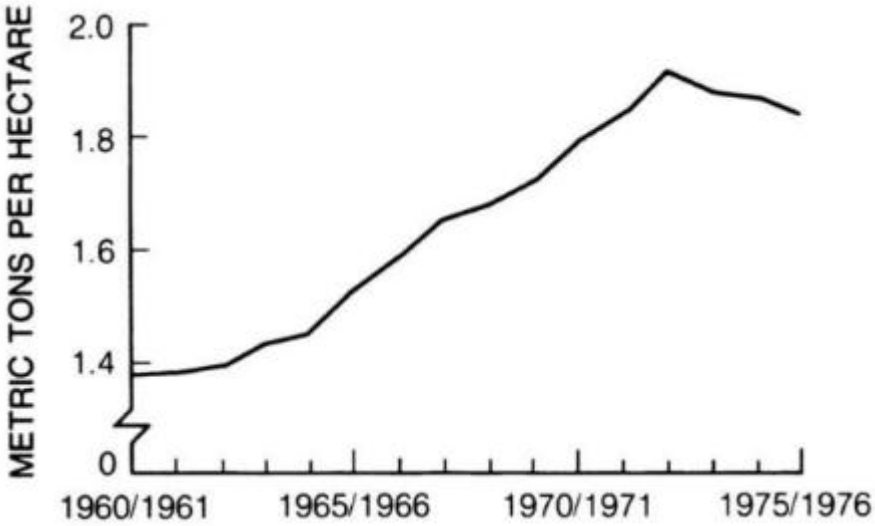

FIGURE 7-23 World grain yield per hectare, 1960-1976. Excludes rice; plotted as three-year sliding averages. (From Lester R. 1975, p. 1058.) Copyright 1975 by the American Association for the Advancement of Science.

Some additional factors, which like Brown's last two are directly related to population pressures (although they could be alleviated by better farming methods and resource management), could be added to this list. These include: irrigation with inadequate drainage, leading to accumulation of salts in the soil; increased soil erosion and accelerated silting-up of rivers and reservoirs caused by deforestation; expansion of cultivation into poor and unsuitable land, especially in mountainous regions; expansion of desert areas, largely because of overcultivation and overgrazing of the fragile desert-edge environment. [184]

By the mid- 1970s, average yields from HYVs in many less-developed countries were also dropping. One reason was that the best land was planted first in these varieties, and less spectacular improvements in yield resulted from expansion onto poorer-quality land. In addition, some of the smaller farmers who were adopting the new technology may have been less able to provide all the necessary inputs in the right amounts and at the right time. In some areas, pest and crop diseases began to invade and to reduce harvests. Finally, the picture was clouded by the simultaneous occurrence of several years of unfavorable weather and the 1974 fertilizer shortage, both of which were discussed earlier.

These trends suggest that, although improved crop strains, better technology, and careful land and resource

[183]Brown, *Politics and responsibility*, p. 27.
[184]Eckholm, *Losing ground*.

management might allow substantial increases in yield on good land where the Green Revolution has not yet been introduced, overall it will be increasingly difficult in the years ahead for food production in less developed regions to keep pace with population growth. The easier gains have

already been made; successful exploitation of remaining opportunities will require proportionately much more effort, capital, energy, and care in avoiding untoward results.

As promising as high-yield agriculture may be, the funds, the personnel, the ecological expertise, and the necessary time to develop its full potential unfortunately may not be at humanity's disposal. Among other things, there is a serious *rate* problem. Even if research can create new technology quickly enough, there are apt to be considerable lags in getting the new technology into practice. [185] Revolutionizing agriculture, especially in the tropics, will be a time-consuming proposition, and population growth will not wait. Fulfillment of the Green Revolution's promise could come too late for many of the world's hungry, if it comes at all. Even its most enthusiastic boosters, including Norman Borlaug, who received the Nobel Peace Prize for developing the miracle wheats, have asserted that the Green Revolution cannot possibly keep food production abreast of population growth for more than two decades or so. Since a birth-control solution to the population explosion will inevitably take much longer than that, the prospects for avoiding massive deficits in food production in many less developed regions seem dim indeed. Unless food can be transferred from the rich nations on an unprecedented scale, the death rate from starvation in LDCs seems likely to rise in the next few decades.

FOOD FROM THE SEA

Perhaps the most pervasive myth of the population-food crisis is that humanity will be saved by harvesting the "immeasurable riches" of the sea. Unfortunately, the notion that vastly greater amounts of food can be extracted from the sea in the near future is an illusion. Biologists have carefully measured the riches of the sea, considered the means of harvesting them, and have found them wanting as a solution to the world food problem.

Fisheries Yields

The basis of the food-from-the-sea myth seems to be some theoretical estimates that fisheries' productivity might be increased to many times current yields. However, an analysis in 1969 by J. H. Ryther, of the Woods Hole Oceanographic Institution, put the maximum sustainable fish yield in the vicinity of 100 million metric tons, only about 43 percent more than the record 1971 harvest of just over 70 million metric tons (see Box 7-3). [186] Some marine biologists, more optimistic than Ryther, have estimated that a global fisheries yield of 150 million metric tons might be attained. [187] More recently, it has been suggested that even Ryther's estimates may be too high. [188]

In 1950, total world fisheries' production was about 21 million metric tons. For the next twenty years, production rose each year at an average rate of about 5 to 6 percent. [189] This rapid, sustained increase was largely due both to more intensive fishing and to the increasing use of technology, and probably also in part to more accurate and complete reporting.

In 1971, the rise in fisheries production came to a halt; in fact, the total catch of 70 million metric tons represented only a slight increase over the previous year. In 1972, there was an abrupt decline to less than 66 million tons. The catch in 1973 was about the same, and in 1974 it recovered slightly to 69 million tons (Figure 7-24).

For the growing human population, declines in the total catch of world fisheries mean even greater drops in per-capita yields (Figure 7-25). Since only about 2 percent of the world's calories come from the sea, one might easily draw the conclusion that a reduction of per-capita yield is not particularly important. On the contrary, it is extremely serious. Although food from the

Box 7-3 Productivity of the Sea

It is common for laymen to consider the oceans of the world a virtually limitless source of food. They would do well to heed the words of marine biologist J. H. Ryther, "The open sea -- 90 percent of the ocean and nearly three-fourths of the earth's surface -- is essentially a biological desert. It produces a negligible fraction of the world's fish catch at present and has little or no potential for yielding more in the future." The upper layer of open seas, where there is enough light for photosynthesis, lacks the nutrients necessary for high productivity. The photosynthetic producer-organisms (phytoplankton) that live in this layer are extremely small in size. As a result very small herbivores and lower-order carnivores are able to function in food chains, and roughly five steps in the chains are interposed between the producers and human consumers. Thus not only are the basic mineral resources for the producers in short supply, but the energy losses in repeated transfers up the long food chains result in further reductions in the potential harvest.

Close to shore, and in certain offshore and coastal areas where powerful upwelling currents bring nutrients to the surface, productivity is 2 to 6 times higher; phytoplankton are larger, and food chains thus tend to be shorter. It is these areas that supply humanity with virtually all of its seafood. But the coastal areas are also the most subject to pollution. In many areas one-quarter to one-half of fishing production is dependent on estuaries, directly or indirectly -- but people are busily destroying many of the world's estuaries. The fisheries situation as viewed by Ryther is

summarized in Table 7-23. Note that Ryther's productivity estimates are in the same ball park as those given in Table 4-6 when adjusted for the different classification of areas in that table, which were:

Area	Percent of ocean	Average production
Open ocean	92.0	57
Continental shelf	7.3	162
Upwelling zones	0.1	225
Algal bed and reef	0.2	900
Estuaries	0.4	810

The major differences in estimated maximum fisheries yields come from the multiplicative effects of variations in average productivity estimates (especially on the coastal zones), in the calculation of number of trophic levels (which depend primarily on assumptions about ecological and tissue-growth efficiencies), and in assumptions about the percentage of the production that can be harvested. *

TABLE 7-23 Productivity of the Ocean

Area	Percent of ocean	Area (square kilometers)	Average productivity (grams of carbon per square meter per year)	Average number of trophic levels (approximate)	Annual fish production (millions of metric tons)
Open ocean	90	326,000,000	50	5	1.6
Coastal zone *	9.9	36,000,000	100	3	120.0
Coastal upwelling areas	0.1	360,000	300	1.5	120.0
Total annual fish production					241.6
Amount available for sustained harvesting **					100.0
Fisheries yield in 1971, the largest catch so far					70.2

*Including certain offshore areas where hydrographic features bring nutrients to the surface.

**Not all the fishes can be taken; many must be left to reproduce or the fishery will be overexploited. Other predators, such as seabirds, also compete with us for the yield.

sea provides comparatively few calories, it supplies about 14 percent of the world's animal protein directly, and a further portion indirectly as livestock feed. For some countries, especially for those where fishes provide a greater-than-average proportion of high-quality protein, the loss of this protein would be catastrophic. The Japanese, for instance, depend on seafood to provide somewhat more protein than is available to them as meat or poultry. Per-capita annual consumption of seafood in Japan is 71 pounds; [190] that of meat (most of which is imported, moreover) is only 51 pounds.

The anchoveta fishery. A major portion of the sudden 1972 decline in world fisheries yields and its subsequent fluctuations can be traced to changes in the Peruvian anchoveta fishery. In 1970, the yield from this fishery alone was almost 13 million tons; by 1973 it had declined to little more than 2 million tons, because of an interaction between people and nature. In 1972/73, warmer tropical waters invaded the cool, nutrient-rich Humboldt current that supports the fishery. Because they periodically recur around Christmas time, these inversions are known as El Niño (The Christ Child). [191] This natural event normally depresses the anchoveta population size; when applied to a population in which the adult stock was already badly depleted by overfishing, it triggered a catastrophic decline (Figure 7-26). [192] The Peruvian government imposed stringent regulations, but only a slight recovery was registered in 1974 and 1975. [193] It seems doubtful whether, even with careful management, sustained yields of anchovetas could ever exceed the 1970 level; the maximum sustainable yield has been estimated at about 9.5 million metric tons. [194]

Increasing the yields. Because the anchoveta fishery is potentially a significant element in the total harvest from the sea, it is difficult to predict future trends. If the anchovetas recover, worldwide yields may resume their

pre- 1971 upward trend. Even if the global fish catch could be increased by the year 2000 to 100 million metric tons (Ryther's estimate of the maximum sustainable yield), however, there would still be less fish consumed per person than in 1970 (unless the human population growth rate decreases substantially in the meantime). Although such large increases in the fish catch would be desirable, the possibility cannot be dismissed that catches have now leveled off -- and, indeed, that dramatic declines in many fish catches, similar to the anchoveta story, may soon occur.

To surpass the potential annual fish production of 70 to 150 million metric tons would require moving down the food chain from the large fish ordinarily found in fish markets to the harvesting of smaller animals or phytoplankton. All signs at the moment indicate that this will not be feasible or profitable in the near future, with the possible exception of some 25 to 50 million tons or more (some estimates range over 150 million metric tons) that might be harvested from populations of shrimplike krill in the Antarctic. [195] It has been speculated that in recent decades the supply of krill may have been greatly increased by the decimation of the populations of baleen whales that feed upon them (see the following section of text). But there is no evidence that the krill population has grown. Numerous other organisms also depend on them for food, including several kinds of fishes, seabirds, penguins, and seals. These may well have taken up any slack resulting from reduced whale predation.

Krill are a rich source of protein and apparently are reasonably palatable; they occur in dense, easily harvested swarms. Hence, they have attracted interest in several fishing nations. A paste made of krill and a krill/cheese product are already commercially available in the Soviet Union and reportedly are selling well. The Russians have also been using it as a livestock feed supplement. The Japanese, too, have been experimenting with foods based on krill. [196]

Adding krill or other plankton to the ocean harvest might increase the total fisheries yield, but it would not necessarily improve its quality or reduce its cost. The expenditure of money, fuel, and human energy required to harvest and process most kinds of plankton would be even greater than those demanded by distant fishing and would be colossal in relation to the yield. In many cases, the product would require considerable processing to be made palatable as human food. In addition, harvesting plankton in most areas would result in the depletion of stocks of larger fishes living farther up the food chain -fishes that could themselves be far more easily and cheaply harvested and that would be more welcome on the dinner table.

Two things stand between humanity and the future achievement by more conventional methods of even 100 million metric tons of fisheries yield. The first is overexploitation; the second is oceanic pollution (which is discussed in Chapter 11). The setbacks of the 1970s may mean that these two problems have already overtaken us.

Whaling

The story of the whale fisheries serves as a model of overexploitation. [197] It differs from other fisheries in that whales have been harvested primarily not for food but for whale oil, although they are now used extensively for food as well as for the production of a multitude of products from perfumes to fertilizer.

In 1933, a total of 28,907 whales were caught, producing 2,606,201 barrels of whale oil. In 1966, a third of a century later, 57,891 whales were killed, almost exactly twice as many as in 1933. But twice as many whales yielded only 1,546,904 barrels of oil -- just about 60 percent of the 1933 yield. The reason can be seen in the charts of Figure 7-27. As the larger kinds of whales were driven toward extinction, the industry shifted to harvesting not only the young individuals of large species, but, with time, smaller and smaller species: first the gigantic blue whale, then the fin, the sei, and the sperm. By 1973, most of the whales caught were sperm or minke, a small species formerly considered beneath the whalers' notice. [198]

Pacific Discovery, vol. 29, no. 1, 1976.

Overall, it has been estimated that whale stocks have been reduced by at least half through uncontrolled hunting during the past half century. Populations of the most heavily exploited species have been cut to a tiny fraction of their former sizes, whereas some of the smaller species have so far been relatively unaffected. Table 7-24 shows the depletion of ten important whale species. For the three species for which only fragmentary information exists, what there is suggests that they too have been reduced by half or more. It is disturbing to note that little or no recovery has been noted in stocks that have not been hunted for several decades, with the single exception of the California grey whale.

Technological "space-age" advances have greatly aided the whalers in this overexploitation. Ship-based helicopters locate whales and then guide killer boats to the quarry. The killer boats hunt by sonar, killing the quarry with an explosive harpoon head attached to a nylon line with an eighteen-ton test strength. The dead whale is inflated with compressed air so it will not sink, and a radio beacon is attached to the catch so that the towboat can find it and tow it to the factory ship, where it is quickly processed. Some attempts have been made to introduce more humane methods of killing the whales, but they seem not to have been accepted so far.

Efforts to curb the slaughter were remarkably unsuccessful until the 1970s, when public indignation began to be felt. Box 7-4 describes the history of international efforts to regulate whaling.

The killing of highly intelligent aquatic mammals is becoming even more common because of the recent escalation in the killing of small whales -- belugas, porpoises, dolphins, and the like. Not only have these animals increasingly been candidates for hunting as the large whale species

have been pushed toward commercial extinction, [199] but they are also being killed in large numbers in the course of commercial tuna fishing. For unknown reasons, porpoises are commonly associated with schools of yellowfin tuna (they do not feed on them) and are often trapped in the purse-seines of the tuna fishermen. Many of the trapped porpoises panic and dive, become entangled in the net, and drown. An estimated 200,000 to 500,000 per year were killed in that manner in the early 1970s. [200] By 1974, public concern over this slaughter had grown to the point that U.S. tuna vessels were required to incorporate a safety panel in their nets to aid the porpoises in escaping. The efficacy of this and other proposed measures remains to be seen -- porpoises were still being needlessly killed in large numbers by tuna fishers in 1975 and 1976. [201] In early 1976, a court decision effectively banned U.S. tuna fishers from purse-seining tuna schools accompanied by porpoises. The result, however, may be a transfer of ownership of the tuna fleet to foreign registration rather than a change in fishing methods. [202]

So, not only are the giant blue and fin whales threatened (the largest animals that have ever lived -- a blue whale weighs roughly 30 times as much as an elephant and is larger than the largest dinosaur), but so are the smaller whales whose intelligent behavior has

received much publicity on television and in films and fascinated millions at marine parks. For even if the tuna-related slaughter of porpoises abates, commercial fishing of the small whales seems likely to increase.

Tragedy of the commons. It thus behooves us to ask, "For what?" What is gained by reducing the chances that future generations of people will be able to observe the behavior of these endlessly interesting animals and perhaps even communicate with them? For what does humanity risk silencing forever the fascinating songs of the humpback whale, which can range over 10 octaves, last for up to 30 minutes, and be repeated virtually verbatim? The answer is, for the profit of a few corporations, private and state.

Whale products are a trivial part of world commerce (worth about $170 million per year), and every single one of them has readily available substitutes from other sources. For sperm-whale oil, for instance, which has been claimed to be uniquely suited for automatic transmission fluid in cars and as an industrial lubricant, there has been found to be an analog produced by an obscure cactus, the *jojoba*. [203] Jojoba oil can be produced in large quantities at far lower cost than that of hunting whales. And, if cultivated, the plant would be in no danger of extinction. In short, whaling is not only cruel, but also, in the broad view, absurd.

Apart from these considerations, what can be said about the whaling industry's performance? Its drive toward self-destruction seems on the surface to contradict the commonly held notion that people will automatically change their behavior if they realize that it is against their own self-interest. Fully informed by biologists of the consequences of their behavior, the whaling industry has nonetheless continually operated against its own self-interest since 1963. Short-term self-interest, the lure of the "quick buck," clearly has been too strong to allow the long-run best interest of everyone to prevail. Those who own the industry apparently plan to make more money in the long run by forcing both the whales and the industry to extinction and then investing their ill-gotten gains elsewhere after the final collapse of the whale stocks. [204] Behavior that appears on the surface to be irrational thus turns out to have a perverse "rationality" in the context of the prevailing economic system.

As biologist Garrett Hardin pointed out, the sea is a "commons," analogous to a communal pasture open to all. [205] From the point of view of an individual herder exploiting such a pasture commons, there seems to be every reason to keep adding to his herd; although the grass is limited, he will get a larger share if he has a larger herd. If his animals do not eat the grass, someone else's will. Such reasoning, of course, is followed by each user of the commons. Individuals struggle to increase their herds until, at some point, the carrying capacity of the pasture is exceeded and it is destroyed by overgrazing.

Similarly, in the sea each individual, company, or country exploiting a whale or fish stock (equivalent to the grass of the pasture) strives to get a maximum share of the catch because each increment represents further immediate profit. Unless some strict agreement can be reached about how the fishery is to be used, maximum exploitation seems to be the best short-range strategy from the point of view of each user. After all, reason the Japanese, if we don't get the whales or the fish, the Russians will. The Russians take a similar view, as do the Norwegians, South Africans, and all the others. Unhappily, the end result of all these individual optimum strategies for dealing with the commons is disaster for all.

The whale story also illustrates the impotence of scientific advisory bodies in the face of entrenched economic interests -- at least until public opinion is rallied on the side of the scientists. Sadly, it provides an example, too, of the willingness of many "captive" scientists to provide answers that suit the interest of their governmental or industrial employers. The Japanese scientists who essentially invented estimates of the stocks of blue whales in the Antarctic [206] provide an extreme example of this kind of behavior.

Box 7-4 International Regulation of Whaling: A Case History

After World War II, the 17 countries interested in whaling established the International Whaling Commission (IWC). This commission was charged with regulating the annual harvest, setting limits to the catch, and protecting whale species from extinction. In theory, commissioners from the various nations were to be responsible for ensuring the compliance of their nation's whalers with IWC decisions, but in fact their powers of inspection and enforcement were nonexistent. Instead of setting quotas on individual whale species, the IWC unfortunately established quotas on the basis of "blue-whale units." A blue-whale unit (bwu) is one blue whale or the equivalent in other species: two fin whales, two-and-a-half humpback whales, or six sei whales. Basing harvests on such units, of course, was ecological insanity. By making the mistake of lumping population units that was discussed in Chapter 4, the IWC guaranteed that disaster would occur. No rational conservation of stocks would be possible under such a system. The nations engaged in whaling in the Antarctic fishery were allowed a combined quota of 16,000 blue-whale units. Since the blue whales were the largest, they were the most sought after. Up until about 1950, blues continued to be taken, but their numbers declined sharply, which meant that the next largest, the fin whales, were hunted more vigorously.

In 1960 the Commission appointed a committee of biologists to investigate the stocks of Antarctic whales. Catches of blues and fins continued to decrease in the interval between establishment of the committee in 1960 and its report in 1963. The report detailed the overexploitation of the fisheries and warned that blues and humpbacks were in serious danger of extinction. It recommended that blues and humpbacks be totally protected and that the take of fins be strictly limited. It also urged abandonment of the system of blue whale units in favor of limits on individual species.

The committee also made some predictions. Their report stated that if unrestricted whaling continued in 1963-1964, no more than 8500 blue-whale units would be taken, and that 14,000 fins would be killed. Predictably, the warnings were ignored, and the limits were set at 10,000 bwu. The whalers killed 8429 bwu that season, and 13,870 fins were taken: the biologists' predictions proved uncannily accurate. An ominous note in these figures is that the catch of fin whales was about 35 percent of the estimated total population -- probably three times the estimated *sustainable* yield.

When the results for 1963-64 were in, the biologists recommended a bwu total of 4000 for 1964-65, of 3000 bwu in 1965-66, and of 2000 bwu in 1966-67, in order to allow for recovery of the whale stocks. Again their advice was ignored. All four countries then engaged in Antarctic whaling -- Japan, the Netherlands, Norway, and Russia -- voted against accepting the recommendation, and instead agreed only to limit the 1964-65 season's catch to 8000 bwu, double the recommended number of units.

What happened in 1964-65? Only 7052 blue whale units were taken, well short of the 8000 quota. Furthermore, only 7308 fins were taken, and the majority of the remaining bwu consisted of almost 20,000 seis, well over a third of the total estimated population of that species. In both 1963-64 and 1964-65 the total Antarctic catch of whales was less than that from other areas of the world -- an unprecedented situation. Meanwhile, the Netherlands had given up whaling and sold her fleet to Japan.

In an emergency session in May of 1965, the IWC decided to limit the 1965-66 catch to 4500 bwu, which again exceeded the biologists' recommendation. The IWC also tried unsuccessfully to give the now heavily fished sperm whales some protection. The whaling industry did not catch the 4500-bwu limit in 1965-66; the total was only 4089 units, and sei whales made up the majority. Meanwhile, whaling stations in Peru and Chile (not members of the IWC) killed 449 more blue whales, which were already dangerously near extinction.

Subsequent attempts to reach agreements to limit the take of fin, sei, and sperm whales in Antarctic and other waters failed. In 1966-67 there were four Japanese, two Norwegian, and three Russian antarctic whaling expeditions; the take was 3511 bwu (4 blues, 2893 fins, and 12,893 seis). Outside the Antarctic, seven factory ships and 24 land stations processed 29,536 whales, many of them sperms. In the calendar year 1967 a grand total of 52,046 whales were slaughtered, 25,911 of them sperm whales. In addition, Japan, hungry for protein, killed 20,000 porpoises. In

1968 Norway was forced out of the Antarctic whaling industry, leaving that field to Japan and Russia.

In 1968 the IWC failed to implement the International Observer Scheme that had been informally discussed in 1967. The scheme would have placed observers from other nations on whaling vessels to ensure that protected species or size classes were not harvested. In 1969 the Scientific Committee of the IWC again recommended the abolition of the pernicious blue whale unit system, but the IWC did not comply. In 1970 a small step forward was made when, although the bwu was retained for the Antarctic harvest, individual species limits were set for fin and sei whales in the North Pacific.

In 1972 the 24th meeting of the IWC met in a dramatically changed international atmosphere. In June 1972 the United Nations Conference on the Human Environment, held in Stockholm, Sweden, just two weeks before, had come out in favor of a ten-year moratorium on the commercial killing of whales; 53 nations had voted in favor of the moratorium, three had

abstained, and none had opposed it. The supporters of the moratorium contended that it was necessary both to permit endangered stocks to begin recovering and to allow time for research to establish a basis for harvesting without depleting stocks after the moratorium.

Not unexpectedly for a child of the whaling industry, the IWC rejected the moratorium, claiming that "regulation by species and stocks was the only practical method of whale conservation." International pressure did, however, result in both the abandonment of the bwu and the implementation of the Observer Scheme. The latter, of course, led to the Japanese observing the Russians and vice-versa, rather like the fox and the coyote taking turns guarding the henhouse!

Pressure from conservation groups changed a number of IWC votes on the moratorium issue. It passed by a simple majority in the Scientific Committee, but fell short of the three-fourths majority required in the IWC Plenary Session. (There was, of course, no guarantee that either the Soviets or the Japanese would abide by the decision if a moratorium were voted; the IWC has no enforcement powers.)

In 1974 a watered-down version of the moratorium, called the New Management Procedure (NMP), was adopted by the Commission. It became effective in 1975 and automatically places on the protected list any population that the Scientific Committee considers to be below the population size providing an optimum sustainable yield (OSY), which in essence is the maximum sustainable yield (see Chapter 4) adjusted for economic, ecological, and sociopolitical factors. Thus, from 1976 on, the fin and blue whales should be totally protected, as should certain sei stocks. [*]

Two other categories were also established: "Initial Management Stocks," populations that can be reduced to the size providing optimum sustainable yields; and "Sustained Management Stocks," which are thought to be at about optimum size. If a stock drops significantly (about 10 percent) below OSY, it becomes protected.

It remains to be seen whether and how well the NMP will be observed, but there were some encouraging signs in 1975. The 1975 kill quotas were set about 20 percent below those of 1974 and included areas and shore stations not previously regulated. Rumors circulated that both Japan and the USSR had reduced their whaling fleets.

In addition to the tightening of IWC regulations, several nations have acted independently to discourage whaling. The U.S. government has put eight whale species on the Department of Interior's endangered species list, banned whaling by American companies or by foreign ships using American ports, and passed a law allowing economic pressure to be brought against another country that violates good fishery-management practice. The U.S. also no longer permits importation of whale products. Canada too has ended its whaling activities.

Ultimately the results of the ongoing Law of the Sea Conferences may determine the fate of the whales, but what the outcome will be is not yet clear. Several nations have extended their coastal territorial zones to a width of 200 miles, including the United States. If this becomes universal, over half the whale populations would be subject to protection by individual nations.

*The basic source of the post- 1967 chronology is the Friends of the Earth, *Whale campaign manual*; post-1974 information is from V. B. Scheffer, *The status of whales*.

But in whaling controversies (or nuclear-power or pesticide controversies), the opinions of scientists employed by the special interests involved can be relatively easily detected and disregarded. More threatening and less understandable are those independent workers who, often on the basis of faulty assumptions or misinformation, give aid and comfort to exploiters. For instance, in 1972 marine biologist Ray Gambell argued against a whaling moratorium, basically on the grounds that maximum sustainable yields (MSY) and sustainable yields (SYs) for whale stocks could be accurately estimated. [207] But, as was explained earlier (Chapter 4), calculations of MSYs are based on certain assumptions about population units, density-dependent reproductive responses, lack of certain social structures, and genetic systems; assumptions that are likely not to be met by the whale populations. Gambell's discussion also was based on MSY in numbers rather than in weight, even though the latter would be more compatible with the long-term interests of humanity, the whales, *and* the industry (*if* the industry had any long-term interests). [208] Unfortunately, harvesting to maximize the weight of the catch would require stringent immediate conservation efforts to build up the population if it were to achieve beneficial results over the long term.

Only two major whaling nations remained by the 1970s: Japan and the USSR. The Soviets are less open than the Japanese about their intentions -- although they seem to be in business on the same exploitative basis -and have not done much to defend their whaling activities. The Japanese, on the other hand, have been very active in justifying theirs. One claim is that whales are not really endangered, which defies all the evidence available. [209] A more prudent position would be to assume the worst rather than risk the irreversibility of extermination.

A second argument has been that most of the damage to whale stocks was done early in the game by Westerners, and it is therefore unfair to campaign against Japanese cruelty. Needless to say, the Japanese have no monopoly on cruelty or stupidity, and many nations have withdrawn from whaling on economic, *not* on compassionate grounds. But the Japanese whaling industry is nonetheless one of the two remaining major forces pushing the whales toward the brink of extinction today, and therefore it must be a target of those who are trying to save the whales.

A third argument is that the Japanese need the food. In the long run they might well need it, but at the moment whales supply only 0.8 percent of Japanese protein, and the consumption is decreasing. [210] Furthermore, the sperm whale accounts for some 40 percent by weight of the total catch now, and its meat is not suitable for human consumption. [211] If the Japanese whaling industry were truly concerned about the future diets of the Japanese people, it would be clamoring for a moratorium on whaling until stocks were built up to a verified MSY in weight.

There is no question that what progress has been made in retarding the all-out destruction of the whales has been achieved through aroused public pressure. The first reaction of the whaling interests seemed to be astonishment that anyone cared about the whales. But the technological age, which has provided more efficient means of exterminating whales, has also allowed

scientists to study them. Their recordings and films in turn acquainted the public with the whale's extraordinary qualities. Why biologists-and poets-oppose unrestricted whaling was beautifully expressed by Victor Scheffer:

Whales have become newly symbolic of real values in a world environment of which man is newly aware. They have become symbolic of life itself. I believe that we ought to stop killing them unless for human survival only, and then humanely. I see no need to extend this protective ethic to rabbits, or chickens, or fish. Whales are different. They live in families, they play in the moonlight, they talk to one another, and they care for one another in distress. They are awesome and mysterious. In their cold, wet, and forbid-

ding world they are complete and successful. They deserve to be saved, not as potential meatballs but as a source of encouragement to mankind. [212]

Overexploitation by Technology

The race to loot the sea of its protein is now in full swing. Japan, China, and the USSR took the lion's share of the world's fish catch in 1973, jointly landing over 40 percent of the total. Norway, the United States, and Peru came next, landing some 12 percent among them. [213] The remaining 48 percent of the seafood harvest went to all the other nations. Despite their relatively great need for cheap protein, less developed countries obtained only one-third of the catch.

Technological advances similar to those of the whaling industry are also being applied to other major fisheries around the world, even though many stocks are already overexploited and others evidently soon will be. Japan, the Soviet Union, and several eastern European nations have moved into big-time fishing with a vengeance. A single Rumanian factory ship equipped with

modern devices caught in one day in New Zealand waters as many tons of fish as the whole New Zealand fleet of some 1500 vessels (see Figure 7-28).

Simrad Echo, a Norwegian periodical published by a manufacturer of sonar fishing equipment, boasted in 1966 that industrialized herring fishing had come to the Shetland Islands, where 300 sonar-equipped Norwegian and Icelandic purse-seiners had landed undreamed-of quantities of herring. An editorial in the magazine queried, "Will the British fishing industry turn . . . to purse-seining as a means of reversing the decline in the herring catch?" Another quotation from the same magazine gives further insight: "What then are the Shetlands going to do in the immediate future? Are they going to join and gather the bonanza while the going is good--or are they going to continue drifting and if seining is found to have an adverse effect on the herring stocks find their catches dwindling?" The answer is now clear. In January

[212]Scheffer, *'The status of whales*.
[213]UN, *Statistical yearbook*, 1974.

1969, British newspapers announced that the country's east-coast herring industry had been wiped out. The purse-seiners took the immature herring that had escaped the British drifter's nets, which are of larger mesh, and the potential breeding stock was destroyed.

Other examples of overexploited stocks are east Asian and California sardines; [214] northwest Pacific and Atlantic salmon; [215] cod in many areas; menhaden; tuna in the Atlantic, Pacific, and Indian oceans; flatfish in the Bering Sea; plaice in the North Sea; halibut, hake, and haddock in the North Atlantic; and bottom fish in the western Pacific and eastern Atlantic oceans. Figure 7-29 shows the record of fish catches for three major overexploited fisheries in the North Atlantic. Figure 7-30 shows where and when depletion had occurred in overfished North Atlantic stocks by the late 1960s.

Some fish stocks, such as Pacific hake, South Atlantic herring, Yellow Sea bottom fish, anchovy off California, and clupeids in the Atlantic and Indian oceans, are as yet underexploited. It seems unlikely they will remain so for long, at least wherever they are not too mixed with other species or too dispersed for efficient fishing.

As more and more important fisheries have become depleted and yields have dropped, the pressures of competition have become more obvious. Soviet fishing boats have regularly made headlines by fishing close to both coasts of the United States and Canada. In American coastal waters (within 200 miles of the shore) in 1973, foreign fishing fleets (mainly Soviet and Japanese) caught more than 5 times as much seafood (3.6 million metric tons) as American fishermen did (635,000 metric tons). [216] One reason is that, except for the tuna fleet, American fishermen are still operating traditional, small fishing trawlers. In 1973, Japan sent 629 large trawlers, 23 enormous factory ships, and 60 support ships (for fueling the fishing fleet and carrying processed fishes back to Japan) to the Alaskan fishing grounds. Small wonder American fishermen are resentful. Efficient operations on that scale quickly drive small, independent fishermen out of business, especially once the fishery begins to be depleted.

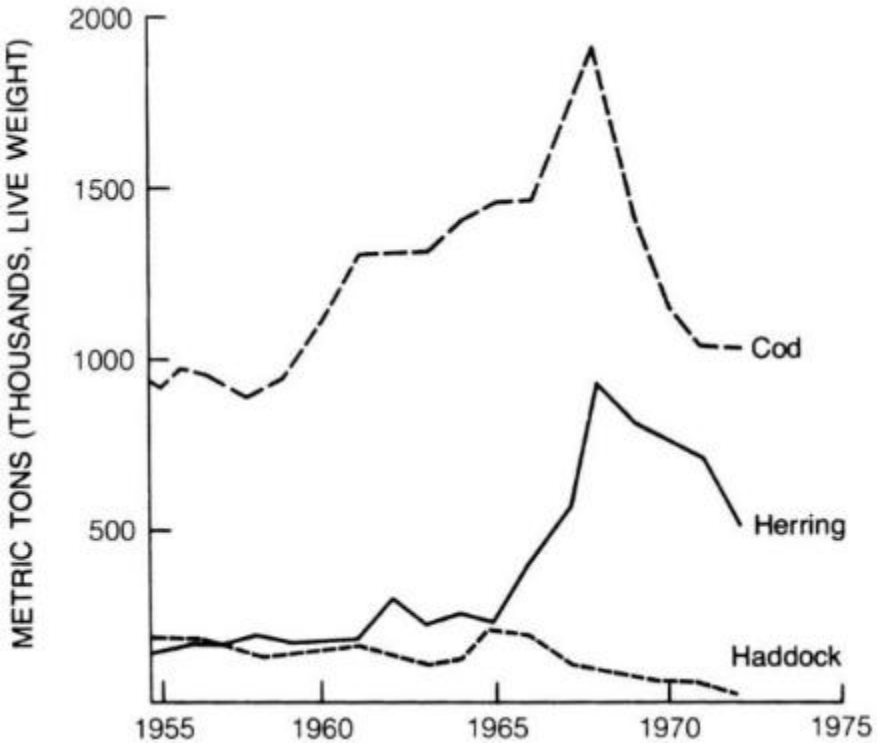

FIGURE 7-29 Annual catch of selected species in the northwest Atlantic, 1954-1972. (Adapted from Brown and Eckholm, By *bread alone*.)

In 1975, the U.S. Coast Guard seized 21 foreign vessels that were caught fishing inside the 12-mile territorial limit or had exceeded their negotiated quotas. Nearly $4 million in fines were collected and two vessels were confiscated. In early 1976, Congress passed a law extending U.S. jurisdiction over coastal waters to 200 miles, effective in March 1977. There is considerable alarm among American fisheries concerns over the state of diminishing fisheries. One government study indicated that, with proper management, 9 to 18 million metric tons of seafood a year might be harvested on a sustained basis from U.S. coastal waters. [217] But, even in the face of intensive effort, the total catch by both U.S. and foreign fishermen in 1973 was only 5.6 million metric tons. [218]

The competition for seafood resources is by no means limited to U.S. coastal waters. Between 1961 and 1971, the Peruvian government seized 30 United States tunafishing boats, and Ecuador had taken 70 others, in disagreements over the limits of territorial waters. For

FIGURE 7-30 Overfishing in the North Atlantic and adjacent waters began in the 1890s in the North Sea, when further increases in fishing the plaice stock no longer produced an increase in the catch of that fish. By 1950 the same was true of North Sea cod, haddock, and herring; of cod, haddock, and plaice off the North Cape and in the Barents Sea; of plaice, haddock, and cod south and east of Iceland; and of ocean perch and haddock in the Gulf of Maine. Between 1956 and 1966 the same became true of ocean perch off Newfoundland and off Labrador, and cod west of Greenland. It may also be true of North Cape ocean perch and Labrador cod. (From S. J. Holt, The food resources of the ocean, *Scientific American*, Sept 1969.

over a decade, Ecuador and Peru have claimed sovereignty over the ocean within 200 miles of their shores and have become increasingly tough in enforcing their claims. In 1975, the Ecuadorian government confiscated American tuna catches and even jailed the fishermen until their fines of $3 million were paid.

In the summer of 1973, Iceland and the United Kingdom seemed on the verge of war in their dispute over the North Atlantic cod fishery. [219] A settlement was negotiated, but proved to be short-lived; in late 1975 the argument flared up again. Iceland, heavily dependent on fishery exports for survival, in 1972 extended its territorial fishing jurisdiction to 50 miles from shore to protect the threatened cod fishery. In 1975, the limit was increased to 200 miles, and Iceland tried to persuade the United Kingdom to cut its codfish quota to barely half its 1974 catch. Meanwhile, Iceland had increased its fleet and begun fishing farther afield, including into North Sea herring. In December 1975, matters were so tense that Icelandic gunboats were patrolling; one was damaged in a collision, and a few weeks later it fired on a British ocean tug. [220] Ultimately, the U.K. agreed to a reduced codfish quota, and the dispute was settled--for the time being.

[220]*Time magazine*, The war for cod, December 29, 1975; *New Scientist*, Is the Cod War really a red herring?

Disputes can even arise within nations, it seems. In Cornwall, local day-fishermen, who still use poles and lines, have found their livelihoods threatened by large purse-seiners, which are wiping out the local mackerel population on which the day-fishermen depend. [221] Quotas were to be established from 1977 on, and the seiners were trying to push their 1975 and 1976 catches (on which quotas would be based) as high as possible. If the all-out fishing fails to destroy the stock, quotas set too high may later succeed. Judging from the fishing industry's past behavior toward the sea, one would suppose that if they were to go into the chicken-farming business, they would plan to eat up all the feed, all the eggs, all the chicks, and all the chickens simultaneously, while burning down the henhouses to keep themselves warm.

International fisheries management: too little too late? The list of fisheries conflicts keeps growing and will undoubtedly continue to do so until truly effective international regulation of the ocean commons becomes a reality. Just how and when this will be achieved cannot be predicted; it depends on the outcome of the Law of the Sea Conferences. (For more on these negotiations, see Chapter 15.)

Some progress has been made in that most major fishing nations now are aware that oceanic fisheries are endangered worldwide and that something must be done to protect these valuable resources if there is to be a significant harvest for future generations. There has been an increasing frequency of bilateral agreements between nations on fisheries management. A few regional international regulatory agencies have been established, such as the North West Atlantic and North East Atlantic fishery commissions (the latter has been involved in attempts to settle the Iceland-United Kingdom dispute, among others), and the General Fisheries Council for the Mediterranean. Although such commissions are gaining in strength, they still have no enforcement powers and must rely on individual nations to abide by decisions, agreements, and quotas. Like the United States, many nations have considered extending territorial limits to 200 miles, partly "in case" the Law of the Sea fails or is enacted too late to save major fish stocks, and partly to protect stocks already disappearing as other nations, not subscribing to regional commission regulations, "vacuum the sea."

As international regulation of fish resources becomes increasingly likely, the economic and national fishing interests have become more nervous and, evidently, more determined to get theirs while the getting is good. Japan, for instance, has figured that if all nations enforced 200-mile limits and excluded foreigners, Japanese fishing grounds (and yields) would be reduced by 45 percent. The jobs of half a million people employed in fishing (not including thousands employed in processing and canning) would be endangered, a major industry seriously damaged, and the diets of the Japanese people drastically changed. Even so, Japan has dropped its opposition to the 200-mile economic-zone policy (it is a major plank in Law of the Sea discussions and seems likely to be included), and apparently has resigned itself that international management of fish resources will be an inescapable part of the future. [222] But there has been no

abatement of Japanese fishing activities so far. Once agreements are concluded and regulations established, Japan will probably be first in line applying for a large share of quotas and rights to fish in other nation's territories.

Aquaculture

What about "farming" the sea? Unfortunately, the impression that sea farming is here today or is just around the corner is illusory. For the most part, people still hunt the sea today or, in a relatively few cases, herd its animals (for example, oysters and a few kinds of fishes are herded). Indeed, the total annual world production from aquaculture of all kinds (salt, fresh, and brackish water) in the early 1970s was only about 5 million metric tons. This, however, amounted to half of all inland fisheries production. Moreover, the harvest from aquaculture supplies a substantial proportion of the fish and shellfish consumed in some nations--roughly 40 percent in China, 20 percent in Indonesia, and 6 percent in Japan. [223]

[222] Washington Post Service, Japanese fishermen fear "nightmare," *Honolulu Advertiser*, March 19, 1976.

[223] T. V. R. Pillay, *The role of aquaculture in fishery development and management*; FAO, *State of food and agriculture*, 1974.

Fish culture is a long-established practice in the Far East, where it is commonly integrated into the agricultural system in a closed-cycle resource chain. Farmers stock flooded rice fields with small fishes, whose wastes help fertilize the rice. The fishes feed on mosquito larvae and other aquatic pests, reducing the need for pesticides. When the fields are drained, fishes and rice are harvested together, and some of the fishes are saved for restocking in the next rice season. [224]

Not all present schemes for fish-farming are so frugal with nutrient resources, however. Fish have been raised in enclosures in the Po River estuary of Italy since Roman times, but today those fish are fed Peruvian anchovetas. [225] Similarly, many of the expanding aquacultural operations in the United States have concentrated on producing luxury seafoods such as lobster, shrimp, catfish, and salmon, largely by feeding them cheaper foods. Some of the fish farms and hatcheries run by American agribusiness corporations are located in poor Latin American countries, but the products are marketed in the United States. [226] This obviously contributes nothing to the food needs of those countries (although it may provide jobs and foreign exchange).

Not all American fish-farming attempts require extra resource inputs to support them, however. One small company in Chicago raises fishes in tanks on vegetableproduce wastes obtained from supermarkets; some others more nearly parallel the integrated systems of Asia, combining crops, bacteria, algae, and fish. [227]

Marine biologist John Ryther at Woods Hole Marine Laboratory has been experimenting with a project raising clams and mussels on algae grown on sewage sludge. Effluents from the shellfish

also nourish sea worms and a sea plant called Irish moss. The sea worms are fed to flounder in separate tanks, and the Irish moss supports a colony of abalone. The cleaned-up municipal water can also be used again. [228] Similar experiments producing carp have also been carried out in Britain and some European countries with considerable success. [229] Such projects do present problems, of course: notably the possible transmission of diseases from the sewage to consumers of the shellfish, and the potential build-up of heavy metals from municipal wastes in the food chain (see Chapters 10 and 11); but these problems appear to be surmountable. [230]

Fish-farming may within a few years make a significant contribution to American diets. People in the business anticipate that the share from fish-farms of total U.S. seafood consumption may rise from 5 percent in 1974 to 15 percent in 1982. [231]

A more important question about aquaculture is whether and how much it potentially could enrich the scanty diets of the world's poor people. The answer depends on how effectively aquacultural technology can be introduced and utilized by the farmers, whether suitable water areas can be opened up without conflicting with land agriculture for resources (fertilizer, energy, etc.), and whether sufficient funds can be found for research and development. There is no question that, if established, aquaculture could produce high-quality protein at little cost for local consumption in many poor countries.

In Asia, where pond or rice-paddy fish-culture is part of tradition, expanding operations should be fairly easy if farmers are encouraged and provided with fry for stocking and markets for the fish produced. Indeed, pond-culture is now very widespread in China and is quickly becoming so in the Philippines, South Korea, and Indonesia. In Africa and Latin America, where no such tradition exists and the fishes themselves, as well as the technology, are unfamiliar, establishment of aquaculture may be somewhat more difficult.

But the potential exists, especially in regions where there are lakes, marshes, and ponds, all of which are naturally productive sites biologically. Fish-ponding can be carried on in combination with raising ducks or rice and other crops. (Of course, increased use of pesticides on crops may threaten such enterprises, although the fishes can contribute to pest control.) In Asia, duck- or livestock-fertilized ponds yield up to 2000 or 2500

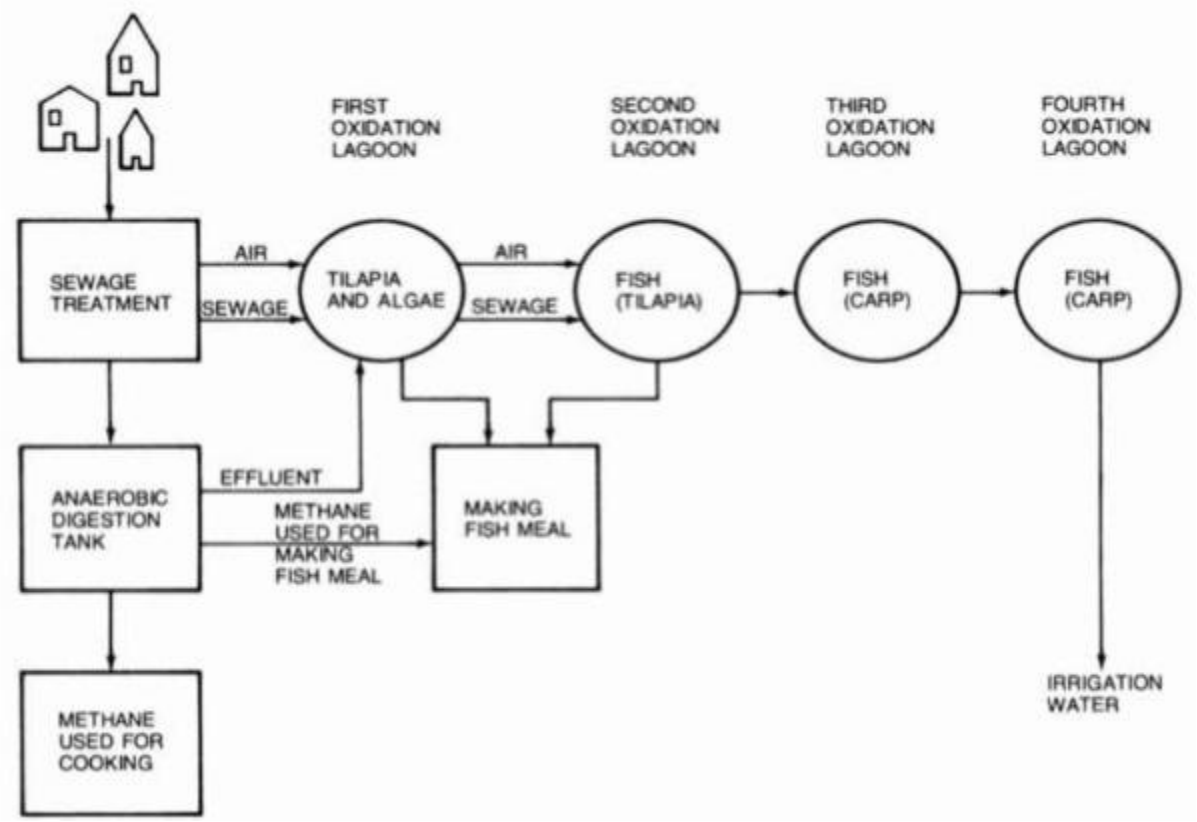

FIGURE 7-31 Fish culture using recycled human wastes. Supplementary feed is often the largest single operating expense in fish farming. Using sewage effluents avoids this cost and helps solve a sanitary problem as well. In this arrangement, air and treated sewage effluent pass through two oxidation lagoons where tilapia (or other rough fish) are grown. Such fish grow and reproduce rapidly and are harvested at a maximum sustained yield. Some of the tilapia is made into fish meal, using methane gas produced by anaerobic digestion of the sewage. The cleaner water passing through the third and fourth lagoons supports carp. After that it is used for irrigation. In an agricultural setting livestock wastes could be added to the effluent, and some of both the human and livestock effluents could be used to fertilize the land. (After *Ceres*, Food and Agriculture Organization, vol. 8, no. 3 (May/June 1975), p. 67.)

kilograms of fishes per hectare of water surface per year. (By contrast, the same land before flooding produced 11 kilograms of beef per hectare per year. [232]) Such projects generally use tilapia (mouth-breeding cichlid fishes) or carp. Figure 7-31 diagrams a fairly elaborate closed-cycle fish-culture scheme for raising both tilapia and carp by using sewage as fertilizer and producing methane gas as a by-product.

In 1967, the President's Science Advisory Committee postulated that a yield of some 15 million tons from pond-culture alone was possible by the year 2000. [233]

More recent estimates by the FAO indicate that yields from all inland waters, including at least half from aquaculture, may reach 17 million metric tons by 1980, and that (if the necessary research and development are carried out, and increasing pollution does not defeat the effort) inland fisheries production worldwide could rise to 50 million metric tons by the end of the

century. This would be a fairly impressive achievement, even though such a harvest would remain trivial compared to total world food needs (which by 2000 may include more than 2 billion metric tons of grain annually). Its value primarily would be as a source of crucially needed high-quality protein in many less developed regions. Again, it must be emphasized that this can be achieved

[232]H. L. Morales, *The Blue Revolution*; Ian Payne, *Tilapia: A fish of culture*.
[233]PSAC, *The world food problem*, vol. 2.

only if the requisite investments in research, development, and rural assistance to LDCs materialize.

Besides freshwater resources, brackish and saltwater lagoons and estuaries (also naturally abundantly productive) offer opportunities for aquaculture, although farming the open sea (mariculture) presents some formidable problems. The Japanese now "farm" the young of salmon, then release them to the ocean, from which they later return to spawn. [234] There are several "fishfarming" salmon projects in the United States, as well, but they are relatively new. [235] Expansion of such enterprises is possible, but may, like inland aquaculture, be limited by growing pollution of inshore waters, as well as by outright destruction of estuaries, drainage of swamps and marshes, and the like.

Apart from shellfish, crustaceans, and finfish, ocean waters produce aquatic plants, which are also potentially nutritious. These are not much exploited by the human population, except in Japan, where seaweed is cultured, sometimes in combination with fish-farming. Farming the seas' plant life would not be easy--just consider the difficulty of fertilizing and harvesting, for instance. Nonetheless, if the sea is emptied of its fishes and shellfishes by thoughtless human exploitation and pollution, perhaps some kind of phytoplankton (tiny marine plants) farming could be attempted (if the sea is not by then too badly poisoned by pollution). The crop would probably be relatively costly and not very tasty, but in desperation humanity might give it a try. For the immediate future, however, sea-farming of oceanic plants (unlike fish-culture) offers no hope at all of substantially affecting the world food problem.

Food from the Sea: The Outlook

The prospects of increasing the yield of food from the sea to support human life are decidedly not bright. Humanity apparently is very close to the limits of what can be harvested by methods now employed. Already, for example, in the North Sea "natural deaths are the exception among fishes of usable sizes." [236] Because of the predominance of the relatively sterile open ocean, the seas, which make up 70 percent of the planetary surface, account for only about a third of global net primary productivity (NPP). What potential there is for increasing the human food supply lies mainly on the 30 percent of Earth's surface that is land--where at least theoretical limits to productivity are somewhat more distant.

Indeed, far from being the answer to the food problem, the seas may not even be able to continue supporting the modest yield now being extracted from them. The setbacks of the early 1970s may have been the beginning of a long downward trend, even in the face of intensified fishing activity. Plans for increasing the yield from the sea generally have disregarded the effects of pollution on marine populations, especially those that are dependent on bays and estuaries for at least part of their life cycles. Unfortunately, even though some progress has been made toward protecting these ecosystems in developed countries, increasing use of farm chemicals (let alone growth of industrial effluents) in less developed countries by itself essentially guarantees a rise in oceanic pollution in coming decades. And the likely result will be reductions in the sizes of many fish populations.

Furthermore, expectations of higher fisheries yields have been based on the premise that fish stocks will be harvested rationally, but the history of fisheries so far gives little hope that rationality will prevail. Simultaneous attempts to harvest young and old of the same species, as well as both large species and the smaller species that the large ones eat to live, can be expected to continue, unless some kind of control can be imposed on the oceanic commons.

It is quite likely that the question of whether humanity will obtain a reasonable harvest from the sea and inland waters (equal to or better than that of 1971) at the end of this century will have been decided by the mid-1980s. Prompt establishment of a strong, effective Law of the Sea compact, or some other mechanism to protect oceanic and freshwater resources from environmental destruction and overexploitation, would allow humanity to continue enjoying their fruits. But if such cooperative management efforts are postponed into the 1980s, it may be too late--there may be precious little left to protect and conserve. And recovery, if it occurred at all, in many cases could take a very long time.

NEW AND UNCONVENTIONAL FOOD SOURCES

Efforts to increase food supplies for the growing human population in the next several decades will undoubtedly rest mainly on expanding supplies of traditional foods (albeit perhaps high-yielding versions) grown on presently cultivated land. There are nevertheless possibilities of enriching the diets of the poor or of making foodproduction systems more efficient by the use of unconventional foods. Such foods have sometimes been heralded in the popular press as "solutions" to the food problem, or at least as a means of filling the "protein gap." Such overstatements notwithstanding, some of these ideas (aquaculture, for example), if supported by research, development, and distribution, could make important contributions to human nutrition in some regions.

Protein Supplements

Some of the most unusual and most technologically sophisticated proposals have been in the realm of protein supplements. [237] Although totally "synthetic" food--a term occasionally still heard--has no reality (if it could be done, it would be far too costly in both money and energy to be useful), certain processed-food novelties do have potential as protein supplements.

Single-cell protein. Protein-rich material can be produced by culturing single-celled organisms on petroleum byproducts, sewage sludge, or other substrates. In theory, some of the protein deficit in LDCs could be made up with protein from such sources in the last two decades of this century. Knowledgeable people think it conceivable that such single-cell protein (SCP) could be made sufficiently pure for human consumption by 1980, although whether the purification costs would make it uneconomical is another question. [238]

Although it will be many years before SCP suitable for human food will be available, it already is beginning to make an indirect contribution as animal feed, especially in Europe and the USSR. It can, for instance, replace feeds such as corn, soybeans, and oilseed cakes, which alternatively can be fed to people. Obviously, SCP from petroleum hydrocarbons will be available only as long as supplies of petroleum last and are not prohibitively expensive. However, since the substrates usually are waste byproducts, SCP may have a role to fill temporarily, if all the technical, social, and economic problems can be worked out and if it can be produced without too great an energy subsidy.

Perhaps most difficult of all, people would have to be convinced that SCP is food. As has been mentioned before, people tend to be extremely conservative in their food habits. [239] The hungriest people are precisely those who recognize the fewest items as food because they have always existed on a diet of limited variety. Even though most Americans are used to an extremely varied diet, many would choose to starve to death rather than eat grasshoppers or snakes--which are perfectly nutritious, but are not generally acceptable as food in our culture.

A related project is the development of a protein supplement from algae grown especially for this purpose. A West German company is experimenting with a powder form that can be added to milk or other foods to raise protein content. It appears to have been beneficial in treating children with kwashiorkor and as a supplement for mothers on inadequate diets. It is expected that the product eventually can be made as cheaply as soy protein. [240] Unfortunately, the algal supplement suffers from many of the same drawbacks as SCP--particularly that of acceptability.

A high-quality protein and vitamin-rich concentrated food familiar to American health-food buffs is brewer's yeast, which also can be produced quite cheaply. However, it has not been seriously promoted as a food supplement, presumably because it is thought that the strong flavor might not be widely acceptable.

Perhaps the greatest disadvantages of these exotic proposals are that, because they involve fairly sophisticated manufacturing processes, they consume more

---

energy (non-solar) than raising crops, and they are relatively expensive. The people who need them most are the least able to afford them. In addition, these products must be transported and distributed to the consumers, unlike foods they could grow themselves or obtain locally. [241]

Producing SCP from agricultural wastes by new, simple techniques may be a more practical approach for less developed countries. The product is a concentrated feed-supplement for pigs and poultry, and could be produced at the village level with a minimal energy input. [242] Even so, it might be more useful and efficient to use agricultural wastes as compost and fertilizer instead.

Research comparing the efficiencies (measured by total food produced and its nutritional value relative to energy and other inputs) of such alternative strategies is badly needed, but so far little has been done. Part of the difficulty is that one approach might for various reasons be suitable for one area, but not for another. For example, the reasons could be physical (soil, climate, amount of rainfall, etc.) or economic or social (costs of fertilizer, availability of farm labor, local food habits, or social organization).

Water hyacinths, FPC, leaf protein, and other ideas. Still other unorthodox sources of protein supplementation have been proposed, some of which are under preliminary investigation. One of the more interesting is the idea of converting water hyacinths and other aquatic weeds to cattle feed. But, although water hyacinths are abundant in the tropics (and pestiferous--they clog waterways) and contain protein that is high in the essential amino acid lysine (commonly lacking in cereals), their dry weight is only 5 percent of their wet weight, which presents a tremendous obstacle even to processing them into cattle feed. An attempt to herd manatees (walruslike animals), which eat the hyacinths, has proven unsuccessful.

Much has been written about fish-protein concentrate (FPC) as a valuable protein source. [243] It may help, but it is no panacea. Its chief advantage is that it might exploit fish stocks that are largely unexploited at present; but the corollary disadvantage is that these often supply food for stocks that are being fished. FPC harvesting is subject to all the problems of fishing in general, and the processing is relatively complex and demands an expensive factory. It also seems to be more costly, at least at the present stage of development, than protein concentrates from other sources. Finally, the acceptability of FPC presents the same problems that exist for SCP and other novel foods.

Leaf-protein extracts also present the same social and economic drawbacks that affect SCP and FPC. A technical difficulty is the extraction of the protein concentrate from the fiber content of the leaves, but this has been done successfully in small-scale projects and presumably could be done on a wider scale if the appropriate equipment were available to farmers. [244] The leaves of forage crops such as alfalfa and sorghum produce large proportions of high-quality protein. Alfalfa yields as much as 2,400 pounds of protein per acre--more than twice as much as

soybeans. It has been estimated that, in an area equivalent to about 7 percent of all the land now under cultivation, enough alfalfa could be raised to provide the minimum protein needs of the world's population in 1970. The fibrous residue can be used as fodder for ruminant animals such as cattle, and the protein extract and other fractions can be fed to pigs and poultry, used as fertilizer, or made into a protein supplement for human consumption. Moreover, forages can be grown on soils too poor or hilly to support food grains. The advantages of leaf-protein appear to justify a reasonably large effort to develop it. But, even with substantial investment in research and development, it obviously will be many years before production can reach the point where it makes a significant contribution to the world food supply.

Still other ideas have been circulated, among which are making cattle-feed from wood and culturing algae in the fecal slime of sewage-treatment plants. The growing pressure for other needs on the world's forests (Chapter 6) makes the practicality of using them to feed cattle seem remote, to say the least. And the reaction of people in LDCs (or DCs for that matter) to proposals to feed them protein grown on sewage can well be imagined (although

[244]N. W. Pirie, *Leaf protein as human food*; Walter J. Bray, *Green crop fractionation*.

such algae would have some value as feed for livestock or fish-culture).

It is important, of course, to press ahead with the development of the most promising novel foods and to find ways of making them acceptable to diverse peoples. But it is reasonably clear that few of them will be major factors in the world food picture during the critical decade or two ahead. If the problems can be worked out, the most ecologically, economically, nutritionally, and aesthetically desirable of these processes eventually may be integrated into normal food supplies. Some may make their contributions indirectly as livestock feeds. Substituting SCP or leaf protein for foods acceptable to most people (such as soybeans and peanut meal) would release those foods for human consumption without reducing meat consumption by those who can afford it (and who seem less than eager to give it up).

New food combinations. The presscakes that remain after oil is squeezed out of soybeans, cottonseed, peanuts, and sesame seeds may be the most readily accessible, untapped source of protein for human consumption. Until recently, most presscakes were used as livestock feed or fertilizer; the rest were wasted. In DCs this situation is changing; as meat prices have risen, so have demand for and acceptance of soy products among consumers. [245]

Special foods have been created from conventional ones in some less developed countries by combining oilseed protein concentrates with cereals and sometimes with milk. The best known of these is Incaparina, developed by INCAP (Institute of Nutrition for Central America and Panama). It is a mixture of corn and cottonseed meal, enriched with vitamins A and B. Another

product is CSM formula (corn, soya, milk), a mixture of 70 percent processed corn, 25 percent soyprotein concentrate, and 5 percent milk solids. A third is Vita-Soy, a high-protein soy-based beverage that has been marketed very successfully in Hong Kong. Another product using peanut meal and soy is being distributed in India to children, and a bun fortified with milk solids has been given to schoolchildren in the Philippines. [246]

These and all similar products should be viewed more as future hopes than as current cures. As valuable protein and vitamin supplements, they hold considerable promise, but the economics of their production and distribution are not well worked out. In general, they seem best suited to urban areas, where distribution is less of a problem. They could be provided to children in schools and nurseries, for instance, and to pregnant and nursing mothers at health clinics. More important, the question of general acceptability remains open. Incaparina has been available in Central America for more than a decade, but its impact remains insignificant, in spite of determined efforts by private and commercial organizations to push its acceptance, and in spite of tremendous worldwide publicity. In 1973, the Quaker Oats Company gave up producing it. Other products seem to have been more successful, however, especially those in Asia.

A commonly wasted "by-product" of food processing is whey, [247] the residue from cheesemaking. In 1975, although some whey was being used as animal feed and was beginning to find other uses, a great deal of it was still discarded, to become a serious pollutant in rivers and streams. Within a few years, whey's usefulness as a protein, vitamin, and mineral supplement (in place of milk, for instance, in some products), as fertilizer, as a binding agent in pills, and as a livestock feed supplement, will probably end the pollution problems. There have even been successful attempts to make wine out of it! A product combining whey with soy milk is being tested in Latin America as a weaning food for babies. [248]

Increasing the Efficiency of Agriculture

Although novel foods may make at best a modest, and often only indirect, contribution to the human food budget in the next several decades, an avenue more likely to make a significant difference is that of improving the quality of traditional foods, while increasing their production. This approach minimizes acceptance problems and generally also involves the introduction of less elaborate and energy-consumptive new technologies.

[248]Brown and Eckholm, *By bread alone*.

Some of the more interesting agricultural research now underway is that being done on improvement of traditional staple crops. [249]

Crops: beyond HYVs. One of the goals of this research is to improve the protein quality of grains -- that is, produce grains containing a better balance of the amino acids essential for

human nutrition. This, of course, can be done fairly cheaply by enriching flour with processed amino acids (usually lysine, tryptophan, and methionine). Lysine-enriched wheat, for instance, has been shown to be beneficial both to laboratory rats and to human babies under carefully controlled conditions. Like other processed food supplements, however, such a solution may be of little use to the world's poorest and hungriest people, most of whom are subsistence farmers or farm laborers and purchase little or none of their food in markets. Even if they did, fortified grain or flour might be sufficiently more expensive than the ordinary kind to be out of their reach. [250]

An alternative to fortified grain is to breed new varieties with more complete protein balances or other desired characteristics. Increasing protein content or improving its quality in cereal strains can be achieved, but unfortunately such strains usually have higher energy and nitrogen requirements than those with standard protein content. Thus protein gains may be made at some cost in yield and/or significantly higher requirements for nitrogen fertilizer, either of which might make these strains economically unattractive to farmers. [250a] Such breeding programs in general take a good deal of time, but in the long run, successful ones may substantially contribute to the improvement of human diets. Some have already shown promise.

Using a naturally occurring mutant strain (known as Opaque-2 because the kernels are opaque), plant breeders have developed a strain of corn (maize) with digestible protein levels twice as high as those of ordinary corn and with adequate proportions of lysine and tryptophan. Opaque-2 corn has been shown to be nutritionally far superior in tests with farm animals and, subsequently, with malnourished Latin American children. But homozygous Opaque-2's softer, lighter kernels resulted in reduced yields, greater susceptibility to pests, and different milling characteristics. By interbreeding Opaque-2 with traditional strains, scientists at CIMMYT in Mexico have produced several new, improvedprotein strains suitable for various climatic conditions. These were being field-tested around the world by 1976, and most appeared to yield as well as or better than traditional strains, and to retain both the traditional milling traits and the high-quality protein. The last major hurdle, if performance continues to fulfill its early promise, is to distribute seed to the farmers and the harvested grain to those who need it. [251]

A similar program is in progress to improve the quality of sorghum, which is the fourth most important grain in human diets, widely consumed in Asia and Africa, especially by the poor. Two strains of high-protein sorghum have been found in Ethiopia and are now the basis of a breeding program to develop a pest-resistant, highyield variety. Such protein-improved corn, sorghum, and other cereals (if they are developed) no doubt can make important contributions to diet improvement among the poor, who subsist mainly on such foods.

Nutritionally speaking, though, one can question the wisdom of thereby encouraging large numbers of people to become even more dependent on a single food and further restricting the variety of foods eaten. Even if improved maize could be shown to provide an adequate supply of all known required nutrients (it does not), what of others that may exist, but are not yet discovered? And what if the local monoculture is wiped out by a drought or pest outbreak, as in the Irish potato famine?

Biologists are concerned about another possible pitfall to such improved crops. If they provide a nutritionally nearly complete food for people, they would also nourish pests very well. This is

certainly true for rodent pests. Not enough is known about insect nutrition to say whether this applies to them as well, but the possibility clearly exists (see Chapter 4). Such hazards, of course, can be dealt with or avoided, and the benefits of developing and disseminating these new grains may

[251]Tony Wolff, *Maize*; "Super grain" of the future?

outweigh them. But it nevertheless seems wiser to us to encourage more production of pulses and other foods to supplement a grain-based diet than to try to make grains into an all-purpose food.

One of the more interesting developments in agricultural research is the cross-breeding of wheat and rye to produce a completely new grain called *triticale*, which gives promise of incorporating the best characteristics of each parent species. Among these characteristics are: (from wheat) high yield and high protein content for a cereal, and (from rye) higher proportion of lysine, ruggedness, resistance to disease, and adaptability to unfavorable climates and soils. In some respects, triticale may even outperform both parents. For instance, some strains rival the miracle wheats in yields? [252] In the mid-1970s, triticale was still being field-tested, but it is likely that, if a stable, fertile seed is developed, it will be widely grown by 1985.

Research is proceeding on developing for grains a nitrogen-fixing capacity, like that in the roots of legumes. The hope is that, if the procedure is successful, the need for nitrogen-containing fertilizers would be greatly reduced and protein content of crops might be boosted. [253] Nitrogen fertilizer manufacture consumes very large amounts of fossil fuel; on the farm it is often the single largest element of energy input.

Some preliminary research in which corn has been innoculated with a nitrogen-fixing bacterium, *Spirillum lipoferum*, is underway, but it is too early to know whether this approach will be fruitful. [254] Preliminary research also indicates that some species of *Rhizobium*, the bacterial genus that fixes nitrogen in symbiotic association with legumes, may be transferable to nonleguminous crops. [255] Another possibility is to induce the nitrogen-fixing ability in the crops themselves by selective breeding or cell-culture manipulation. [256] Or presently inept microorganisms may be given genes for nitrogen fixation by such genetic-engineering techniques (see Chapter 14).

Cell-culturing also appears to be a means whereby botanists may produce new kinds of crops. Plants that cannot be cross-fertilized might be genetically combined or specific mutations introduced into a strain by cell culture. Desired genotypes also can be screened out in early stages and rapidly propagated by cloning -- a procedure now commonly used in research on several crops. [257]

Research on nitrogen fixation and most potential applications for cell-culture technique is still in the early stages, and results are not yet predictable. The possibilities are exciting, however, and the research efforts clearly deserve support and encouragement. The same can be said of attempts to increase the photosynthetic efficiency of crops, another line of investigation just getting underway. [258]

Most of these unorthodox lines of research on crops are unlikely to pay practical dividends before the end of the century, unfortunately, which is no comfort for the hungry millions of today. The exceptions are triticale and improved-protein corn, which are in relatively advanced stages of development. But the built-in momentum to population growth guarantees that the "food problem" will not go away; hence long-term development projects are every bit as essential as those projects that will help augment food supplies within a few years.

One of the most encouraging trends in agricultural research is a renewed interest in, and appreciation for, what could best be called "ecological agriculture." Organic farmers in the United States and parts of Europe -long regarded as a lunatic fringe by the agricultural establishment -- have stuck by this approach since the chemical age first reached the farm. Now agronomists are learning from their ideas and borrowing traditional, basically ecological techniques from peasants around the world.

Thus, the IRRI found a traditional "floating rice," crossed it with a dwarf, and created a high-yield floating rice that can survive productively in the frequent monsoon floods of India, Bangladesh, and Southeast Asia. [259]

[258]Israel Zelitch, *Improving the efficiency of photosynthesis*.
[259]Juan L. Mercado, *High-yield, floating rice may help countries where food shortages are greatest*.

And it has been discovered that paddy-rice yields can be enhanced by 50 to 100 percent when grown with a water fern (*Azolla*) that carries a symbiotic nitrogen-fixing alga (*Anabaena*). [260] How to maintain the fragile water fern during the summer was once a closely guarded secret in two North Vietnamese villages; now the secret is out, and all Southeast Asia may benefit from higher rice yields without dependence on imported fertilizers.

These are only examples of innovations that can bring improvement in food supplies with relatively small changes and little social disruption. Aquaculture is another example in areas where some kind of fishing is part of the tradition. So are the varieties of intercropping and

multiple-cropping that are being experimented with in many tropical and subtropical regions. The ecological approach produces less dramatically impressive increases than a switch from traditional to "miracle grains," but if widely adopted it could prove, when all the benefits are added up, to be a major contributor to future increases in the harvest. Indeed, as other chapters will explain, *failure* to adopt ecologically sound agricultural practices may foredoom other efforts to expand and maintain the food supply.

New sources of animal protein. Opportunities for making more efficient use of food resources also exist in animal husbandry, besides using animals that are productive on pasture and range and do not require feedgrains. It has been proposed, for example, that herding native antelope species in tropical Africa might prove more productive than herding cattle and would avoid several problems, especially that of the tsetse-borne cattle disease, *nagana*. The indigenous antelopes are naturally resistant to nagana, for instance, and they are welladapted to exploitation of the local vegetation, which is often inadequate for cattle.

A recent study in the Serengeti Plains described an ecological association among migrating wildebeests and Thomson's gazelles and the grasslands on which they feed. [261] The huge herd of wildebeest appears to devastate the forage as it passes through. But, in actuality, the grazing seems to prevent senescence of the plants and to stimulate rapid new growth and increased productivity. When the gazelles arrive at the beginning of the dry season, a month after the wildebeests' passage, they graze the luxuriant new growth in preference to the dried-out old grass missed by the wildebeests. Such natural systems, if they are studied and knowledgeably exploited, rather than destroyed by imposing agricultural systems developed in other settings, probably could be adapted to support large numbers of human beings.

Some early experiments with antelope herding have indicated that several species can be successfully tamed and that many of them are much more productive, especially in the dryer areas, than cattle are. In addition, their grazing (or browsing) seems to be far less environmentally damaging. The oryx, particularly, may prove to be a superior animal for such dry areas as the Sahel, where overgrazing around wellheads by cattle and goats contributed heavily to the recent six-year famine. Oryx can survive on about one-tenth as much water as cattle, and will eat plants that cattle will not eat. [262]

Another promising animal is the eland (which we can attest produces very tasty meat). Because it is a browser rather than a grazer, eland can be fed on the same pasture with cattle without competing for the same food resources. Thus a given area's productivity of meat could be increased by a considerable amount. [263]

Although herding native antelopes instead of cattle might substantially improve meat yields from African plains, it may be practical only where cattle herding is not already practiced. Many African herders base their culture on an extraordinarily intricate relationship with their cattle. Their economy, their social structure, indeed, their entire lives revolve around their animals. [264] These groups might not take kindly to antelope herding.

An interest in indigenous meat animals has led to efforts to domesticate the North American buffalo (bison). Unfortunately, the once vast herds were nearly destroyed in the last century -- a

classic case of overexploitation. Interbreeding buffalo with cattle has also been attempted, but with little success until recently. In the 1960s, a California rancher succeeded in producing a

fertile hybrid, which has been called *beefalo*. [265] Beefalo reportedly is very tasty and is leaner and more productive (faster-growing and requiring no grain feed) than beef, and the animals are hardier and easier to raise than cattle. If the public accepted it, beefalo could cause a minor revolution in American meat-eating habits and in the meat industry, with significant benefits to health, pocketbooks, and the world food situation. At the very least, beefalo could be an attractive alternative to beef, pork, and lamb.

Although the danger of losing genetic resources in crop plants has become fairly well recognized in recent years, little attention has been given to the same problem with domestic animals. There are numerous varieties of cattle, sheep, goats, and chickens that have become genetically adapted to different environments. But as with crops, modern (Western) animal husbandry tends to reduce stocks to one or two supposedly superior varieties. In the United States, for instance, the cattle industry is heavily based on Herefords and shorthorns for meat and Holsteins, Jerseys, and Guernseys for dairying.

In Britain, by contrast, there are some 60 varieties of sheep (the principal domestic animal). Many of these, even though domesticated, have in effect evolved for centuries in response to their local surroundings, including the climate, the soils, and especially the vegetation on which they feed. [266] Often a locally developed breed of sheep can be productive in a locale where introduction of other varieties has failed. Replacement of rare breeds with more conventional varieties may, especially in the harsher environments, create problems for farmers and even result in lower productivity.

Moreover, these indigenous varieties with their often special characteristics represent an invaluable pool of genetic variability for any future livestock-breeding programs. Their disappearance would be a permanent loss for humanity, like the loss of indigenous varieties of wheat, corn, or rice. And a large livestock monoculture, like a crop monoculture, has a built-in susceptibility to pests and disease epidemics.

In Britain there is now a movement to protect rare breeds of livestock. Elsewhere, although endangered wildlife is increasingly being protected, rare domestic breeds of animals are not. The United States seems to have few such breeds -- partly because it was settled relatively recently and only a few breeds quickly became established -- but it could join England in encouraging their preservation in long-established traditional societies. A given breed may seem to have no special value, but who knows when a change in climate, social customs, or the economics of

feeding might make a particular characteristic of an obscure sheep, alpaca, or cow suddenly very valuable indeed?

SHOULD WE BE PESSIMISTIC?

The world food situation during the mid- 1970s was very precarious, mainly because reserves were so low and harvests failed to meet "normal" expectations in many areas. The outlook for achieving greater food security by the 1980s is not particularly bright, despite unquestionably great potential for increasing food production worldwide. This potential is greatest in less developed countries, but the obstacles to realizing it there are also very great. Their rapid population growth simultaneously makes expanding the food supply imperative and hinders progress toward it. The rich countries have more than enough food, and their needs for more are growing relatively slowly; even so, their capacity for expanding production may be approaching limits.

As must be apparent by now, we tend not to share the enthusiasm of many for some of the proposed "solutions" to the world food problem. Serious constraints and difficulties lie in the path of even the most practical general solution, that of increasing yields on land already under cultivation. Recent efforts have concentrated on the food-short LDCS; but agricultural programs such as the Green Revolution have usually been carried out with too little consideration for either their ecological or their social consequences. This neglect may have manifested itself as a contributing factor in the slackening spread of Green Revolution technology and the faltering foodproduction record of the 1970s. Regardless of whether this is so, it is clear that continued neglect of these vital

---

[266]G. L. H. Alderson, *The value of rare breeds*.

factors could sooner or later effectively sabotage efforts to raise world food production.Despite the hazards and difficulties, there is of course no choice but to push on with the most feasible agricultural programs. Among other things, some badly needed time might be bought to start bringing the population explosion to a halt. It is certainly evident that no conceivable increase in the food supply can keep up with current population growth rates indefinitely. In 1967 the Report of the President's Science Advisory Committee's Panel on the *World Food Problem* stated: "The solution to the problem that will exist after about 1985*demands* that programs of population control be initiated now." [267] We emphatically agreed then, and the situation is even more urgent today.But population growth is by no means the only factor that will influence whether or not the human population's food needs can be met during the rest of this century and beyond. The food problem cannot be solved -- or even intelligently discussed -- without consideration of resource (water, energy, etc.) constraints, land-use and tenure policies, environmental constraints, economics, social and cultural settings, and so forth. (Many of these interrelated problems are described in other chapters.)For increasing food production, however, the key questions for the next decade or so seem to be:

Will the weather be favorable?
Can the Green Revolution begun in LDCs be expanded and converted into a real revolution in spite of the substantial problems associated with its achievement?
Will the ecological costs of the Green Revolution, especially the decay of genetic variability, prove too high?
Will environmental deterioration caused by overintensive farming, deforestation, overgrazing, and accelerated erosion nullify the positive impact of the Green Revolution by reducing yields in many areas?
Will the rich nations make a serious effort to help LDCs raise their food production?
Can international agreements for rational use of the sea be instituted before its food resources have been too far depleted?
Can a worldwide system of adequate food reserves be established and maintained?
Will all nations cooperate to establish and carry out a Global Food Strategy, as outlined at the Rome Food Conference in 1974?

The world food problem *can* be solved, but not easily. All the associated problems must be attacked simultaneously along with the task of producing more food. It will take a great deal of careful, committed effort in all nations and a considerable amount of luck as well. Obviously, the most prudent course is to work very hard for the best, but be prepared for the worst.

SECTION III
Energy and Materials

It seems clear that the first major penalty man will have to pay for his rapid consumption of the earth's nonrenewable resources will be that of having to live in a world where his thoughts and actions are ever more strongly limited, where social organization has become all pervasive, complex, and inflexible, and where the state completely dominates the actions of the individual.

-- Harrison Brown, 1954

The material prosperity of modern industrial society has been built largely on a one-time windfall of rich, accessible fuels and metallic ores. These resources were formed and concentrated by biological and geologic processes operating over thousands of millennia. The natural subsidy provided for human enterprises by this situation has now nearly been used up. The most accessible, most concentrated deposits of coal, oil, natural gas, copper, iron, chromium, and tin have been found and exploited. They have built the buildings, bridges, railroads, highways, communication networks, and machinery of the industrial world. The processes that formed the windfall continue, but at so slow a pace that 10 million years would hardly suffice to build up again what society has extracted in the past decade.

Yet society is not running out of energy or raw materials in any absolute sense. Nuclear fuels, geothermal heat, and the continuing energy income from the sun represent enormous energy sources--enough to run a civilization even more energy-hungry than today's for millions of years and more. The metals remaining in Earth's crust in less concentrated form than the deposits exploited until now represent staggering tonnages of material, and even the metals already mined are not really gone but rather, at worst, dispersed. The essence of the situation, then, is not that resources of energy and materials, in general, are near exhaustion; it is that the cheap and easy ones are nearly gone.

In Chapter 8 we examine in detail the patterns of human energy use and the technical, economic, and environmental characteristics of energy sources available now and likely to become available in the next few decades. From the welter of detail a few clear messages emerge: the energy sources to which society must now turn will be substantially more costly than oil and gas have been; no energy source,

old or new, is free of significant environmental liabilities; and using energy more efficiently can alleviate both the economic costs and the environmental risks that would be associated with continued rapid expansion of energy supply. The briefer review of patterns of materials supply and demand in Chapter 9 reveals many parallels with the energy situation and a similar prescription: whatever else is done, society must learn to use materials more efficiently in the future than it has in the past.

Some readers may wonder why we have chosen to devote quite so much attention to energy--Chapter 8 is the longest in the book. There are several reasons. First, energy has played a particularly fundamental role in shaping today's industrial economies, and virtually all published visions of the future of technological society are built around conceptions (or misconceptions) of

what future energy sources will be like. Second, the extraction, conversion, and application of energy have been dominant ingredients of industrial society's assaults on the environment; to understand the environmental impact of energy is to grasp much of the environmental predicament as a whole. Third, there is an enormous variety of approaches to supplying energy. Since one of the central energy problems facing contemporary policy-makers is choosing from this menu of alternatives the least undesirable combination of sources, a text with any pretension to practical application must provide some detail about all of them. Moreover, because energy probably has been the most-studied resource, there is a good deal of relevant information to summarize. Finally, the energy situation can be thought of as a precursor of predicaments with other resources in the future: Energy is the first of technological society's "wells" to be perceived worldwide as threatening to run dry. And both the symptoms of this situation and the responses to it contain lessons that will apply to resource problems to come.

Chapters 8 and 9 deal only peripherally with implications for policy, concentrating instead on the somewhat less controversial technical, economic, and environmental aspects of energy and materials. Our own conclusions about the appropriate directions for energy policy and materials policy are summarized in Chapter 14 and Chapter 15. It may be useful, however, for the reader to have certain policy-related concerns in mind from the beginning.

Consider, for example, the implications for policy of the imminent depletion of the energy and materials windfall--that is, the deposits for which the subsidy by natural processes of concentration is very large and the additional investment of effort by society needed to obtain the resource in usable form is small. What would a society that must operate with much leaner resources be like? What technological choices would minimize such a society's vulnerability to interruption of its flows of energy and materials? Are there choices that could minimize the impact of depletion of the windfall on the prospects of poor countries for achieving a modicum of prosperity?

One particularly important concern, expressed by Harrison Brown in the passage that begins this introduction, is that the depletion of the windfall will lead to a loss of human freedoms. This may indeed be so. The usual reason for expecting this

outcome is the supposition that government will have to impose tight restrictions on behavior in order to minimize inefficiency and waste. At least as threatening, however, are the centralization of authority and other constraints on human freedoms that might be associated with attempts to stave off scarcity by deploying complex, fragile, and unforgiving supply technologies. (Repressive measures that might be deemed necessary to protect electric power grids and nuclear fuel processing plants from sabotage come to mind.)

The last policy-related issue we will mention here is the desirability of diversity in energy and materials technologies. There is no single best energy source for all regions and all purposes or any way to obtain, say, fiber for clothing or construction material for buildings that is best in all circumstances. This would be true even if knowledge about society's needs and about the side effects of various ways to satisfy those needs were perfect: the mere fact of cultural and

environmental diversity implies that technological diversity will be necessary to ensure good fits. But knowledge is not perfect, either about the nature of needs, technologies, and environments today or about future changes in any of them. In the face of incomplete information, technological diversity performs an additional function: it is the best insurance policy a society can buy against the unpredictable and the unexpected. (This is, of course, one of the functions of diversity in nature as well, as discussed in Chapter 4.)

Society must expect to pay for such insurance, of course. Diversity is not free. Payment is made when government spends money for investigation and development of energy and materials technologies that private enterprise is unwilling to support and when industry or government deploys for commercial operation technologies that are more expensive than the apparently cheapest alternative of the moment. (Consider an example: For many years before 1973 the cheapest way to generate electricity in some parts of the United States was to burn oil. Building only oil-fired generating plants then because it was cheapest would have proven to be a costly mistake when the price of oil suddenly quadrupled in 1973.) It should also be remembered that the general desirability of diversity does not mean society must or should embrace *all* alternatives. Part of the usefulness of diversity is having the option of rejecting alternatives that are found to be completely unsuitable.

CHAPTER 8
Energy

No one is going to repeal the second law of thermodynamics, not even the Democrats.

-- Kenneth Boulding, 1970

Energy is the ultimate resource and, at the same time, the ultimate pollutant. The solar energy continuously intercepted by Earth drives the geophysical and ecological machinery that make the planet's surface habitable by human beings. The remarkable growth of the human population and the development of civilizations are attributable largely to the singular progress of our species in learning to harness natural flows and accumulations of energy and turn them to human ends. Human beings have learned to tame fire for warmth and light and protection; to organize (and later subsidize) photosynthesis as agriculture, thus allowing people to specialize and thereby promoting the growth of cities; to tap the energy of wind and running water for transportation and mechanical work; and to unlock the concentrated energy of coal and oil for extracting, concentrating, transporting, and applying the many other resources upon which society depends.

Yet, no means of harnessing energy--and no means of applying it--is completely free of adverse environmental

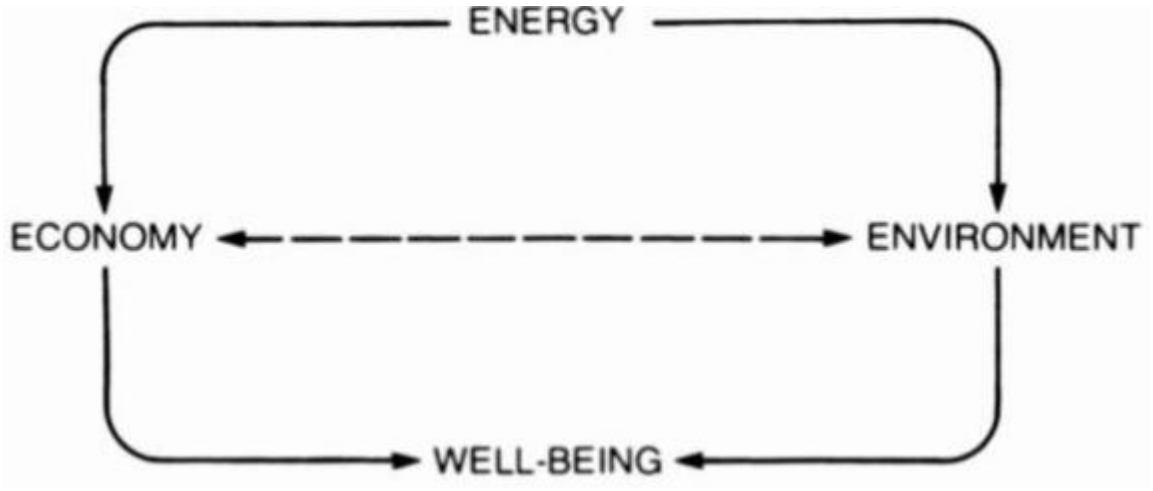

FIGURE 8-1
The relation between energy and well-being. Energy exerts its influences on well-being through the economy and through the environment. Energy's contribution to the production of goods and services in the economy exerts a largely positive effect on well-being. The adverse effects of the production and use of energy on the environment damage human health directly, as well as undermining environmental services that support the economy.

impacts. The impacts manifest themselves at all stages of energy-processing, from exploration to disposal of final wastes. Many of these impacts can be significantly controlled, at some expense in money and in energy itself. But, in consequence of the fundamental characteristics of energy and matter, reflected in the laws of thermodynamics (Box 2-3), the impact can never be averted entirely. All the energy people use ends up in the environment as heat; and energy, unlike other physical resources, cannot be recycled.

It is the dichotomy between energy's roles as ultimate resource and ultimate pollutant that generates the deepest of the several dilemmas that make up "the energy problem." Those two roles of energy--and the associated dilemmas--are represented schematically in Figure 8-1. The economy, which provides goods and services in support of human well-being, depends on energy and on raw materials supplied with the assistance of energy. But both the economy and the physical health of the population depend also on services provided by the nontechnological environment, and those services can be disrupted by the adverse effects of energy technology. In the expansion of any particular technology and in the expansion of civilization's energy use as a whole, a point must eventually be reached where the benefits to wellbeing of adding energy to the economic side of the relationship do not compensate for the damage to wellbeing caused by the environmental impact of making the extra energy available.

This conclusion leads directly to some crucial questions. Is it possible for modern economies to grow more rapidly (as measured by gross national product, GNP) than the energy supply grows? Or is it possible for them to grow at all if the rate of energy use is stationary or declining? Is it possible for human well-being to grow faster than GNP? If the links between energy and GNP and between GNP and well-being are as inflexible as many government officials and energy-industry spokespersons seem to believe, then the dilemma is sharp indeed: the economic imperative to expand energy use, driven in part by the legitimate needs of the poor, must

confront the environmental imperative to limit energy use. This could be a crushing--indeed, catastrophic-collision. If, on the other hand, there is flexibility in the links between energy and GNP and between GNP and well-being, then the dilemma can be softened by *learning to do more good with less energy*. This is a more promising prospect, for the poor and for everyone.

Whether the rate of energy use is growing, constant, or shrinking, the question of what technologies are used to provide energy is critical. What are the choices, now and in the future? Which technologies are limited by finite resource supplies to the status of being interim measures, and which can serve for the long term? What are the environmental and social characteristics of the various options?

In this chapter, we review past, present, and possible future patterns of energy use, we survey the availability of major energy resources, and we discuss the characteristics of the various technological means of harnessing these resources. The special "resource" of energy conservation-that is, using energy more efficiently--is also treated here. The perhaps more controversial social and economic elements of the energy situation--the price of energy and its relation to broader problems of economics and equity; the organization of the energy industries; the character and quality of government planning, spending, and regulation in the energy field; the international politics of energy--are taken up in Chapter 14 and Chapter 15.

TABLE 8-1
Approximate Energy in Selected Fuels and Processes

	Energy produced or used (MJ)
Energy to feed 1 person for 1 day	10
Nonfood energy use per person per day, world average	200
Nonfood energy use per person per day, U.S. average	1,000
1 tank of gasoline (15 gal.)	2,000
1 barrel of oil (42 gal.)	5,900
1 metric ton of coal	29,000
Boeing 707 flight, San Francisco-New York	1,400,000
1 kilogram uranium-235, completely fissioned	79,000,000
Summer thunderstorm	160,000,000
Fuel input to 1000-Megawatt power plant, 1 day	260,000,000
Hydrogen bomb (1 Megaton)	4,000,000,000
Total human nonfood energy use per day	800,000,000,000
Sunlight striking top of atmosphere, 1 day	15,000,000,000,000,000

Note: 1 megajoule (MJ) = 948.4 British thermal units (Btu) = 239.0 kilocalories (kcal) = 0.2778 kilowatt-hours (kwh).

SIZE AND SOURCES OF CONTEMPORARY ENERGY USE

World energy use in 1975 amounted to roughly 260 trillion megajoules (see Box 2-1 and Table 8-1, concerning units of measure), not including energy in food and in dung, in wood, and in agricultural wastes burned for cooking and heating. [1] The latter, largely untabulated sources may amount to two-thirds or more of energy use in the poorest LDCs; they would add perhaps 15 to 20 percent to the global total. [2] Of the tabulated energy use, 45 percent was supplied by petroleum, 32 percent by coal, 19 percent by natural gas, 2 percent by hydropower, and 2 percent by nuclear energy. Sources of the energy used in the United States differ from those world averages mainly in that the proportions of coal and natural gas are reversed. The dominance of the fossil fuels--more than 95 percent of the total for the world and for the United States--is overwhelming. Equally striking is a comparison of energy use in DCs and LDCs: the former, with about 32 percent of the population, account for 83 percent of the world's use of energy. [3]

Data on energy use per person and GNP per person in selected countries appear in Table 8-2. (More complete figures appear in Appendix 1.) Although such data often are placed on a graph with a straight line "fitted" through the middle to support the contention that energy consumption and prosperity are tightly linked, the facts do not justify this view. It is obvious that poor countries use only a little energy per person and rich countries a lot, but within a given prosperity bracket the correlation is very weak. (This is so even if one ignores the notorious unreliability of GNP as a measure of comparative prosperity among countries.) Sweden, for example, has a higher GNP per person than the United States, but only about half the energy consumption per person. New Zealand has just over half the energy consumption per person of the United Kingdom, but a larger GNP per person. These examples show that there is substantial flexibility in the link between energy and GNP-flexibility that could reward further study of just how countries like Sweden, Switzerland, and New Zealand get so much apparent prosperity from so comparatively little energy.

Energy resources are distributed unevenly in the world, and the pattern of this distribution does not match the pattern of consumption. The imbalance in energy use reflected in the "annual energy consumption" column of Table 8-2 thus can be maintained only through substantial international flows of energy resources. The percentage of the dependence on energy imports in each country listed appears in the right-hand column of the table. The largest part of the international energy flows is in the form of petroleum, whose global patterns of production,

consumption, and transportation are represented in Figure 8-2. Some of the international transactions in money and influence that accompany the energy flows are taken up in Chapter 15. It is enough to note here that for the industrialized minority to depend so heavily on energy resources not controlled by them is economically, politically, and even ethically precarious, for consumer and producer alike.

How is energy used in human society? The pattern of supply and use of energy in the United States in 1975 is shown in Figure 8-3. If we ascribe to each end use all of the primary energy that

had to be supplied to make the end use possible (including losses in any transformation and transportation steps leading to that end use), [4] we conclude: about 25 percent of energy used in the United States is burned as fuel in transportation, 21 percent is used in residences, 14 percent is used in commercial buildings and enterprises, and 40 percent is used for industrial and other uses. (Transportation includes passengers and freight, civilian and military; commercial uses include government and private offices, stores, hospitals, and educational institutions; industrial uses include agriculture as well as manufacturing and other industrial activities.) The end uses of energy are treated in more detail at the end of the chapter, where we discuss the potential for energy conservation.

One-fourth of the U.S. primary energy supply is converted to electricity before being distributed for end use. With the exception of the hydroelectric component, this electricity is presently produced via a series of transformations of the form: potential energy of fuel (chemical or nuclear) → thermal energy → mechanical energy → electricity. The overall efficiency of this process, defined as the ratio of the electrical energy produced to the potential energy extracted from the fuel, averages only about 33 percent. The other two-thirds of the energy extracted from the fuel is discharged to the environment as thermal energy of very low availability (that is, the temperature of this thermal discharge is only slightly higher than that of its surroundings). The electricity, for which so high a price in fuel has been paid, is itself very high-grade energy and generally pays back

[4]The term *primary energy* refers to the basic energy sources--such as fossil and nuclear fuels, sunlight, the energy of falling water--from which *secondary energy* forms such as electricity and synthetic fuels can be made. Losses refers to that part of the energy that becomes degraded to unused or unusable forms (generally heat) in the course of processing and application (refer to Box 2-2).

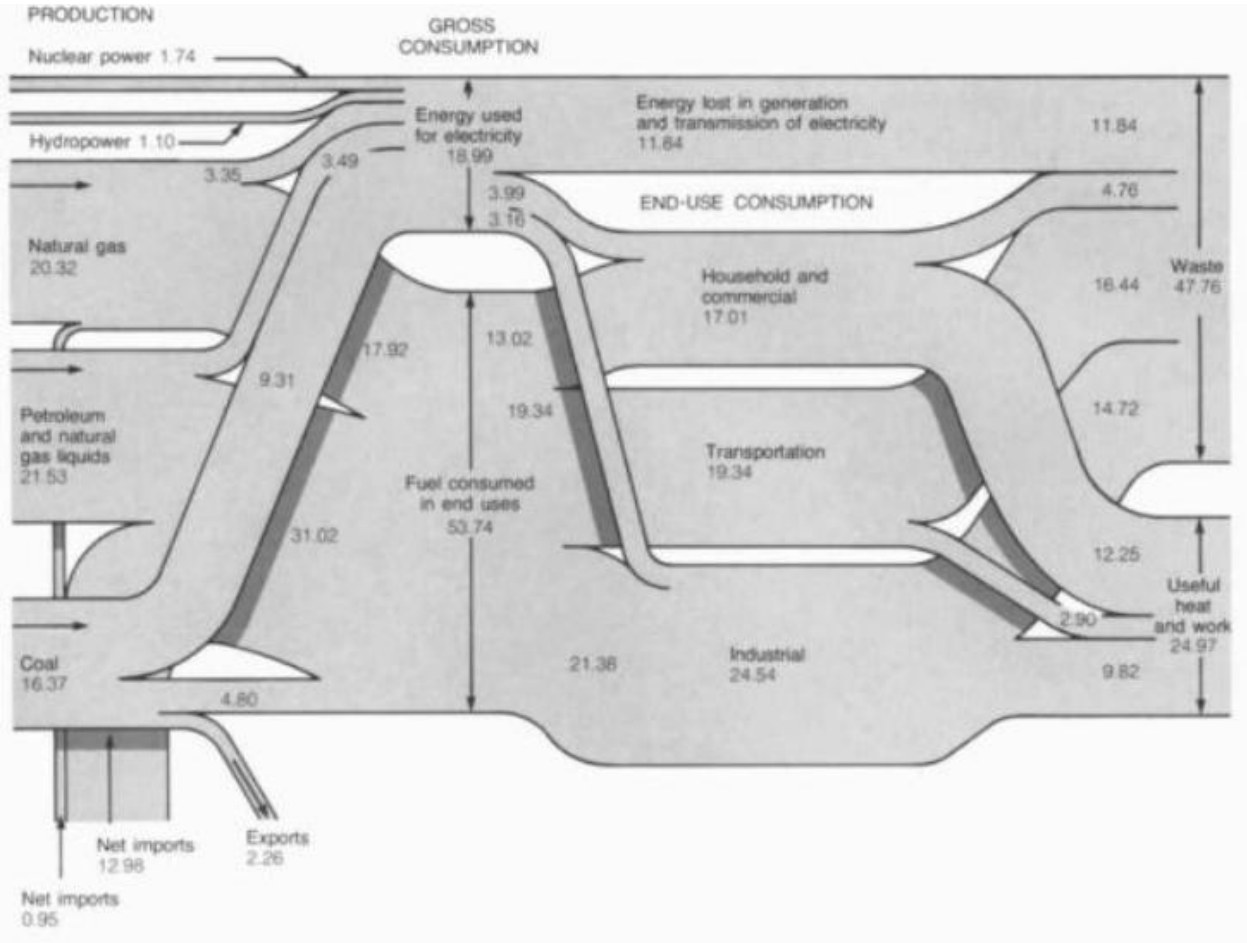

FIGURE 8-3
Energy flow in the U.S. economy, 1975. Food energy is excluded. All figures are in trillions of megajoules (1012 MJ = 1015 kJ = 0.95 × 1015 Btu). Hydropower is computed as 100-percent efficient. Changes in inventories (invariably relatively small) are lumped with net imports or exports. Industrial consumption includes nonfuel uses of energy resources (e.g., asphalt, petrochemicals). Efficiency figures used to disaggregate useful heat and work from waste are Cook's very rough estimates of first-law efficiency: household/commercial, 72 percent; transportation, 15 percent; industrial, 40 percent. Electric generation efficiency averages about 38 percent when hydro is included. (After Cook, 1976, updated using U.S. Bureau of Mines news release, 5 April 1976.)

some of the investment as high efficiency at the point of application. (The concept of efficiency is discussed further in Box 8-1.)

Energy use in the United States, as diagrammed in Figure 8-3, amounts to about a third of the world's total. The pattern in other DCs is similar to that in the United States, although typically a smaller fraction goes to transportation. In the Federal German Republic (West Germany), for example, transportation accounts for only about 15 percent of energy use; in Sweden, the figure is 16 percent. [5] Worldwide, about 25 percent of all primary energy used goes to generate electricity, as in the United States. Few reliable data are available on detailed patterns of energy consumption in LDCs. [6]

GROWTH AND CHANGE IN ENERGY FLOWS

Many of the most interesting and problematic aspects of the energy situation involve not merely the sizes that the energy flows within civilization have already attained, but the rates at which those flows are growing and the rates at which the patterns of supply behind them are changing. The growth of energy use in the United States between 1880 and 1975, broken down into the major

[6]But see Makhijani and Poole, *Energy*, for the best available information on the subject.

sources of supply, is shown in Figure 8-4. Note the decline in the importance of wood as a fuel, from 50 percent of the total supply in 1880 to perhaps 1 percent in 1975. Total U.S. energy use in 1975 was about 15 times what it was in 1880, with a U.S. population in 1975 that was 4.3 times what it was in 1880. Hence, energy use per person increased by a factor of 3.5 in that period. Thus we can say, as a crude first approximation, that population growth and energy use per person were about equally "responsible" for the increase in total energy use. The average annual rates of growth of energy use and population in the United States in different periods are indicated in Table 8-3.

In the global context, wood, dung, and agricultural

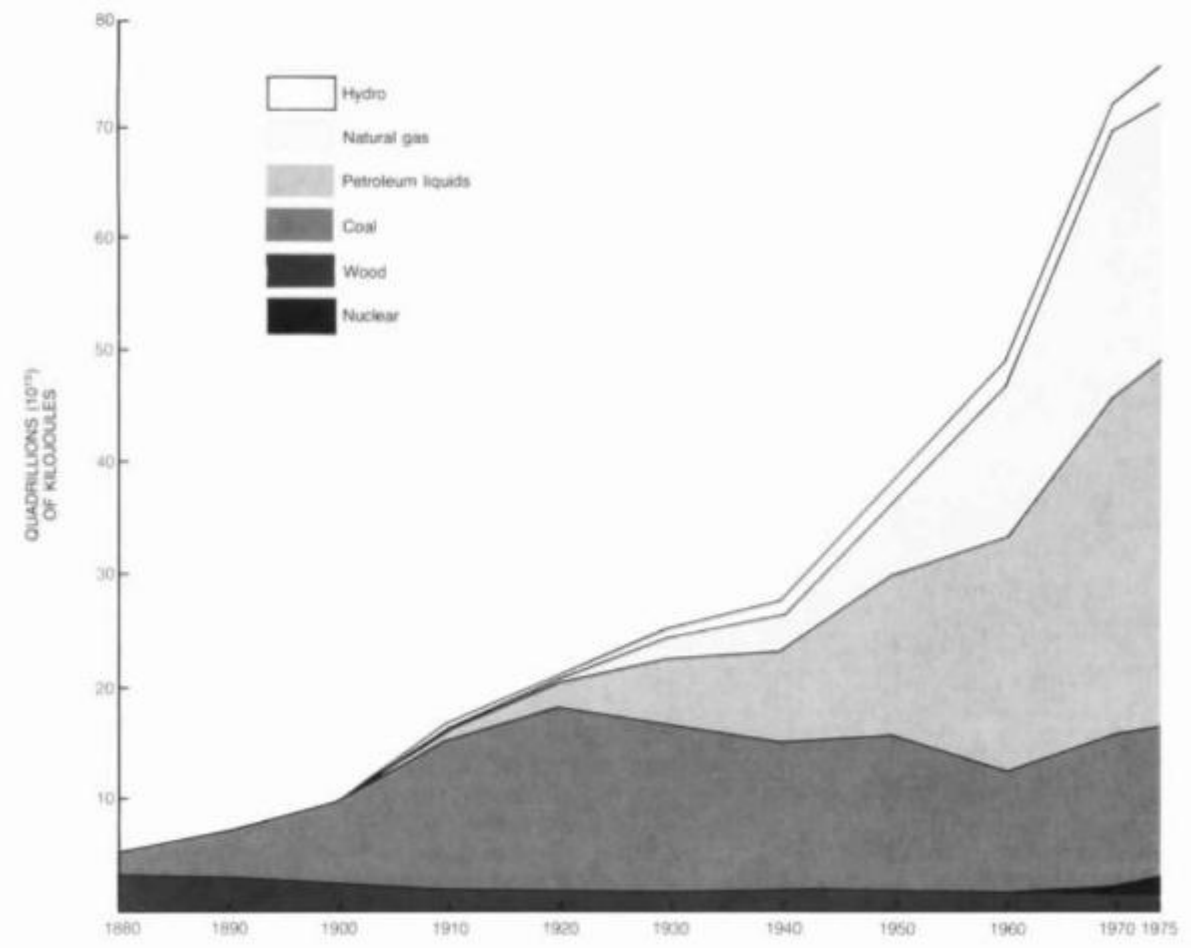

FIGURE 8-4 The evolution of energy use and sources of energy supply in the United States, 1880-1975. Note the continuing dominance of fossil fuels.

TABLE 8-3
Growth of Energy Use and Population in the United States

	Average annual rate of growth (%)		
	Population	***Energy use per person***	***Total energy***
1880-1910	2.0	1.8	3.8
1910-1929	1.5	1.1	2.6
1929-1932	0.8	-9.3	-8.6
1932-1945	0.9	3.8	4.7
1945-1965	1.7	1.2	2.5
1965-1975	1.0	2.0	3.0

Box 8-1 Efficiency

A definition of efficiency that is suitable for some purposes is:

efficiency = amount of energy delivered in the form and place desired / amount of energy that must be supplied to achieve the above.

This efficiency takes no explicit account of the thermodynamic quality of the energy supplied, only the quantity, so it is called the *first-law efficiency*. (Recall from Box 2-2 and Box 2-3 that the first law of thermodynamics helps analysts keep track of the quantity of energy, while the second law helps them keep track of the quality of energy as well -- that is, its availability for doing work.)

Applying the concept of first-law efficiency to the entire U.S. energy economy, Earl Cook has obtained the overall figure indicated on the right-hand side of Figure 8-3 (about 36 percent of the energy in the primary sources finally appears as useful heat and work). * The remaining 64 percent might be said to have been wasted, but that is an ambiguous term. Some of the energy was lost from the useful column because of imperfections in the energy technologies that were used, and some represented the toll that, according to the second law of thermodynamics, could not be avoided even by perfect technologies. The concept of first-law efficiency does not distinguish between these two kinds of waste.

It is therefore useful to define another kind of efficiency that measures *by how much* the performance of a device or process falls short of what is theoretically attainable. To do this, one must keep track not of energy per se (which, according to the first law, is not used up at all) but rather of the availability of energy to do work (which is the important thing and is used up). The desired measure, called *second-law efficiency*, is the ratio

minimum amount of available work needed to perform a desired function / actual amount of available work used to perform the function.

The term *available work* is coming into widespread use as shorthand for "availability of energy to do work," which, again, is the value used up in all physical processes. The available work in a chemical fuel is approximately equal to its so-called *heat-of-combustion*. The available work in an object of mass m suspended a height h above the ground is equal to its gravitational potential energy ($m \times g \times h$, where g is the acceleration of gravity). The available work in a quantity of heat Q at temperature T_1 in an environment of temperature T_0 is $Q \times (1T_0/T_1)$, where the temperatures must be relative to absolute zero. **

wastes have remained somewhat more important energy sources than in the United States, but have declined from supplying 50 percent of worldwide energy use in 1880 to 20 percent in 1960 and perhaps to 15 percent in 1975. The growth in total energy use worldwide averaged 2.6 percent per year from 1880 to 1950 and about 3.5 percent per year from 1950 to 1975. The growth of population climbed steadily from 0.6 percent annually to perhaps 1.5 percent in the first period and averaged almost 2 percent per year between 1950 and 1975. Thus, the global rate of growth of energy use per person has stayed roughly in the range of 1 percent to 1.5 percent per year for essentially a century. Growth of the use of fossil fuels, which have supported most of the increase in world energy consumption since 1900, has recently been much more rapid -- almost 5 percent per year between 1950 and 1972, compared to an average of 3.1 percent per year from

1880 to 1950. The per-capita growth rates in the use of fossil fuels during the spurt of growth since 1950 have ranged from 2.5 percent to more than 4 percent per year.

Many forecasts have projected enormous increases in U.S. and worldwide consumption of fossil and nuclear fuels over the next several decades, on the assumption that recent annual growth rates of 3 percent to 4 percent

---

*Earl Cook, *Man, energy, society*.

**The best detailed exposition of the concepts of available work and second-law efficiency is American Physical Society, *Efficient use of energy*, pt. 1, A physics perspective.

The difference between first-law efficiency and second-law efficiency is made clearer by an example. Consider the task of heating a house, with the desired indoor temperature being 20° C (68° F) and the outdoor temperature being 0° C (32° F). An ordinary furnace operating under these conditions might manage to deliver to the rooms of the house I unit of energy as heat for every 1.5 units of energy extracted from its fuel. Its first-law efficiency would then be

$$\frac{\text{1 unit of heat in the rooms}}{\text{1.5 units of energy supplied from fuel}} = 0.67 = 67 \text{ percent.}$$

.

Application of the second law of thermodynamics to the situation reveals that the minimum amount of available work required to deliver 1 unit of heat at 20° C to the inside of the house is only 0.07 units. (This is the amount of available work needed to operate the most efficient possible *heat pump* between the outside and inside temperatures specified, per unit of heat delivered. Heat pumps are further discussed later in this chapter.) Thus the second-law efficiency of the furnace in the application in question is

$$\frac{\text{0.07 units of available work (minimum needed to deliver 1 unit of heat)}}{\text{1.5 units of available work (heat of combustion of fuel actually used by furnace)}},$$

or about 4.7 percent.

Second-law efficiencies, we emphasize again, give a measure of how much improvement in performance is theoretically attainable (a low second-law efficiency means there is much potential for technological improvement). Widespread use of first-law efficiencies, which are

usually much higher, may have led to the erroneous belief that potential gains in the efficiency of energy uses are small. In 1974, when a study group of the American Physical Society investigated the second-law efficiencies of the U.S. energy system, the figures they obtained were: industrial processes, 25 percent; space heating and cooling, 6 percent; transportation, 10 percent; and electricity generation, 30 percent. [†]

Obviously, there is a good deal of theoretical potential for improving efficiency of energy use before thermodynamics calls a halt. It must be remembered, however, that energy usefully applied, as well as the energy "lost" in the process, eventually ends up in the environment as lowgrade heat. High efficiency reduces the total of that heat burden but cannot eliminate it.

per capita in the use of nonagricultural energy (rates we know are anomalous in historical terms) will be maintained. If such forecasts were accepted as descriptions of what the future should or must be like, there would be no choice but to embrace every available option for expanding energy supply -- and quickly, with little time to deliberate about environmental and social impacts. Many people have suggested precisely this approach for U.S. and world energy policies. As a wise observer has remarked, however, trend is not destiny. Projections are not reliable as predictions; they merely give some idea what the future might be like under various sets of assumptions. If society does not like the picture of the future that some of the projections provide, it is at liberty to work to change the trends and assumptions that lead to those results.

To understand the implications of continuing recent trends in energy use -- and to evaluate possibilities for modifying those trends -- requires first of all a careful look at the technical side of the energy situation. In the next two sections of text, we investigate some of the main technical issues: the magnitude of energy resources, and the characteristics of the technologies available or under development for harnessing those resources.

[†]American Physical Society, *Efficient use of energy*.

ENERGY RESOURCES: SUPPLIES, DEPLETION, LIMITS

Among the major questions that arise in connection with present and projected patterns of energy use are those concerning the adequacy of the supplies of energy resources. Which resources are scarce and which abundant? What does it mean to run out, and how accurately can such eventualities be predicted? What is the potential for harnessing inexhaustible sources?

It is useful at the outset to distinguish between stocklimited, or *nonrenewable*, resources and flow-limited, or *renewable*, ones. The first category refers to fuels of which the Earth is endowed with fixed stocks; once the stocks are depleted, no more will be available on any time scale of practical interest. The main examples are the fossil fuels (principally coal, petroleum, natural gas, tar sands, and oil shales) and the nuclear fuels (principally uranium, thorium, deuterium, and lithium). The fossil fuels were accumulated over hundreds of millions of years, when plant material incorporating stored solar energy was separated from the energy cycle of the biosphere by biological and geophysical happenstance. The nuclear fuels are thought to have originated

when the constituents that eventually became our sun and its planets were fused together from elemental hydrogen in more distant stars. How long the fixed stocks of fuel materials will last depends on how much is ever found in exploitable form (it is not obvious that all that exists will be found) and on the rate at which civilization chooses to exploit what is found.

Flow-limited resources, by contrast, are virtually inexhaustible in duration but limited in the amount of energy that is available per unit of time. The most important example is solar energy, including not only the incoming radiation from the sun but also the various other harnessable forms of energy into which sunlight is converted by natural processes: falling water, wind, waves, ocean currents, temperature differences in the oceans, and plant materials. A much smaller flow-limited source is the energy of the tides, which is derived from the kinetic and potential energy of the Earth-moon-sun system.

Geothermal energy is more difficult to classify as stock-limited or flow-limited, having some characteristics of both. At present, the exploitable form of geothermal energy consists of isolated pockets of hot water or steam. Those local stocks are depleted by use, but on a time scale of decades, or perhaps centuries, they can probably be replenished from the much larger stock of geothermal energy in the Earth's molten core. Future methods of tapping the geothermal energy stored in relatively deep dry rock will also be stock-limited in a short-term sense but flow-limited (by the rate at which heat flows from surrounding regions into the depleted rock) in the long term.

Analysis of the depletion of conventional stocklimited energy resources is itself a complicated enterprise. Much confusion is sometimes engendered in this connection by failure to distinguish clearly between reserves and resources. The term *reserves* generally refers to material whose location is known (proved reserves) or inferred from strong geologic evidence (probable reserves) and which can be extracted with known technology under present economic conditions (that is, at costs such that the material could be sold at or near prevailing prices). The *resources* of a substance include the reserves and, in addition, material whose location and quantity are less well established or which cannot be extracted under prevailing technological and economic conditions. The term *ultimately recoverable resources* describes an estimate of how much material will ever be found and extracted (implicitly including an assessment of how effective technology will ever become and how much civilization will ever be willing to pay for the material). Such estimates are necessarily very crude. The relation between reserves and resources is illustrated in Figure 8-5.

Probably the least sophisticated approach to the analysis of depletion is to estimate the lifetime of the supply by dividing present proved reserves by the present rate of consumption. This approach is the origin of the oftenheard statements to the effect that, "We have X years' worth of petroleum left." The method errs because consumption is not likely to stay constant and because proved reserves often bear little relation to ultimately recoverable resources. Generally it doesn't pay to do the exploration and evaluation needed to establish new proved reserves when the material will not be extracted and turn a profit until fifteen or twenty years in the

future; this is the main reason proved reserves rarely amount to more than a few decades' supply.

A somewhat more instructive way to assess the lifetime of a fuel is to divide available estimates of the ultimately recoverable resources by a level of consumption several times the present one (on the assumption that consumption will level off before too long) or a level of consumption continuing to grow as it has in the recent past. A shortcoming if a constant consumption is assumed is the sensitivity of the result to highly uncertain estimates of the resource and of the equilibrium level of consumption; if continuous growth is assumed, the result is not so sensitive to errors in the resource estimate but is very sensitive to the growth rate chosen.

The most realistic approach seems to be one devised by geologist M. King Hubbert. [7] He notes that the production cycle for any stock-limited resource is likely to be characterized by several phases: first, increasingly rapid growth in the rate of exploitation as demand rises, production becomes more efficient, and costs per unit of material fall; then a leveling-off of production as the resource becomes scarcer and starts to rise in price; and finally a continuous decline in the rate of exploitation, as increasing scarcity and declining quality proceed more rapidly than can be compensated for by improving technology, and as substitutes are brought fully to bear. Hubbert's approach incorporates explicitly the fact that society never really runs out of anything suddenly or completely; it merely uses the most concentrated and accessible supplies first and then gradually works its way into material of declining quality, until what remains is so dilute or so deep or so hard to find that it no longer pays to look for it and extract it.

A generalized illustration of Hubbert's production cycle appears in Figure 8-6. Note that the area under the production curve at any time represents the cumulative production up to that time and the amount under the "completed" curve represents the magnitude of the ultimately recoverable resources. The important measures of the lifetime of the fuel in this approach are the year in which the level of consumption reaches its peak (Y_p) and the year at which 90 percent of the ultimately recoverable resources has been extracted (Y_{90}).

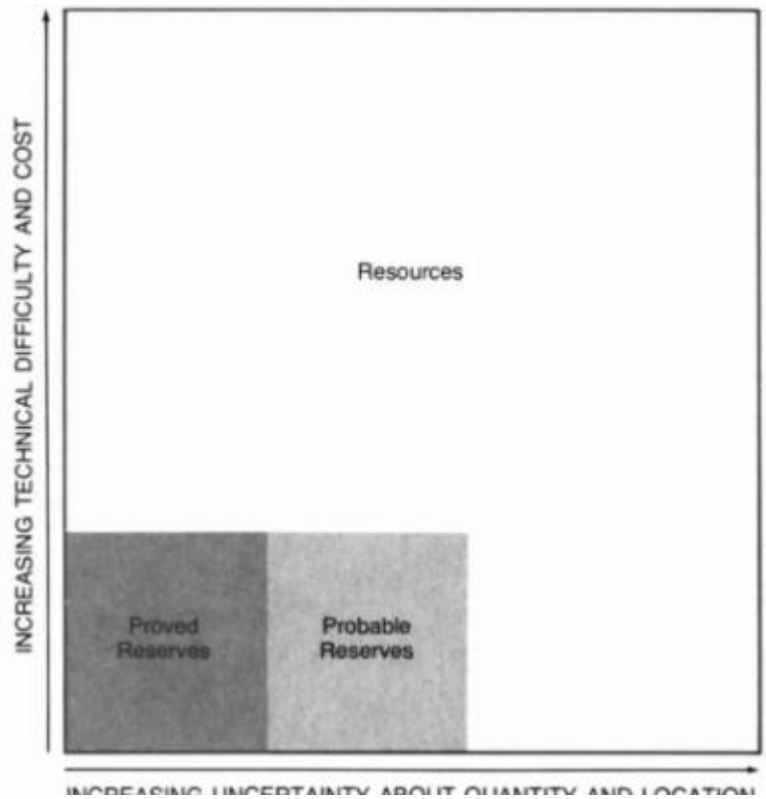

FIGURE 8-5 The relation between reserves and resources. Reserves comprise the of the total resources that is extractable with present technology at or present prices and the location and quality of which are well establis (Redrawn from J. Holdren, *Energy resources,* in Environment, 2d ed. W. Murdoch, ed., Sinauer Associates, Inc., by permission of the publisher.)

Conventional Fossil Fuels: Petroleum, Natural Gas, Coal

Summarized in Figure 8-7, for both the United States and the world, are values of recent annual consumption, proved reserves, and estimated remaining ultimately recoverable resources of the mainstays of today's energy use -- petroleum, natural gas, and coal. [8] Note that the vertical scales in the figures are logarithmic, on which each major interval represents a multiplicative factor of 10. The difference between the low and high estimates of the remaining ultimately recoverable resources of petroleum liquids in the United States is more than a factor of 5. This point is the focus of a vigorous debate in the scientific community, reflecting varying interpretations

[7] M. K. Hubbert, *Energy resources*. A recent update is M. K. Hubbert, *U.S. energy resources. A review as of 1972*.

[8] The main sources of the data on reserves and resources are Cook, *Man, energy, society*; Hubbert, *Energy resources*; and *U.S. energy resources*; P. K. Theobald , S. P. Schweinfurth, and D. C. Duncan, *Energy resources of the United States*; National Academy of Sciences, *Mineral resources and the environment*.

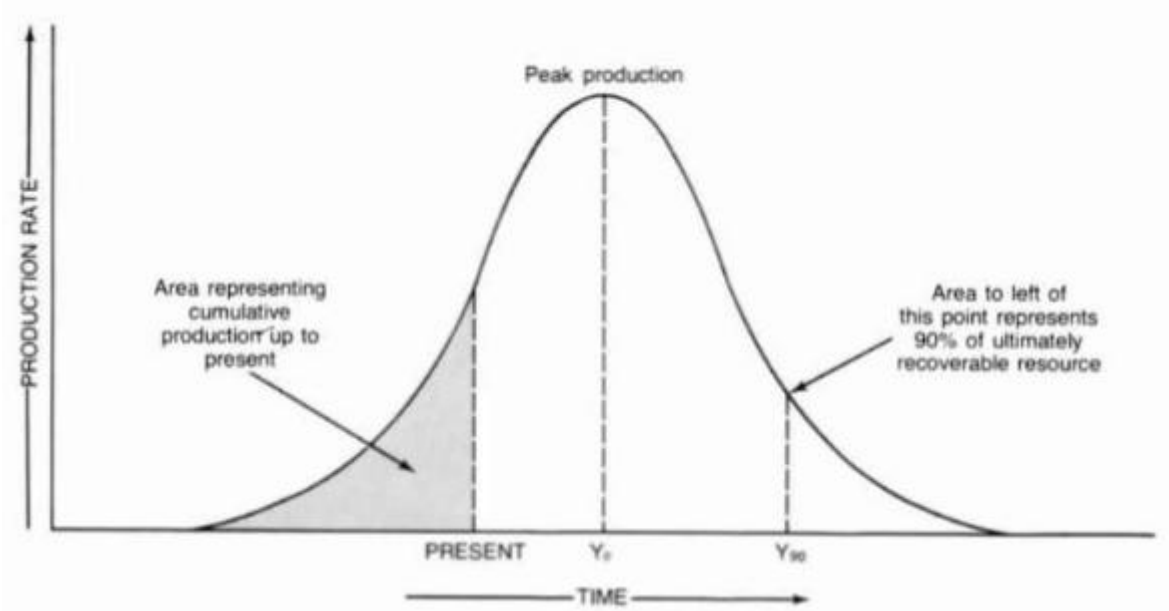

FIGURE 8-6 The pattern of depletion of a finite resource. The rate of use increases exponentially at first as improved technology is brought to bear and economies of scale are exploited. Later, declining quantity and quality of the resource take over, and the rate of use levels off and then falls. Cumulative production up to any given time is represented by all the area under the curve to that time. (Redrawn from J. Holdren, *Energy resources*, in Environment, 2d ed., W. Murdoch, ed., Sinauer Associates, Inc., by permission of the publisher.)

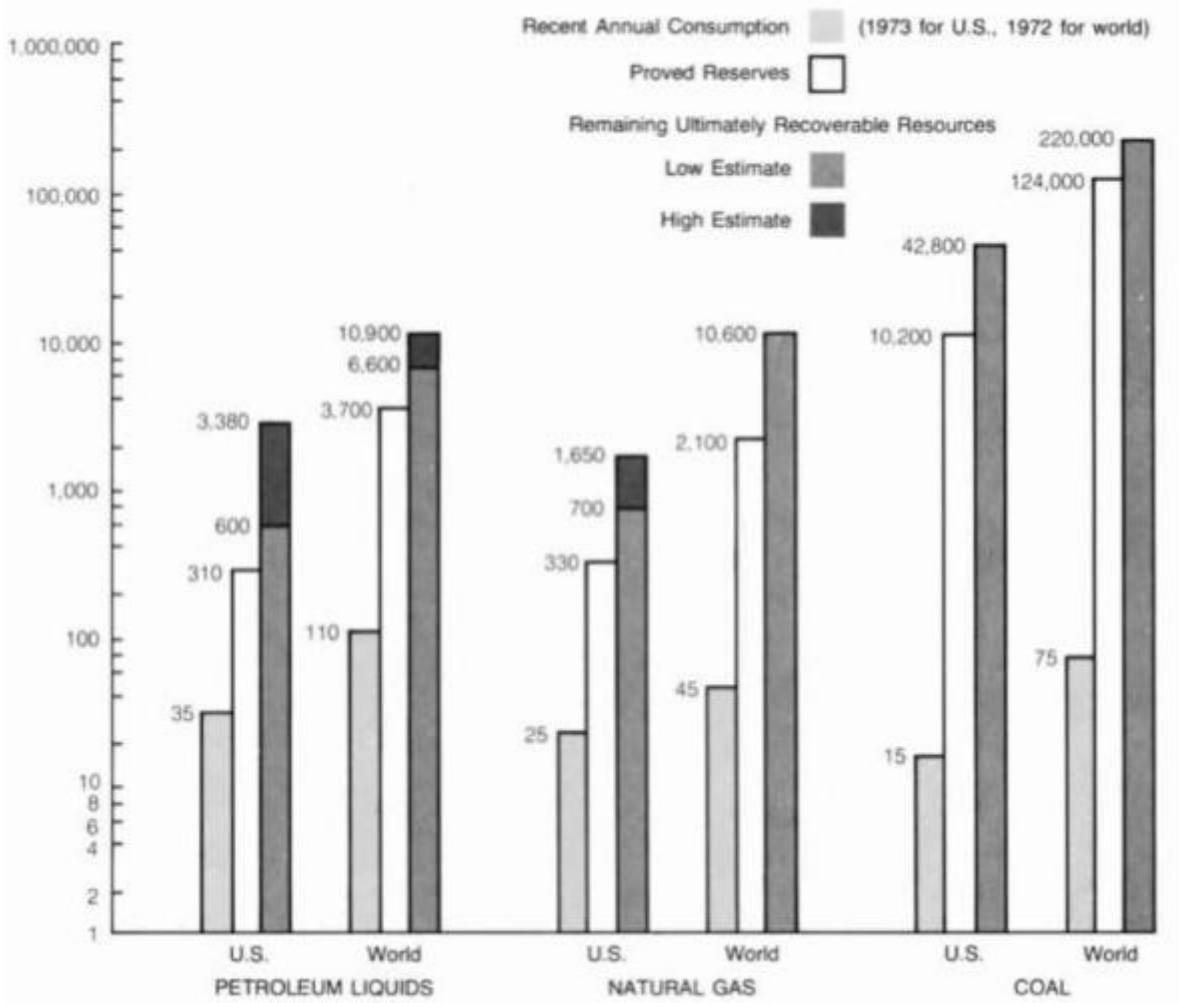

FIGURE 8-7 Reserves and resources of conventional fossil fuels (in trillions of megajoules). Estimates of reserves vary somewhat with the definitions used by the tabulating agency. Resource estimates vary even more widely. Note the logarithmic scale. (Various sources.)

of the geologic evidence and differing degrees of optimism about future extractive technologies. [9] While we suspect the lower estimates are more likely to prove correct, even the high estimates provide little leeway for continued growth in the consumption of oil and gas. This point is apparent in Table 8-4, which summarizes the results of applying various methods of analyzing depletion to the data of Figure 8-7.

Indeed, the clear message of Table 8-4 is that, by any method of analysis, U.S. supplies of petroleum and natural gas are severely limited. World supplies of those fuels, moreover, are almost as small in relation to projected demands as the U.S. supplies. Both for the United States and for the world, any significant increase in consumption of oil and gas will lead to the substantial depletion of the recoverable resources of those materials by early in the next century. And if the pessimists are correct, U.S. domestic production of petroleum was already near or even past its peak in 1974, with domestic natural gas not far behind.

U.S. and world supplies of coal are much larger -roughly 10 times the combined supplies of petroleum and natural gas. The coal resources could sustain consumption rates several times larger than today's for hundreds of years. As large as the supplies are, however, they could sustain a level of consumption that was growing continuously at 5 percent per year for only about a century -- another example of the power (and danger) of high growth rates. The more realistic analysis by Hubbert suggests that coal consumption might peak around the year 2200 and that coal would be near the end of its importance as a major energy source some 200 years later.

A greatly expanded use of coal, which seems to be implied by the data on fuel supply, poses a number of problems. For coal to relieve the burden on petroleum and natural gas, it must be interchangeable with those fuels in a variety of applications. This interchangeability can be achieved by means of coal gasification and liquefaction, processes that are known to be technically feasible and capable of delivering 50 percent to 90 percent of the energy of the coal in the final gaseous or liquid synthetic fuel. [10] The facilities needed to accomplish these transformations are large, expensive industrial installations comparable in complexity to oil refineries (discussed below). The problem is not whether it can be done at all, but how quickly and at what cost in capital investment a significant transition from natural gas and petroleum to synthetic fuels from coal can be accomplished. This, along with the environmental liabilities of greatly increased reliance on coal, are discussed at greater length later.

Tar Sands and Oil Shale

Tar sands consist essentially of a mixture of sand and asphalt. The material is mined like rock and processed to convert the hydrocarbons into a synthetic crude petroleum. The principal known deposits are in Alberta,

[10]See, for example, H. C. Hottel and J. B. Howard, *New energy technology: Some facts and assessments*.

[9]R. Gillette, *Oil and gas resources: Academy calls USGS math misleading*; S. F. Singer, *Oil resource estimates*; R. Gillette, *Geological survey lowers its sights*.

Canada, and the energy recoverable from them amounts to about 1800 trillion megajoules. [11] (This is of the same order of magnitude as the remaining recoverable resources of petroleum in the United States.) A small commercial plant (about 50,000 barrels per day) has been in operation at the Athabasca tar sands since 1966, and several other commercial operations were scheduled for development in the late 1970s.

Oil shale consists of fine-grained sedimentary rock permeated by a rubbery solid hydrocarbon called *kerogen*. Oil shale is much more abundant than tar sands, but it is technologically more difficult to convert into synthetic crude oil. The Green River shales of Colorado, Utah, and Wyoming alone contain the equivalent of 2000 billion barrels of oil, or about 12,000 trillion megajoules, at concentrations of between 10 and 100 gallons of oil per ton of shale. Total U.S. resources at concentrations greater than 10 gallons per ton have been estimated at about 160,000 trillion megajoules. World resources of similar quality outside the United States have been estimated at 1,900,000 trillion megajoules. [12] How much of this vast amount of potential fuel can ever be extracted economically is completely uncertain at this time. Rising costs of conventional petroleum in the early 1970s sent major corporations scurrying to investigate the richer parts of the Green River shales. Whether substantial commercial operations develop there will depend for some time to come on investors' guesses about the price of petroleum in the future, as well as on future decisions concerning the environmental acceptability of oil shale operations. It is also possible that the oil shales will serve as the eventual source of hydrocarbons for lowervolume, recyclable uses for such activities as lubrication and the production of plastics, after the cheaper and more accessible sources have all been burned.

Nuclear Fuels: Fission

It has been rather widely assumed until recently that a shift to nuclear energy -- first from fission and perhaps later from fusion -- would provide the next major change in the composition of the world energy supply, augmenting and eventually supplanting the fossil fuels just as they earlier augmented and supplanted wood and agricultural wastes. Substitution of nuclear for fossil fuels is possible with today's technology only in the electricity-generation component of the energy economy, inasmuch as no commercial techniques exist for producing portable fuels in nuclear reactors or for using nuclear heat directly in industrial processes. Even so, nuclear energy production has been expanding at a rate that could quickly turn its 2-percent share of the world energy market in 1975 into a much larger one. A number of projections have suggested, for example, that the fraction of energy used in the United States to generate electricity will increase

from 25 percent to 50 percent by the year 2000 and that nuclear reactors will then be providing half of that electrical half of the U.S. energy budget (or a quarter of the total). A variety of economic and environmental uncertainties that have arisen concerning nuclear fission now make forecasts of so large a role in the year 2000 seem questionable to many observers. One of the controversial issues has been the adequacy of the nuclear fuel supply under various circumstances; we consider that question here, deferring the others to a later section.

To understand discussions of nuclear fuel resources requires some knowledge of the way the fuels are used in fission reactors. This background is provided in Box 8-2. The essential conclusions are that uranium can actually deliver about 1 percent of its theoretical energy content in a contemporary converter reactor and perhaps 2 percent in an advanced converter reactor, and that uranium and thorium can deliver 40 percent to 70 percent of their theoretical energy contents in breeder reactors. Combining this information with estimates of domestic uranium resources published by the U.S. Energy Research and Development Administration (ERDA) and its predecessor, the U.S. Atomic Energy Commission (USAEC), gives the results shown in Table 8-5. [13] The resources are classified according to the so-called *forward cost* of uranium oxide (U3O8) from the

[11] Hubbert, *Energy resources*, and *U.S. energy resources*.

[12] Ibid ; Theobald, Schweinfurth, and Duncan, *Energy resources*.

[13] In late 1974, part of the USAEC was merged with parts of other federal agencies dealing with energy development to form ERDA, and the other part of the USAEC became the Nuclear Regulatory Commission (NRC).

various deposits. The forward cost does not include certain parts of the uranium company's capital investment, nor does it make allowance for profit; it is therefore not to be confused with the *price* at which the uranium will be sold, which might be much higher. The quantities of uranium shown in Table 8-5 are sums of categories ERDA calls *identified resources* and *potential resources*.

The uncertainty in the estimates increases as the grade of ore decreases and the forward cost goes up. The resources in the range between $66 and $220 per kilogram are available only as by-products obtained when phosphorus, lignite, and other mineral products are mined and processed. The total quantity of uranium that can be recovered this way and the speed with which it can be recovered are highly uncertain and subject to factors outside the control of the uranium industry itself. The resources above $220 per kilogram are from the Chattanooga shales of Tennessee and neighboring states. These shales contain only 60 to 70 parts per million (ppm) of U3O8 by weight, compared to 2000 ppm for the Colorado sandstones now being mined at a forward cost (in 1970 dollars) in the range of $18 to $22 per kilogram.

Controversy surrounds several aspects of the uraniumresource question. Some observers think that ERDA's estimate of the quantity of uranium ultimately recoverable at forward costs of $66 per kilogram or less is as much as 3 times too high. [14] Others note that until 1972 the price of U_3O_8 was $16 per kilogram or less, providing little incentive to explore for leaner, more expensive

deposits. The price in 1976 had soared to $80 per kilogram and more, prompting an expectation by many that more intensive (and successful) exploration for uranium in intermediate forward-cost categories would be stimulated. [15] And the size and precipitousness of the price rise worldwide led to suspicions, subsequently confirmed, of the existence of an international uranium canel. [16]

Thorium supply is so far a much less controversial

TABLE 8-5

issue, in part because the lack of many commercial reactors designed to use it means there is little demand. Estimates of the thorium resource by the USAEC appear in Table 8-6.

The cost of electricity generated in nuclear reactors is so insensitive to the cost of raw uranium that the use of U3O8 costing $110 per kilogram is not out of the question, even with the

inefficient 1970 reactor technology. [17] (Should it prove *energetically* infeasible to use lean uranium ores in converter reactors -- which seems quite unlikely -- then this conclusion would have to be modified.) The U_3O_8 supplies listed at $110 per kilogram or less in Table 8-5, if used in present-day converter reactors, could generate almost 300 times the 1975 U.S. electricity consumption. (Of course, the price reactor owners will have to pay for this uranium will be

Box 8-2 Fission Reactors: Where the Energy Comes From

Nuclear fission is the splitting of certain heavy elements into lighter ones, thus releasing so much energy stored in the nuclear binding forces that the associated loss of mass is a detectable 0.1 percent (see also Box 2-2). Fission is induced when the nucleus of a suitable isotope is struck by a free neutron. (An *element* is characterized by the number of protons in the nucleus; different isotopes of the same element have the same number of protons but different numbers of neutrons in the nucleus.) Among the fragments from each fission event are some newly free neutrons -- an average of about 2.5 per fission. The freeing of those neutrons makes possible a chain reaction: one or more of the newly free neutrons induces a new fission, which produces other free neutrons, which induce more fissions, and so on.

If a chain reaction grows very rapidly, the result is a fission bomb. In a 20-kiloton weapon, a kilogram of nuclear fuel is fissioned in a fraction of a millionth of a second, producing 999 grams of fission products and converting the other gram of the original mass into 79 million megajoules of heat, light, X-rays, and blast waves. * In a fission reactor, by contrast, the chain reaction is nurtured carefully to the desired level and then maintained there. In a large reactor generating electricity at a rate of 1000 electrical megawatts, it takes about seven hours to fission a kilogram of nuclear fuel. (Dividing the 79 million megajoules, almost all of which appears in the reactor as heat, by the number of seconds in seven hours gives a rate of 3000 megawatts. This *thermal power* is converted to electrical power at an efficiency of about one-third.) To obtain 79

million megajoules of thermal energy from the combustion of coal requires almost 3 million kilograms -- a startling contrast to the equivalent 1 kilogram of fissioned material.

Isotopes that can sustain a fission chain reaction are called *fissile*. There are three important ones: uranium-235 ($_{92}U^{235}$), plutonium-239 ($_{94}PU^{239}$), and uranium-233 ($_{92}U^{233}$). (The subscript tells the number of protons in the nucleus; the superscript tells the number of protons plus neutrons.) Of the fissile isotopes, only uranium235 occurs in appreciable quantities naturally. It makes up 0.7 percent of the element uranium in nature. Plutonium-239 is produced by a series of nuclear transformations that may ensue after uranium-238 (the other 99.3 percent of natural uranium) is struck by a fast-moving neutron. Isotopes that can be transformed into fissile ones this way are called *fertile*. The other important fertile isotope is thorium-232 ($_{90}Th^{232}$), which upon being struck by a slow-moving neutron may undergo a series of transformations leading to fissile uranium-233. If struck by a particularly energetic neutron, the fertile isotopes uranium238 and thorium-232 may also fission, but they are incapable of sustaining fission chain reactions on their own.

Most present-day nuclear fission reactors use uranium-235 as the primary nuclear fuel. A mixture of uranium-235 and uranium-238 is present in the reactor, and some of the neutrons released by the fission of uranium-235 strike uranium-238 nuclei to initiate the transformation to plutonium-239. Some of that plutonium is subsequently fissioned itself while still in the reactor, thus contributing to the chain reaction. (This process can be thought of as indirect fission of uranium-238.) Some plutonium remains when, after a year or so, the spent fuel is removed from the reactor. That plutonium, if recovered at a fuel reprocessing plant along with the unconverted and unfissioned uranium remaining in the fuel, may be recycled as fuel for the reactor that produced it; it may be saved for use in future reactors; or it may be used to manufacture nuclear bombs. The reactions in this nuclear fuel cycle and the similar one involving thorium are diagramed in Figure 8-8.

When all the details are taken into account, we find that a present-day commercial light-watercooled reactor (LWR), recycling its plutonium, would fission about 10 grams of nuclear fuel (uranium or plutonium made from uranium) for

---

*About 79 million megajoules (in the form of heat, light, and blast waves) would be produced by detonating 20,000 tons of TNT; hence the "20-kiloton" rating of the bomb.

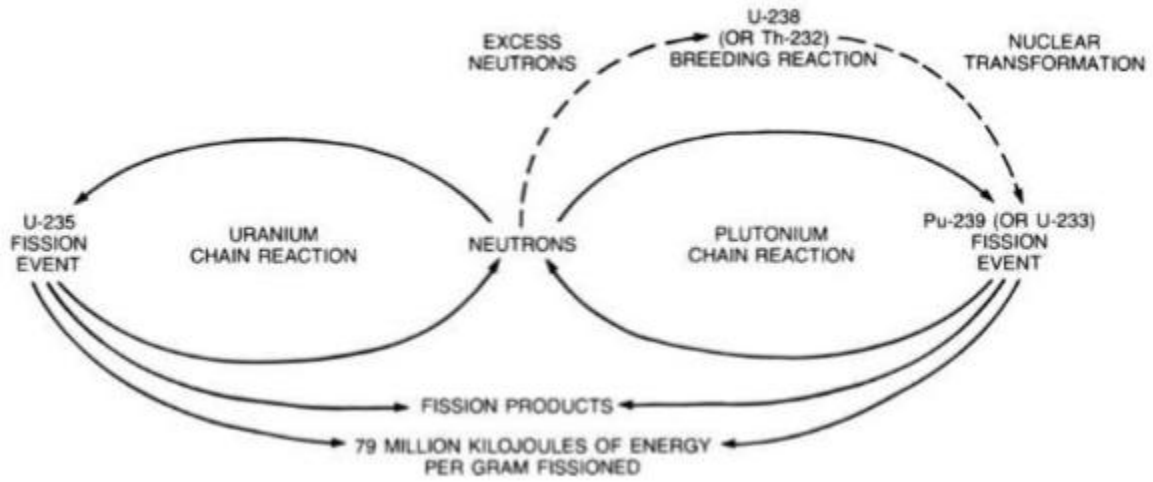

FIGURE 8-8
Nuclear reactions of uranium, thorium, and plutonium. A chain reaction occurs when one of the neutrons from each fission event initiates another fission event. Neutrons in excess of those needed to sustain the chain reaction may initiate transformations of fertile nuclei to fissile ones. In the "thorium cycle," the right-hand chain reaction runs on uranium-233 instead of plutonium. (Redrawn from J. Holdren , in *Environment*, 2d ed., Sinauer Associates, Inc., by permission of the publisher.)

every kilogram of natural uranium that is mined. This is a fuel-utilization efficiency of 1 percent, compared to the unattainable ideal in which every uranium nucleus mined is fissioned, directly or indirectly. If the plutonium is not recycled, the LWR's fuel utilization drops to 0.7 percent, or 7 grams fissioned per kilogram mined. A more advanced, high-temperature gascooled reactor (HTGR) relying on the Th-232 /U-233 conversion process may be able to achieve a fuel-utilization efficiency of about 2 percent, fissioning 20 grams of nuclear fuel for every kilogram of uranium mined. (For that type of reactor, uranium is the limiting resource even though some thorium is used; the fuel cycle requires the mining of only 1 kilogram of thorium for every 5 kilograms of uranium, and thorium is about 3 times as abundant in nature as uranium is.) One commercial-size demonstration plant of this type began operation in 1976 in the United States.

Water-cooled and gas-cooled reactors of the kinds just described are called converters, in reference to their ability to convert modest amounts of fertile material to fissile fuel. When the conversion ratio -- the number of fertile to fissile conversions per fissile nucleus consumed -- is low, the term *burner* is sometimes also used for such a reactor. By means of drastic changes in design, it is possible to build a reactor that converts fertile material to fissile fuel faster than the

reactor consumes fissile fuel in its own chain reaction. Such a reactor is called a *breeder*. In terms of the fission reactions depicted in Figure 8-8, breeder reactors permit elimination of the loop that depends on scarce uranium-235. The fuel utilization of possible future breeder reactors could be perhaps 40 percent for fuel cycles based on the Th-232/U-233 conversion and 60 to 70 percent for fuel cycles based on the U-238/Pu-239 conversion (400 to 700 grams fissioned per kilogram of uranium or thorium mined). [**]

[**] For a more thorough treatment of the physics and technology of fission, see D. R. Inglis, *Nuclear energy. Its physics and its social challenge*.

somewhat higher than the cost given; but it is unlikely that uranium suppliers will try to charge more than operators of existing reactors can pay.) Breeder reactors could even use U_3O_8 priced at $500 or $1000 per kilogram without this expense's noticeably influencing the price of electricity; even prices much higher than forward costs for the leanest resources listed could be tolerated. Used in breeders, all the uranium resources listed amount to about 50,000 times the 1975 U.S. electricity consumption. The situation for thorium is similar: even the most expensive supplies listed in Table 8-6 could be utilized without noticeable impact on the price of electricity. Should our descendants choose to do so, they could probably also extract for use in breeder reactors the 4 trillion kilograms of uranium in the oceans and the even larger quantities of uranium and thorium dispersed in such common rocks as granite.

The rest of the world has been even less thoroughly explored for uranium and thorium than the United States. Estimated recoverable supplies of uranium outside the United States, below $33 per kilogram of U_3O_8, amounted in 1973 to about 1.9 billion kilograms, or 50 percent more than the corresponding U.S. figure. [18] No meaningful figures are available above that cost range. The types of geologic formations that may contain significant concentrations of these fuels are widely distributed around the globe, however, and it is possible that uranium and thorium resources will be found on the various continents roughly in proportion to land area. This does not mean of course, that all countries are likely to be equally well endowed -- or even endowed at all. In the mid-1970s the bulk of the world's identified uranium reserves were in relatively few countries (the United States, Canada, South Africa, France, Australia, Sweden, and Brazil), facilitating the formation of the cartel mentioned above. [19]

In the long term, however, it seems likely that the most serious difficulties with fission power, for the world as well as for the United States, will involve not the total supply or the cost of fuel but the other economic, environmental, and social aspects we discuss later.

Nuclear Fuels: Fusion

The energy of the sun and of the hydrogen bomb comes from the fusing of light nuclei to form somewhat heavier ones, rather than from the fissioning of heavy nuclei. Harnessing fusion reactions in a nonexplosive way on the surface of Earth is far more difficult than harnessing fission. But controlled fusion -- when it is at last achieved -- could offer impressive advantages

over fission with respect to safety, magnitude of long-lived radioactive wastes, and accessibility of an enormous fuel supply (fusion technology is considered in detail below).

The most suitable fuels for Earthbound fusion are the two heavy isotopes of hydrogen -- *deuterium* and *tritium*. Deuterium (1H2, usually abbreviated "D") is nonradioactive, and occurs in seawater in the ratio of 1 deuterium atom for every 6700 atoms of ordinary hydrogen. This does not sound like much, but it is a great deal; the deuterium in a gallon of seawater is equivalent in energy content to more than 300 gallons of gasoline. Tritium (1H3, usually abbreviated "T") is radioactive with a half-life of 12.3 years and is almost nonexistent in nature; it can, however, be produced readily by bombarding lithium with neutrons. Lithium is thus a *fertile* material for fusion in much the same way that thorium232 and uranium-238 are fertile materials for fission.

The principal fusion reactions are illustrated in Figure 8-9. The D-T reaction is significantly easier to achieve than the reactions involving deuterium alone, and early fusion reactors will almost unquestionably rely on it; hence, the tritium-producing reactions and the supply of lithium are of great importance. Lithium in its natural form consists of 92.6 percent lithium-7 and 7.4 percent lithium-6. Some calculations of the effective energy content of lithium as a fusion fuel have erroneously assumed that only the rarer lithium-6 could be used and thus have underestimated the energy available. The lithium-7 reaction consumes some energy, but far less than is obtained when the resulting tritium undergoes fusion. When the use of both lithium-7 and lithium-6 is taken into account, one finds that the net energy derived from converting a gram of natural lithium to tritium and then fusing the tritium with deuterium is between 45,000 and 90,000 megajoules, depending on the technology used. These figures are to be compared with the 30,000

[18] J. Cameron, *A review of long term uranium resources, problems, and requirements in relation to demand 1975-2025*.

[19] United States National Committee of the World Energy Conference, *World energy conference survey of energy resources, 1974*.

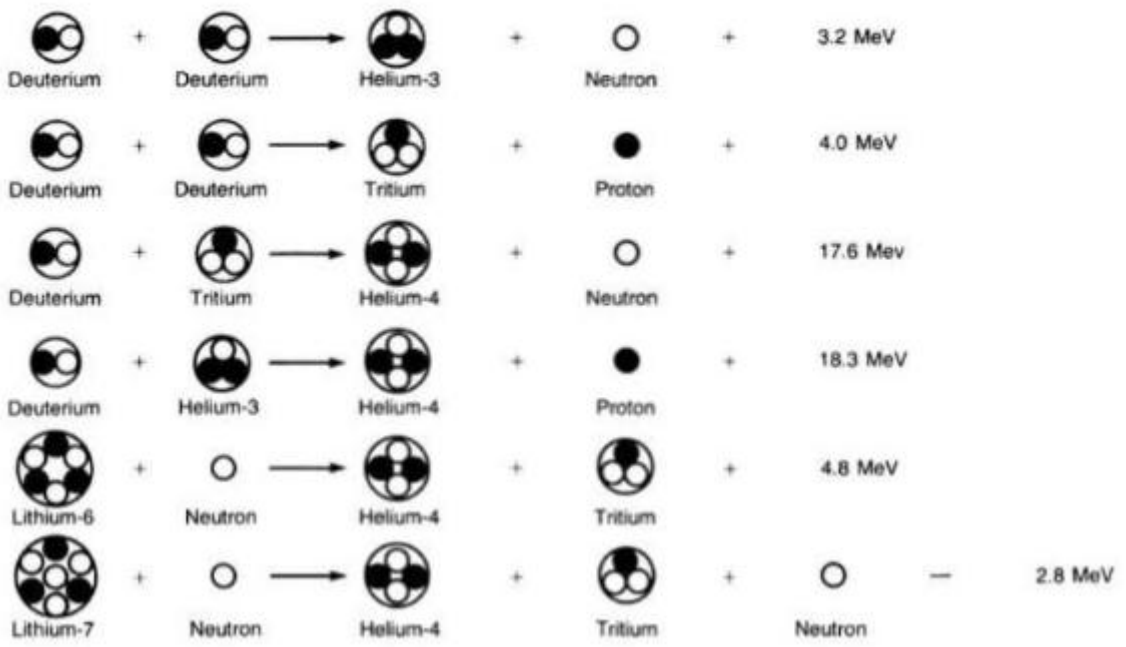

FIGURE 8-9
The most important reactions for terrestrial controlled fusion. The reaction that consumes tritium is the "easiest" to harness. The tritium consumed in this reaction must be produced from lithium by means of the two reactions at the bottom. Energy yields are in millions of electron volts (MeV) per reaction. (After Gough and Eastlund, 1971.)

megajoules one expects from a gram of natural lithium if only the contribution of the lithium-6 is considered. Lithium occurs in mineral ores called pegmatites, in heavy brines, and in seawater at a concentration of 0.17 grams per cubic meter (compared to 33 grams per cubic meter for deuterium).

Table 8-7 outlines the availability of the basic fusion fuels. Deuterium is so abundant as to be almost inexhaustible -- it could supply a world energy demand much larger than today's for billions of years -- and the technology for extracting it cheaply is already well established. Although lithium is less abundant, today's reserves and estimated resources [20] on land could support a greatly increased energy demand for centuries. [21] That should be long enough for technologists to make D-D fusion work or to learn to extract the lithium from the oceans. As with fission, limits on the use of fusion are much more likely to be based on environmental or social restraints than on availability of fuel.

TABLE 8-7
Fusion Fuels and Their Energy Content

Fuel	Quality (billion kg)	Energy content (trillion MJ)
LITHIUM		
U.S. reserves	4.0	360,000
U.S. estimated resources	2.9	260,000

Fuel	Quality (billion kg)	Energy content (trillion MJ)
Reserves outside the U.S.	0.4	
Estimated resources outside the U.S.	2.7	240,000
Oceans	250,000	22,500,000,000
DEUTERIUM (IN OCEANS)	50,000,000	17,300,000,000,000

Geothermal Energy

The size of geothermal energy resources is extraordinarily difficult to estimate, because the amount that can be recovered depends completely on the details of a technology that has only begun to be developed. A 1975 review by the U.S. Geological Survey (USGS) indicates

[20] J. J. Norton, "Lithium, cesium, and rubidium".

[21] John P. Holdren, *Adequacy of lithium supplies as a fusion energy source*.

identified resources of high-temperature geothermal energy in the United States, recoverable with existing technology, as about 270 trillion megajoules. [22] At an efficiency of conversion to electricity of about 10 percent (so low because of the low temperature associated with geothermal heat), this modest amount of energy could deliver electric power at a rate of 27,000 megawatts for only 30 years. This is equivalent to the production of 25 to 30 large fossil-fuel power plants. The only operating geothermal power plant in the United States, at The Geysers in northern California, had a capacity of about 500 electrical megawatts (Mwe) in 1976.

The United States has not been carefully explored for geothermal potential, however, and some experts believe that the potential of a single field in California's Imperial Valley exceeds the USGS figure for recoverable reserves in the entire United States. The USGS 1975 estimate for discovered and undiscovered high-temperature and intermediate-temperature geothermal resources in the ground in the United States was 12,000 trillion megajoules. In addition, the USGS estimated that there might be as much as 46,000 trillion megajoules available with present and near-future technology from geopressure areas, mostly off the Gulf coast of the southern United States. [23] If all these resources materialized, if 50 percent of the energy could be brought to the surface (compared to the 2 to 24 percent that is recoverable with existing technology), and if the energy were converted to electricity at 20 percent efficiency, it would amount to 970 times the 1970 U.S. consumption of electricity. Should it prove practical to tap the geothermal energy of deep, hot, dry rocks, [24] the accessible resource would be even larger. Obviously, the practical potential of geothermal energy depends very much on highly uncertain estimates about the size of the exploitable stock and the efficiency with which it can be harnessed. The *theoretical* potential is great enough that the problem is well worth pursuing.

Viewed as a widespread flow resource rather than a stock to be tapped in particularly favorable locations, geothermal energy is not encouraging. The rate of heat flow to the surface of the Earth,

corresponding very roughly to the rate of heat generation by the nuclear disintegration of radioactive elements in the Earth's crust, is only about 0.063 watts per square meter of surface area (63 kilowatts per square kilometer). At a 20-percent conversion efficiency, a 1000-Mwe geothermal power plant relying on that flow would have to find a way to harness it over 80,000 square kilometers.

Solar Energy

Energy from the sun is a flow-limited resource: the energy income will continue for the lifetime of the sun (billions of years) but the rate of energy flow (that is, the *power*, and hence the amount of energy received in any given span of time) is fixed. This fixed flow amounts to 1400 watts per square meter, facing the sun at the top of the Earth's atmosphere. The average flow reaching the surface of the Earth (averaged over day and night, summer and winter, good and bad weather, and all latitudes) is about 170 watts per square meter, or 170 megawatts per square kilometer. The amount of solar energy falling annually on the surface of the forty-eight contiguous United States (where the average rate is 180 watts per square meter) is 42,000 trillion megajoules, or 650 times the total 1970 U.S. energy use. The important questions, then, are for what uses and with what technologies solar energy can be harnessed economically. The possibilities include not only the direct collection and harnessing of the sun's rays but the collection and use of solar energy stored in the hydrologic cycle, in wind and waves and ocean currents, in the temperature difference between deep and shallow ocean waters (ocean thermal gradients), and in plant material. The average global flows of thermal energy in some of those pathways are: hydrologic cycle, 40 billion megawatts; windwaves-ocean currents, 0.25 billion to 2.5 billion megawatts; net photosynthesis, 100 million megawatts. Compared with worldwide energy use in the mid 1970s of 8 million megawatts, these are all impressive numbers. Actually harnessing a very sizable fraction of any of them would be a huge technological enterprise, however, and not without ecological risks. These aspects are discussed below.

Tidal Energy

Tidal energy is the least significant of the flow-limited energy sources. (See Table 8-8 for a summary of those we have discussed.) The total rate of tidal energy flows in shallow seas, where this energy is most accessible, is about 1.1 billion kilowatts, and only about 13 million kilowatts of that can be harnessed with existing technology. [25] Prospects for significant improvement in this amount are poor, on fundamental physical grounds.

ENERGY TECHNOLOGY

In this section of text we identify and briefly describe some of the most important energy technologies now in use or anticipated. Following descriptions of how those technologies work (including how most associated environmental problems arise) are comparisons of some of the economic and environmental characteristics of the various technologies. The paths by which energy finds its way from origin to application to disposal generally contain many steps, regardless of the energy source. These sequences of steps are called fuel cycles, even where no real cycling is involved. The major steps of most fuel cycles are listed in Table 8-9, with examples of specific activities that occur in each. Until relatively recently, public attention has focused mainly on what goes on at the harvesting and conversion steps -- for example, in coal and uranium mining or in fossil-fuel and nuclear power plants. But complicated, expensive, and environmentally significant technologies are in operation at many of the other steps as well.

Oil and Natural Gas

Exploration. The technology of exploiting petroleum and natural gas begins with exploration. The geology of these hydrocarbon materials, which forms the scientific underpinnings for the search, is a complex subject with a large literature. [26] A variety of analytic

methods and instruments are used to locate the most promising regions. The presence of oil and gas generally can be confirmed only by actual drilling, however, and that is what makes exploration an expensive enterprise. In the United States alone, about 2.25 million wells have been drilled in the search for oil and gas since the first few successful wells in the mid-1800s. Of this considerable number of wells (averaging about 1000 meters in depth but ranging to as much as 8000 meters) only about

[25]Hubbert, *Energy resources*.

[26]For a brief introduction, see Cook, *Man, energy, society*, chapter 4. A more technical synopsis is T. H. McCulloh, *Oil and gas*.

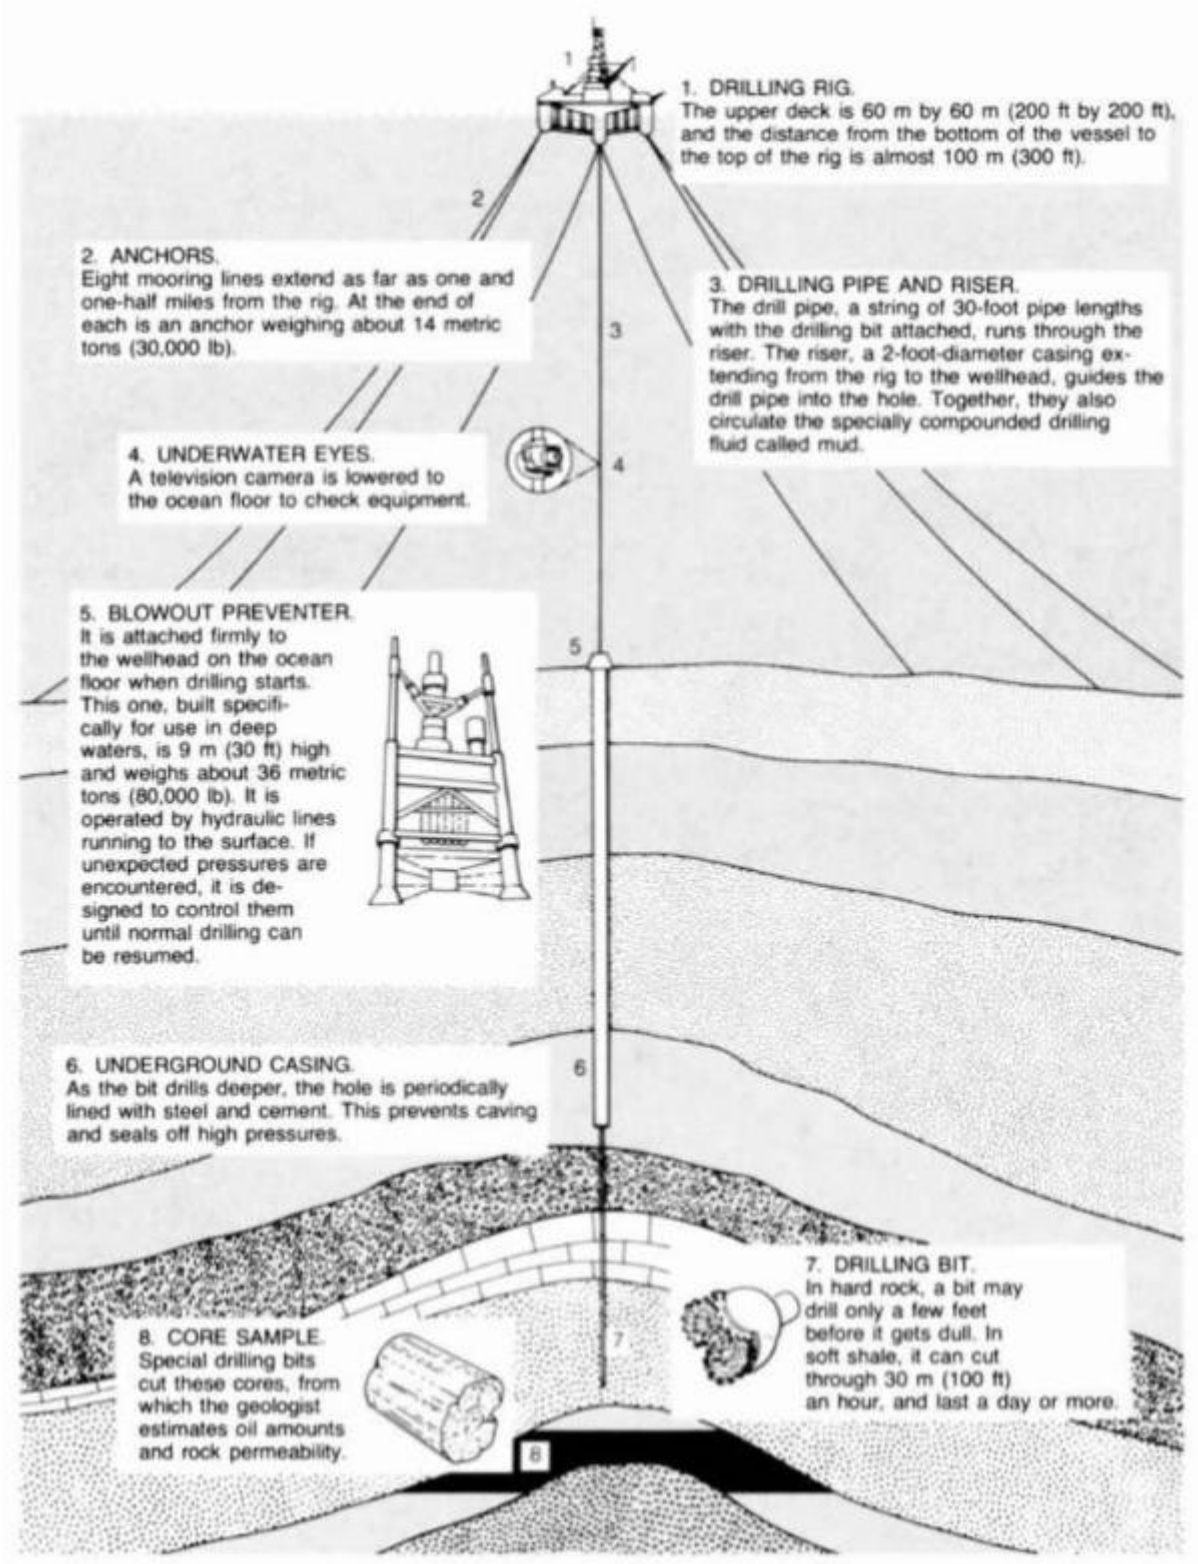

FIGURE 8-10
Diagram of offshore drilling rig. The complexity of this operation suggests one reason why the

price of oil increases as society is forced to get it from less convenient locations. (From Press and Siever, *Earth*, W. H. Freeman and Co., San Francisco, 1974.)

1 exploratory well in 10 has found oil in sufficient quantities to justify production (that is, to pay for the additional costs of setting up equipment to extract oil once the well has been drilled). [27] Only 1 exploratory well in 50 has found enough oil to repay its total costs. (This is not to suggest, of course, that the oil business has not been profitable, but only that one must do a lot of exploratory drilling per good well.)

The complexity, the expense, and the environmental impact of exploratory drilling increase greatly as depletion of the most accessible deposits pushes the search for oil and gas into more remote and more hostile environments. Drilling from platforms offshore in such locations as the North Sea and the continental shelves of the United States is a much costlier operation than drilling onshore in most locations, and drilling in the deeper water of the continental slope will be costlier still (Figure 8-10). Environmentally, the heaviest costs of petroleum exploration are those incurred in the fragile arctic environment, where the scars of access roads and construction sites linger for decades.

Harvesting. Even after exploration is successful, the matter of getting the fuels out of the ground is still not entirely straightforward. This is so because the deposits are not underground lakes of oil capped by natural gas, but, rather, porous rock whose pores are filled (usually) with a mixture of oil, salty water, and natural gas (either dissolved or in separate pockets). Under the natural pressure associated with depth in Earth's crust, much of the gas and some of the oil and water flow up the pathway provided by the well to the surface. *How* much depends on the viscosity of the oil, which varies greatly, and on the porosity of the rock in which it exists. Often, pumping is necessary to bring much oil to the surface. The brine that comes with the oil -- typically about 3 barrels of brine per barrel of oil -- must be disposed of.

Although natural gas is itself a very useful fuel (today considered well worth finding and producing, even where it occurs separately from petroleum), it was once common practice in the United States to dispose of gas produced in conjunction with oil by flaring (burning it in an open flame at the wellhead). This was done because the cost of developing facilities to store and transport the gas to markets was too high in relation to the revenues its sale would bring. Today, major networks of gas pipelines link the producing fields of the United States and Canada with the major markets in those countries, but most of the gas produced in the Middle East, South America, and North Africa is still flared. It can be estimated that the energy content of the natural gas wasted annually in this way is equal to about 3 percent of the annual global consumption of energy in all forms. [28]

Whereas much of the gas that is produced never reaches the market, most of the oil that is discovered is never even produced. It clings tightly enough to the pores of the rock to resist even very elaborate schemes to wrest it out. These include injection of water or gas under high pressure down additional wells, to force the oil in the direction of the producing holes, and the use of detergents, solvents, and even underground combustion to scavenge the oil from rock. When these techniques are applied to oil fields that previously were worked using conventional

techniques, the process is called *secondary recovery* or *tertiary recovery*. In modern practice, stimulated by higher oil prices, these techniques are often applied the first time a field is worked. Overall, the fraction of oil that has been extracted from discovered reservoirs (the *recovery factor*) has been only about 30 percent. [29] This figure is the basis for the estimates of recoverable petroleum resources cited earlier. Naturally, much interest and research has been devoted to the improvement of recovery techniques, in the hope of raising the low average recovery factor, but the most respected petroleum analysts are not yet counting on a higher figure in their projections.

The environmental impacts of oil and gas production fall into three main categories: (1) effects that are simply an expansion of the surface disruption and visual impact of exploration operations; (2) the release of petroleum and brine into the environment as a result of leaks of various kinds and blowouts (uncontrolled eruptions of

gas, water, and oil under subterranean pressure); and (3) the often poorly planned growth in fragile areas of oil-handling facilities and the populations that operate them. These problems are most severe in the Arctic and in coastal regions, where other functions of the environment -- as a wildlife habitat, as a commercial fishery, or as a recreational area -- are particularly valuable and vulnerable. [30]

Transport. The transportation of oil over long distances poses similar hazards: accidental spills from tankers and pipelines; discharges of oil during routine operations (principally, cleaning tanks on the tankers); and preemption of land and the concomitant loss of other environmental services owing to the construction of pipelines and port facilities for tankers. The controversial trans-Alaska pipeline is expected initially to move 500,000 barrels of oil per day (almost 50 metric tons per minute) 1250 kilometers from Prudhoe Bay to Valdez through the hostile and generally fragile Alaskan environment. The eventual capacity is to be 2 million barrels per day. If there is a break in the pipeline -- which could be caused by earthquakes, sagging with the melting of the permafrost underneath, embrittlement from extreme cold, destructive action by ice and current in the rivers the pipeline crosses, or combinations of these and other factors -- the loss of hot oil (80° to 90° C) while the break was being isolated by valves would probably amount to between 15,000 and 50,000 barrels. [31]

More than half the oil produced worldwide moves by sea in tankers. The cost of shipping a barrel of oil is much lower in large tankers than in small ones (given present tanker construction), so the trend has been toward larger and larger ships. The 127,000-ton-supertanker *Torrey Canyon*, which went aground off the United Kingdom in 1967, was for that time a very large tanker. (The tonnage usually given for tankers is in *deadweight tons*, which refers to the ship's carrying capacity in short tons. *Displacement tons* means the weight of the water displaced by the fully loaded ship -- that is, the deadweight tonnage plus the weight of the empty ship.) By the mid-1970s the jargon of tankers had expanded to include the terms VLCC (very large crude carrier -- more than 200,000 deadweight tons) and ULCC (ultralarge crude carrier -- more than 400,000 deadweight tons), and 800,000-ton tankers were on the drawing boards. A typical 300,000-ton VLCC is about 330 meters long (1100 feet) and 50 meters wide, holds more than 2 million barrels of oil, and draws 21 meters (69 feet) of water (Figure 8-11). This draft is too great for most U.S. ports, which typically are dredged to a depth of only about 12

[30] See, for example, Boesch, Hershner, and Milgram, "Oil spills and the marine environment"; Council on Environmental Quality, *Environmental Quality, 1974*; and Chapter 11 of this book.

[31] U.S. Department of the Interior, *Final environmental impact statement, proposed trans-Alaska pipeline*.

meters. The prospect of continuing heavy U.S. reliance on imported oil (which was around 7 million barrels per day in the mid-1970s), has raised the question of constructing new *deep-water ports*. Modifying most existing harbors for this purpose would be prohibitively expensive, and the most promising alternative seems to be installing deep-water mooring buoys for the big tankers, equipped with floating cargo hoses connected to underwater pipelines to shore. [32]

The large tankers claim one safety advantage over smaller ships: by reducing the number of ships needed to move a given amount of oil, they reduce congestion in sea lanes and harbors and hence should reduce the chance of collisions. On the other hand, they are considerably harder to maneuver or to stop, and the consequences of a single accident can be much more drastic. Whether the VLCCs and the ULCCs are structurally strong enough to endure for long the stresses produced by the interaction of their great weight with a violent ocean is debatable, and their record so far gives abundant cause for apprehension. Inasmuch as the basic purpose of supertankers is to provide cheap oil transportation, there is undeniably some incentive to cut corners. Almost without exception the big ships are each driven by a single propeller on a single shaft from a single steam turbine (some have two boilers feeding the turbine; most have only one). In most cases, then, just one major mechanical failure leaves the ship, with no backup system, at the mercy of the sea. [33] Furthermore, when oil begins moving out of the Arctic by tanker, the inherent hazards of tankers will be compounded by the chance of collisions with floating ice. [34]

In an attempt to bring to market some of the large amounts of natural gas now flared in the Middle East and elsewhere, increasing use of tankers that transport gas in liquefied form is likely. Liquefied natural gas (LNG) has 1/600 the volume of natural gas at normal temperature and pressure and must be kept in insulated refrigerated tanks at temperatures below the boiling point of methane (-- 161° C, or -- 260° F). Spilling small quantities of LNG onto water, which might occur in a minor accident involving an LNG tanker, could cause vapor explosions that might rupture adjacent compartments and create a much larger release. Whether a large explosion is possible in those circumstances is not certain, but a major fire or the spread of an asphyxiating cloud of unignited gas are genuine possibilities. [35] If such an event should occur in the harbor of, say, Boston or New York, the toll in life and property could be very high -- tens of thousands or more dead and billions of dollars' worth of damage. The chemical energy stored in a large LNG tanker is roughly equivalent to a megaton of high explosive, or about 40 million gallons of gasoline.

Processing. Natural gas requires virtually no processing between extraction and use as a fuel, but this is not true of oil. Crude petroleum, as it comes from the ground, is a sticky, heavy, viscous mixture of thousands of hydrocarbon compounds; its properties vary significantly from one oil-producing region to another; it is hard to handle and actually rather difficult to burn. Conversion of this messy material into the array of petroleum products used in residences, commerce, and industry is the business of refineries.

Those large industrial complexes process the thousands of chemical constituents of crude petroleum in three general ways -- sorting molecules into classes (distillation), breaking molecules apart (cracking), and reassembling them in new combinations (reforming, hydrogenation, and other processes). The partial removal of sulfur from fuel compounds for

environmental reasons is becoming another important function of refineries. The product mix from a typical U.S. refinery is outlined in Table 8-10. Within limits, refineries can and do vary this composition from season to season, producing (for example) more heating oil in the fall for use in winter and more gasoline in the spring for use in summer. Among the nonenergy uses of petroleum hydrocarbons, subsumed under the term *petrochemicals*, are waxes, ointments, paints, plastics, detergents, synthetic pesticides, films, and fibers such as nylon and polyester.

The larger refineries have capacities of around 300,000 barrels of petroleum per day (corresponding to a chemi-

cal-energy flow of about 20,000 megawatts) and cost on the order of $500 million to construct. [36] Since petroleum products are readily stored, it is not necessary to tailor the output of refineries exactly to the pattern of demand at the moment, which permits the efficient situation in which refineries run almost 24 hours per day, 365 days per year near peak capacity. When demand is less than the refinery output, stocks of refined products are built up, and when demand exceeds refinery capacity, the stocks are drawn down. Stocks and flows in the U.S. petroleum industry in mid-1975 are indicated in Figure 8-12. Note that although stocks of refined products represent little more than thirty days' consumption, the buffer provided against a cutoff of imports is somewhat greater (the combined stocks of products and crude petroleum were equivalent in 1975 to about 120 days' worth of imports). [37]

Refineries themselves have significant effects on the environment. They emit substantial amounts of a wide variety of hydrocarbons to both air and water, which are variously odorous, unsightly, toxic, carcinogenic, or combine these features. Refineries and the associated storage facilities also represent a possibility of major fire, which, if combined with adverse weather conditions that confined the combustion products in a heavily populated area, could have serious public-health consequences.

The apparent limitations on the long-continued availability of oil and gas, brought so forcefully to public attention in the mid-1970s, caused a rapid intensification of interest in the technology of extracting and using the world's much more abundant supplies of coal. The use of oil and gas instead of coal in the first place was stimulated by the portability and versatility of the gaseous and liquid fuels. Now that the substitution must be reversed, it is natural that ways to overcome coal's disadvantages in those respects are being vigorously pursued. Inasmuch as coal mining has been dangerous to miners and/or particularly damaging to the physical environment, the prospect of expanded reliance on coal has focused much attention on these problems as well.

Mining. Coal deposits occur in nature in seams ranging in thickness from a few centimeters to many meters and lying at depths ranging from zero (outcroppings) to 1000 meters and more. Whether a given seam is considered minable at all, and whether surface mining or deep mining is the method of choice, depend on the thickness of the seam, the thickness of the overburden (the depth of the seam underground), the nature of the surface terrain, and the energy content and composition of the coal. Coals with different geologic histories differ markedly in composition and energy content and are classified on that basis into ranks (Table 8-11). A coal of high rank, such as bituminous coal, repays removing more overburden or tunneling deeper to get at a thin seam than does a coal of low rank, such as lignite.

The U.S. Geological Survey calls identified seams of bituminous and anthracite coal reserves if they are thicker than 70 centimeters and if they lie under less than 300 meters of overburden. [38] For lignite and subbituminous seams to qualify as reserves, they must be thicker than 150 centimeters. Coal seams down to 600 meters deep and thicker than 35 centimeters are considered part of the minable resource (that is, economically accessible at somewhat higher prices). As a rule, seams are only classified as surface-minable if they lie under less than 45 meters of overburden, although surface mining is

---

[36]The biggest refinery in 1975 was Exxon's 450,000-bbl/day plant at Baton Rouge, Louisiana, which would probably cost almost $1 billion to duplicate (Council on Economic Priorities, "Cleaning up: The cost of refinery pollution control").

sometimes practiced through as much as 60 meters of overburden. Of particular importance in judging the feasibility of surface mining is the *stripping ratio*, which is the thickness of the overburden divided by the thickness of the seam. For economically viable mining, that ratio ranges up to 30/1 for bituminous coals and up to 18/1 for subbituminous coals and lignites.

Surface mining accounted for about half the U.S. coal production in the mid-1970s, but surface-minable coal makes up only 30 percent of the coal reserves and 10 percent of the estimated coal resources in place in the United States. [39] (The term *in place* means the amount of coal in the ground, some of which is not recoverable.) The main reason for harvesting surface-minable coal so far out of proportion to its representation in the reserves and resources in place is economic; coal can be extracted more cheaply by surface-mining techniques, which use very large machines and relatively little labor, than by deep mining.

Several kinds of surface mining are practiced, depending on terrain and the character of the seam. Open-pit strip mining is for thick, shallow coal beds on even terrain; area stripping removes the overburden from larger areas of flat-lying seams; contour strip mining exploits narrower seams that follow the contours of the land in hilly terrain. All these techniques employ large power shovels and bucket-wheel excavators (Figure 8-13). Auger mining bores into hillsides with augers up to 2 meters in diameter, generally beginning where contour mining has been carried out to the economic limit of overburden thickness. The recovery factor in surface mining (the fraction of the coal originally in place that is actually extracted) generally ranges from 80 to 90 percent. [40]

Hazards to life and limb in surface mining are modest compared to those of underground mining, but other environmental impacts are considerable. The removed overburden and exposed subsurface materials (and the land disrupted by access roads) are subject to erosion and gross down-slope motion, and cause siltation of local streams. In the eastern United States, where the coal and associated rocks are rich in pyrite, that mineral is oxidized to sulfate and sulfuric acid upon exposure to air, creating acid runoff and consequent soil acidification that kills stream life and renders revegetation difficult or impossible. In the western United States, some of the problems are ameliorated by flatter terrain and the very

[39]Theobald, Schweinfurth, and Duncan, *Energy resources*.

[40]For a particularly good discussion of the technology of coal mining, surface and underground, see E. A. Nephew, *The challenge and promise of coal*.

low sulfur content of the coal beds. On the other hand, reclamation in the West is made very difficult by the low and sporadic rainfall. Indeed, a major study by the U.S. National Academy of Sciences has argued that reclamation must be considered essentially impossible in those parts of the West where annual rainfall is less than 25 centimeters (10 inches) per year. [41]

Activities carried out under the banner of the "reclamation" of surface-mined land actually vary widely in aim, quality, and cost. The term *basic reclamation* describes attempts to minimize off-site damage, principally by arranging the displaced overburden in a stable configuration, with the best soil materials on top and the toxic and acid-forming substances on the bottom. Partial reclamation is an attempt to render the stripped land itself suitable for some productive use; this involves regrading of contours (not necessarily to the original shape), preservation or restoration of the original sequence of soil and rock strata, and several years of intensive management to render the soil productive again. Full reclamation, or restoration, means returning the land to its original contours and functions, which requires revegetation with native plant species in addition to the foregoing steps. This may be impossible in some areas--for example, where the amount of coal removed is a significant fraction of the total volume of material stripped.

The costs of reclamation range from around $500 per acre for decent, basic reclamation to $4000 per acre and more for full reclamation, where the latter is possible. [42] The costs increase sharply in steep terrain and in dry climates. Their contribution to the actual cost of coal depends, of course, on how much coal is extracted from each acre of stripped land--that is, on seam

thickness. In the United States the seams are thickest in the West. A typical value for coal recovery in Western stripping is 1.5 million metric tons per square kilometer (6700 short tons/acre), and in Montana the average is about 4 times as high. [43] In the West, reclamation costs of $6000/acre would contribute between 25 cents and $1 per short ton to the cost of coal, to be compared to typical total costs of coal production in 1973 of between $3 and $5 per short ton. Eastern strippable seams yield an average of 730,000 metric tons per square kilometer (3300 short tons/acre); there, reclamation costs of $3000/acre would add about $1 per ton to the cost of coal.

Of the 8000 square kilometers that had been surfacemined for coal in the United States by the mid-1970s, hardly any had been fully reclaimed. Indeed, until the mid-1960s, even basic reclamation was the exception, not the rule. What passed for reclamation was largely a spotty and superficial effort that served the needs of coalcompany public-relations people more than it served the land. One observer close to the subject has described reclamation of stripped land in Appalachia as "the small end of nothing, whittled down to a point." [44] The U nited Kingdom and the Federal German Republic (West Germany), major coal-mining countries in Europe, have better records of successfully practicing full reclamation in many areas. Many states in the United States now have laws requiring basic reclamation or more; how enforceable and effective they will be remains to be seen. [45]

Underground coal mining is more expensive and more hazardous to miners than surface mining, and it also has significant ecological effects. There are two basic techniques for underground mining. In *room-and-pillar mining*, a succession of underground rooms are cut into the coal seam and surrounding rock, and pillars of intact coal and rock are left standing to support the mine roof. In *continuous extraction*, the pillars are mined, temporary supports hold up the roof, and as the mining operation moves forward into the seam the roof is allowed to collapse behind it. In both approaches, the actual removal of the coal from the mine face can be done either by drilling and blasting or by cutting machines.

The most efficient method, where the character of the coal seam permits it, is a variety of continuous extraction called *longwall mining*. It uses a highly automated system of cutting machines, conveyors, and self-advancing roof supports and, accordingly, is more capitalintensive than room-and-pillar mining. Recovery factors and productivities in various methods of underground and surface mining are summarized in Table 8-12. The

average recovery factor for all underground mining in the United States in the early 1970s was around 57 percent.

Underground coal mining is widely known as an extraordinarily hazardous occupation, but not all of the hazard is inevitable. In fatal accidents (largely from falling roofs and methane explosions) per million worker hours between 1968 and 1971, there was a difference of a factor of 5 between the safest of the ten largest U.S. deep-mining enterprises and the least safe. [46] In the nonfatal injury rate in deep mines in the United States, the difference in the early 1970s between the safest company and the least safe company was about a factor of 10. The injury rate in the safest mines was less than the injury rates for the wholesale and retail trade, for real estate, and for higher education. [47] Evidently, underground coal *mining can* be made a reasonably accidentfree occupation, and with existing technology.

A major hazard to underground coal miners in addition to accidents is black lung disease (called coal workers' pneumoconiosis, or CWP, in the technical literature). The disease impairs respiration by scarring and deforming lung tissue because of the inhalation of coal dust. There is no cure; the disease can be prevented only by reducing levels of coal dust in the mines-principally by better ventilation and water-spraying. In the mid-1970s there were about 125,000 identified cases of CWP in the United States and an estimated 3000 to 4000 deaths per year in which this disease was an underlying or contributing cause. [48] The 1969 *U.S. Coal Mine Health and Safety Act* and the 1972 Black Lung Law require the federal government to compensate victims of CWP and their dependents. The payments reached $1 billion in 1973 alone, and the annual expenditure by 1980 may be $8 billion. [49] In addition, the 1969 act established strict dust-level regulations for mines. If these regulations were enforced, black lung disease would be almost completely eliminated, judging by British experience and other medical evidence. [50]

Other major environmental burdens associated with underground coal mining are acid drainage from the mines (the result of the oxidation of exposed pyrites), subsidence of land that has been undermined (about 1 acre in 2 of undermined land subsides in the United States, damaging towns and farmland), and air pollution from slow-burning fires in abandoned mines and waste heaps. [51]

Processing. More than half the coal produced in the United States is cleaned before combustion or further processing in order to reduce the content of ash and inorganic sulfur. (That part of sulfur in coal that is bound into organic compounds, which usually amounts to more than half the sulfur present, cannot be removed this way.) The environmental disruption from cleaning coal

includes significant atmospheric pollution in the form of particles, water pollution ("black water"), and the production of solid wastes. [52]

The motivation for processing coal further is twofold: (1) to remove the contained sulfur more completely, since it is a particularly dangerous pollutant if it reaches the atmosphere when coal is burned in electric power plants; and (2) to convert the coal into practical substitutes for petroleum and natural gas in applications other than electric-power generation. Gasification and liquefaction of coal are technologies that, in different variations, can

[52]Pigford et al., *Fuel cycles*.

serve either goal. *Solvent refining* is a technology not unrelated to liquefaction, but it has the sole purpose of producing a relatively clean fuel for generation of electricity.

Coal gasification has been practiced for many decades in Europe, where natural gas has been scarce and expensive. Indeed, coal gas was a major energy source in many U.S. cities until the 1920s. The basic concept behind gasification is not complicated. The coal is heated to drive off volatile substances [methane (CH_4) and more complex hydrocarbons), and then the remaining carbon is reacted with steam at high temperature to produce hydrogen and carbon monoxide ($C + H_2O \rightarrow H_2 + CO$). The reaction is endothermic (energyabsorbing), and the required heat is generally supplied by the combustion of some of the carbon ($C + O_2, \rightarrow CO_2$) and/or some of the products. The resulting mixture of H_2, CO, a little CH_4, and air has an energy content of 3.3 to 5.0 megajoules per cubic meter (100 to 150 Btu per cubic foot) and is called low-Btu gas or power gas. [53] This seems quite small compared to the 33 megajoules per cubic meter in natural gas, which is mostly methane, but the low-Btu gas is perfectly suitable as fuel for electric power plants that are near the gasification plant. (Because of its low energy density, it is not economical to transport low-Btu gas any significant distance.) The sulfur that was in the coal turns up in the gaseous product as H_2S, which lends itself to very complete removal (more than 99 percent) by reaction with lime or limestone in a desulfurization stage in the gasification plant.

For most industrial uses, a gas with higher energy content is required. The necessary 10 to 20 MJ/m_3 (300 Btu to 600 Btu per cubic foot) can be obtained by operating in oxygen rather than air (which does away with the nitrogen dilutant in the product) and by reacting some of the carbon monoxide with steam to produce more hydrogen. To drive the energy content still higher and produce a substitute for natural gas that can be distributed for domestic use in pipelines (called high-Btu gas, town gas, or pipeline gas), one must make more methane. This is done, starting with the medium-Btu product, by promoting the reaction $3H_2 + CO \rightarrow CH_4 + H_2O$.

While the chemical reactions described here seem simple enough, the technology of bringing them about on a large scale is very complex. How completely and how rapidly the reactions take place depend strongly on temperature and pressure, which depend in turn on the progress of the reactions. Catalysts are needed at some steps, and ways to add and remove specific compounds selectively at specific stages can be very complicated. Controlling all these variables in a large network of pipes and vessels is a tricky business indeed.

The existing European technologies seem best suited to a scale of operations too small for the tasks envisioned for coal gasification in the United States. Consequently, the energy crunch of the early 1970s precipitated a belated rush in the U.S. energy-research community to find ways to adapt or replace those European technologies for bigger units. [54] A few large (250×10^6 MJ/day) gasification plants of both low- and high-Btu types are scheduled to begin operation in the United States in the late 1970s, but to replace any substantial fraction of U.S. natural gas use (about $66{,}000 \times 10^6$ MJ/day in the mid-1970s) in this way would take an enormous construction effort and corresponding investment.

Large gasification plants will not be without environmental impacts--although perhaps they would be less than those of oil refineries, which in many ways they will resemble. It does seem likely from recent assessments that gasification of coal will entail, overall, much less environmental damage than combustion of the coal directly. [55] The thermal efficiency of gasification technologies (the energy content of the product divided by the energy content of the coal input) is expected to range from around 50 percent to perhaps 90 percent. [56]

The idea of gasifying coal underground without even mining it--so called *in situ* (in place) gasification--goes

---

[53] The CH_4 comes from the reaction, $C + 2H_2 \rightarrow CH_4$. For a more detailed discussion of gasification chemistry, see Hottel and Howard, *New energy*; or H. Perry, *The gasification of coal*.

[54] See, for example, A. M. Squires, *Clean fuels from coal gasification*; H. Perry , *Coal conversion technology*.

[55] Pigford et al., *Fuel cycles*; K. Smith, J. Weyant, and John P. Holdren, *Evaluation of conventional power systems*.

[56] Science and public policy program, University of Oklahoma, *Energy alternatives*.

back more than a century. The idea is to drill a number of holes into a coal seam and ignite a slow-burning underground combustion front, fed by air from one set of holes. The advancing front drives off low-Btu gas that can be collected at a second set of holes. This has been done commercially on a very small scale in the Soviet Union, and experiments were underway in the United States in the mid-1970s. [57] The intrinsic geologic and chemical-kinetic obstacles to widespread applicability or high efficiency for this approach seem large, however.

Like gasification, coal liquefaction has a history of several decades in Europe and other parts of the world, but only recently has attracted much interest in the United States. The idea is to

produce liquid hydrocarbons that could replace petroleum as feedstock (input) for refineries or, alternatively, to produce directly a clean liquid fuel for use in electricity generating plants. The technology is similar to that of gasification. (Indeed, gasification is the first step in many of the processes existing or under development.) But higher pressures, the use of different catalysts, and other alterations in the process lead to a liquid rather than a gaseous product. Liquefaction is at least a few years behind gasification on the road to full-scale commercial operation in the United States. Eventually, the thermal efficiencies and costs are expected to be similar to those of gasification. [58]

Solvent refining is a means of extracting sulfur from coal to be used in power plants with less elaborate processing than gasification or liquefaction. The coal is crushed and dissolved in a solvent; then the product is filtered to remove ash and sulfur. The result is a solid fuel with a low melting point, having an energy density about 25 percent higher than the raw coal and a sulfur content about 4 times lower than the raw coal. Some observers believe that solvent refining will be of major importance in the late 1970s and early 1980s because it is easier than gasification and liquefaction. [59] It seems equally likely, however, that the percentage of sulfur that remains after solvent refining will be too high for future air-quality standards to be met if this fuel is used.

Oil Shales and Tar Sands

The problems of extracting oil shales and tar sands are very similar to those of mining coal. Both oil shales and tar sands are solid, occur in seams that vary in depth and thickness, and lend themselves (according to the ratio of depth and thickness) to deep mining or surface mining. The only commercial tar sand operation (Athabasca, in the province of Alberta, Canada) is an open-pit mine using bucket-wheel excavators. Commercial surfacemining operations for oil shale exist in Russia, Brazil, and Manchuria, but not, as of the mid-1970s, in the Green River shales of the western United States, which contain the world's largest identified oil-shale deposits. [60]

Both major North American deposits, the Athabasca sands and the Green River shales, will require deep mining to get at most of the resource. Where the deposits are surface-minable, moreover, they pose special difficulties in reclamation--in the first case because of the harsh northern climate and in the second because of steep terrain and minimal rainfall. The energy density of oil shale and tar sands in place is low--typically 2 to 4 megajoules per kilogram (about 2 to 4 million Btu per short ton) for oil shale and 3 to 6 megajoules per kilogram for tar sands, compared to 15 megajoules per kilogram for lignite and 30 megajoules per kilogram for bituminous coal.

Extracting hydrocarbon liquids from oil shales and tar sands requires elaborate technology. For the shales, the process is called *retorting* and involves crushing the shale and heating it to about 500° C (around 900° F) to drive off the liquid. The heating uses some of the contained carbon as an energy source. Attempts to carry out this simple-sounding procedure on a large scale in practice have encountered many difficulties. [61] Extracting the bitumen (a hydrocarbon mixture) from tar sands involves shaking, screening, heating, centrifuging, steam-treating, and some other steps. There, too, difficulties have been encountered in setting up a large operation, partly

[61]For a concise description of this and other aspects of oil shale, see G. U. Dinneen and G. L. Cook, *Oil shale and the energy crisis*.

because of the wide variation in the properties of the tar sands from even a single deposit. [62] The liquids that result from oil-shale retorting and tar-sands processing serve as synthetic crude petroleum, suitable for input into refineries.

The residue from the processing operations is called *spent shale* in the case of oil shale, and *tailings* in the case of tar sands. In each case, the volume of the residue considerably exceeds the volume of the raw material when it was in place. Thus, the residue more than fills the hole in the ground it came from, so disposal of spent shale and tar-sand tailings becomes a major problem. Significant aspects of the problem, aside from just finding a place to put the material, are the large amount of water required to stabilize it (that is, to keep it from blowing or sliding away) and the leaching of salts from the stabilized waste piles into ground and surface water. Leaching is especially troublesome in the Colorado River basin, where the Green River shales are found, because of preexisting difficulties with a high salt content in the Colorado. [63] One possible approach to the problem would exploit the minable quantities of certain other minerals contained in the spent shale. Extracting them could sufficiently reduce the volume that the residue could be returned to the underground rooms from which the shale was originally extracted (by room-and-pillar mining), and be sealed in, to prevent leaking. [64]

The troublesome aspects of extraction, processing, and residue management of oil shales and tar sands have kindled widespread interest in the possibility of processing these resources in situ. The basic approach is to drill a large number of holes into the seam, fracture the material by using conventional explosives to create permeability, ignite a combustion front and sustain it with compressed air forced down some of the holes, and tap the liquids driven off by the hot combustion gases at another set of wells. [65] This approach seems to solve the solid-residue problem, but its commercial feasibility and widespread applicability remain to be demonstrated. One traditional drawback of in-situ processes has been low fractional recovery of the resource. (For example, Allen estimates 20 to 30 percent for in-situ recovery of tar sands, compared to 50 to 60 percent from underground mining and 85 to 90 percent from open-pit mining.) [66]

Electricity Generation with Fossil Fuels

Electricity generation accounted in the mid- 1970s for about 70 percent of U.S. coal consumption, 15 percent of natural-gas consumption, and 10 percent of petroleum consumption. The technology with which a fossil fuel is used to generate electricity is the same in major

respects, regardless of whether oil, gas, or coal is the fuel of choice. It is called the thermal generation of electricity because heat is deliberately produced as a step in the process.

Operation of thermal power plants. Most thermal-generating plants employ a steam cycle, which consists of the sequence of energy conversions indicated in Figure 8-14. Fuel and air are injected continuously into a furnace, where they are burned (coal has been pulverized first). The furnace is a metal box, which in a large electric power plant can be 30 meters on a side and more than 30 meters high. The box is lined with tubes that make up the boiler. Water flows through them and is heated and turned to steam by thermal energy transferred from the hot combustion products outside the tubes. The steam, which reaches pressures of 70 kilograms per square centimeter (1000 pounds per square inch) and temperatures above 500° C, is then directed into a steam turbine, usually in a series of stages--high pressure, medium pressure, and low pressure (Figure 8-15). A turbine is just a device that turns a fluid's internal energy (associated with temperature and pressure) into the mechanical energy of a rotating shaft. (The fluid can be a liquid, a gas, or a mixture; in a steam turbine it is mostly water vapor--a gas--with some liquid water appearing at the low-pressure end.) The conversion from internal to mechanical energy is accomplished by arranging blades

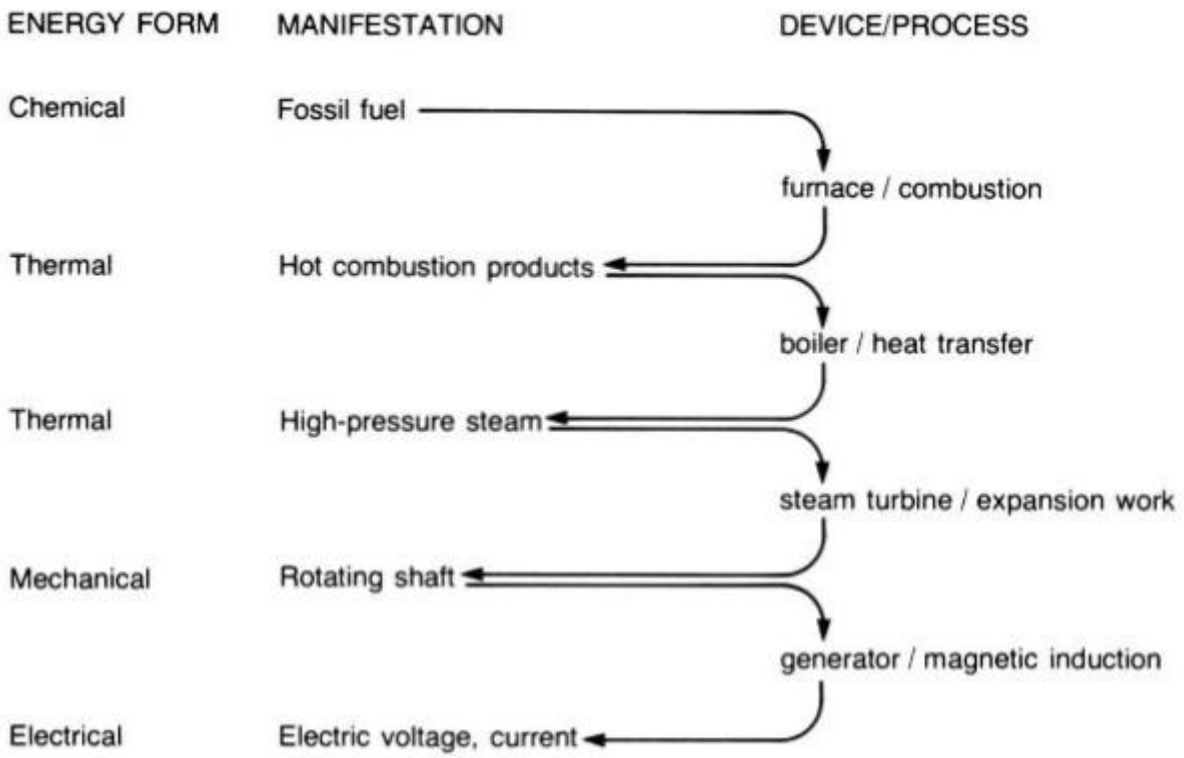

FIGURE 8-14 Energy conversions in thermal electricity generation with fossil fuels. The transformation from chemical to electrical energy takes place in stages, each of which exacts a toll in energy converted to waste heat.

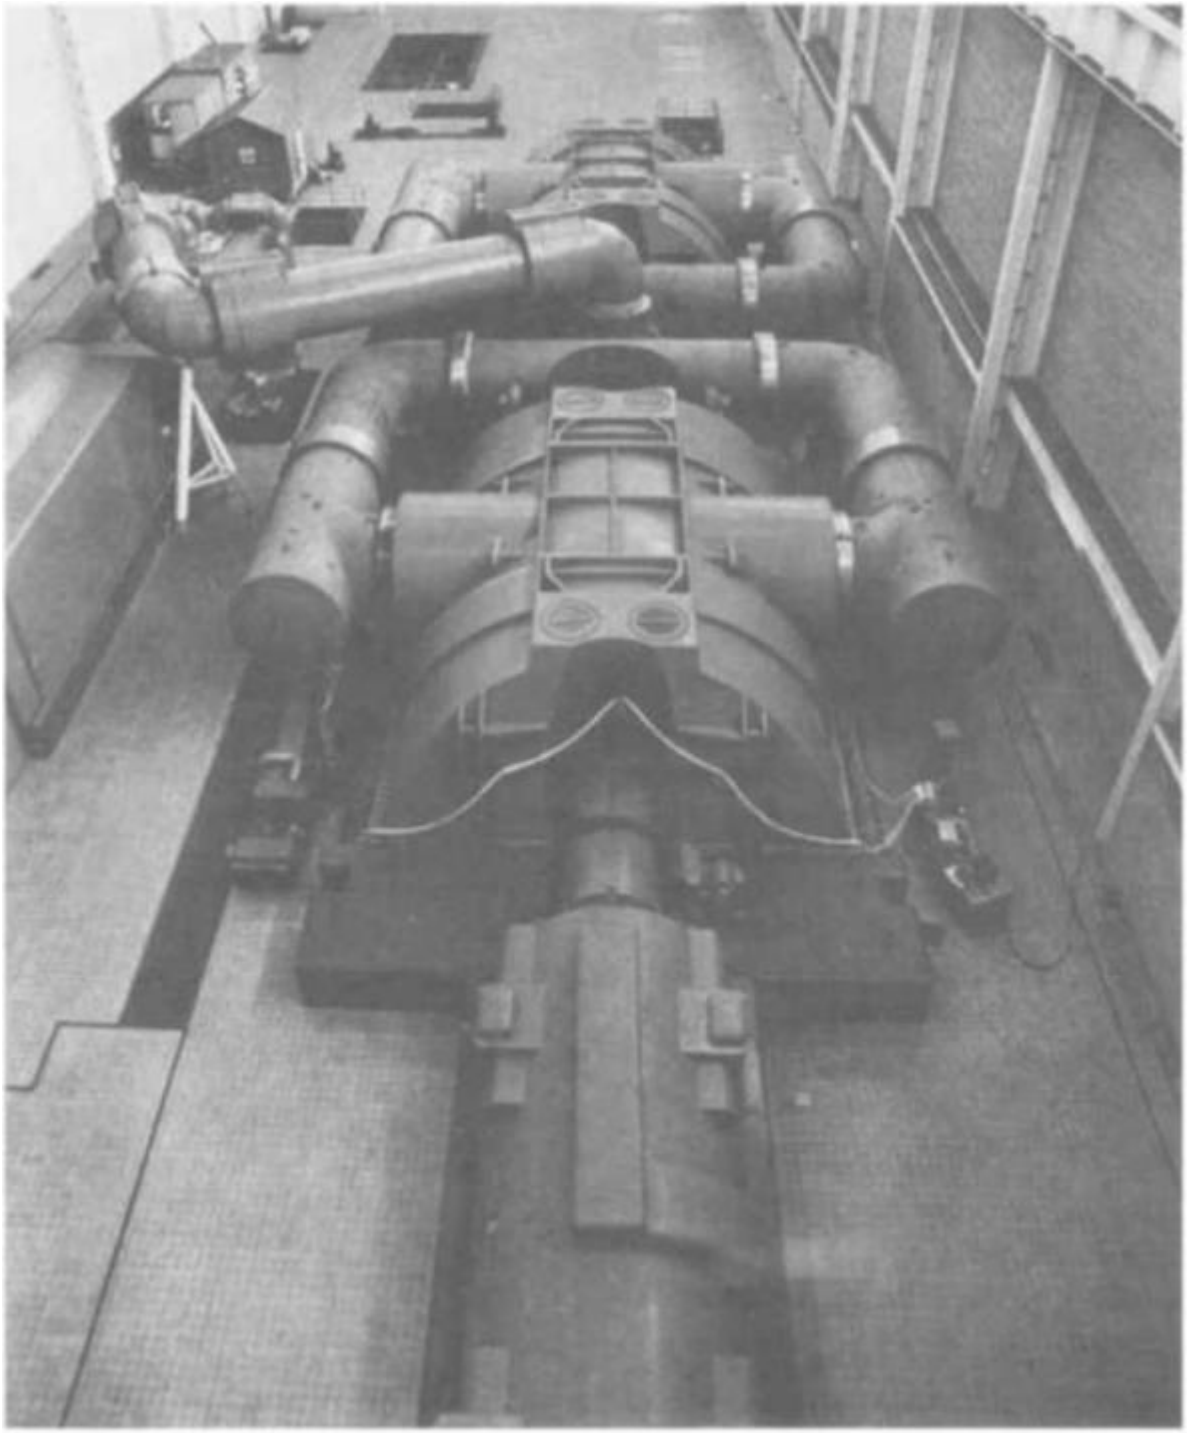

FIGURE 8-15 A compound steam-turbine-generator. The high-pressure turbine (at the left under the sharply angled duct) drives one generator, and the medium- and low-pressure turbines (center) drive another (foreground). The unit delivers electricity at a maximum rate of over I million kilowatts. (Courtesy Ben Rose.)

on a shaft in such a way that the working fluid is forced to turn them as it pushes its way from the high-pressure end of the device to the low-pressure end. Between the high-pressure stage and the medium- or low-pressure stage of the turbines in large thermal-power plants, the steam is usually returned to a special section of the boiler for *reheat*. [67]

The turbine shaft is connected to a generator shaft, which, as it spins, forces electric conductors to move through a magnetic field produced by electromagnets. The motion of a conductor through a magnetic field induces electric voltages, which, when connected to an external circuit, drive currents. [68] Generators used in typical power plants produce alternating current (the direction of the voltage and the current reverses repeatedly, going through about 60 complete cycles per second) at between 10,000 and 20,000 volts. The linked turbine and generator system is often called a *turbogenerator*.

The electricity is the desired output of a power plant, but there are also undesired (and in part unavoidable) outputs. One is waste heat. When the spent steam leaves the low-pressure turbine, it passes into a condenser, where it is returned to the liquid state so it can be returned readily to the boiler. In the process of being condensed to water, the steam gives up heat to a separate stream of water flowing through the condenser for that purpose. The warmed condenser water typically either is returned to the environment by direct flow into the ocean, lake, or river from which it came (once-through cooling), or it passes through a cooling tower, where the heat is transferred to the atmosphere.

That some of the heat produced by the combustion of fuel must be discharged from the steam cycle instead of being converted into electricity is a manifestation of the second law of thermodynamics. (Recall, from Box 2-4, that one of this law's many formulations says no process is possible whose sole result is the conversion of an amount of heat entirely into work. Turning a generator shaft is work.) Any device that converts heat into work is called a *heat engine*. The efficiency of any heat engine (that is, the fraction of the energy it handles that can be turned into work) cannot exceed 1 $-T_{low}/T_{high}$. [T_{low} is the lowest temperature at which the engine discharges heat (the temperature of the *heat sink*), and T_{high} is the temperature of the heat source, measured with respect to absolute zero.]

In a typical fossil-fuel-burning power plant, the *pertinent* value of T high is the maximum steam temperature (around 800° kelvin), and the value of T_{low} is the temperature of the source of cooling water (say, 300° kelvin). Hence, the maximum theoretical efficiency is 1 -- 300/800, or 0.625. Practical power plants are necessarily far from ideal heat engines in many respects--approaching the theoretical ideal too closely in practice becomes prohibitively expensive. The average thermal efficiency (first-law efficiency) of fossil-fueled power plants in service in the United States in the mid-1970s (output of electricity divided by input of chemical energy) was only a bit over half the above figure-about 0.33, or 33 percent. [69] This means that two-thirds of the energy released by burning fossil fuels in electricity generating plants leaves the power plant as heat, not electricity. The most efficient conventional fossil-fueled power plants in operation are about 40 percent efficient, where 60 percent of the fuel's energy leaves the plant as heat. (The management of heat released from power plants is a problem common to all thermal generation of electricity, not just fossil fuels, so more detailed discussion of the associated problems is postponed to the section of text on general environmental problems of energy technology.)

Not all the heat discharged by fossil-fueled power plants leaves at the condenser; some leaves the furnace with the hot combustion products and is exhausted up the stack. Along with that heated air go various environmentally significant combustion products: sulfur dioxide (SO_2), produced by the combustion of sulfur present in the fuel as a contaminant; oxides of nitrogen (NO and NO_2, often labeled together as NO_x) produced when nitrogen in air and in the fuel combines with oxygen in

[67]An excellent introduction to the technology of energy conversion is W. C. Reynolds, *Energy: From nature to man*; see also C. Summers, *The conversion of energy*.

[68]See Reynolds, *Energy*, chapter 6, or any basic physics text.

[69]For a more thorough explanation of just how the second law exerts its toll in a steam power plant, see the very readable text by T. J. Healy, *Energy, electric power, and man*, chapter 5 (1974). For explanations of the inefficiencies beyond those described by the second law, see Summers, *The conversion*; and Reynolds, *Energy*.

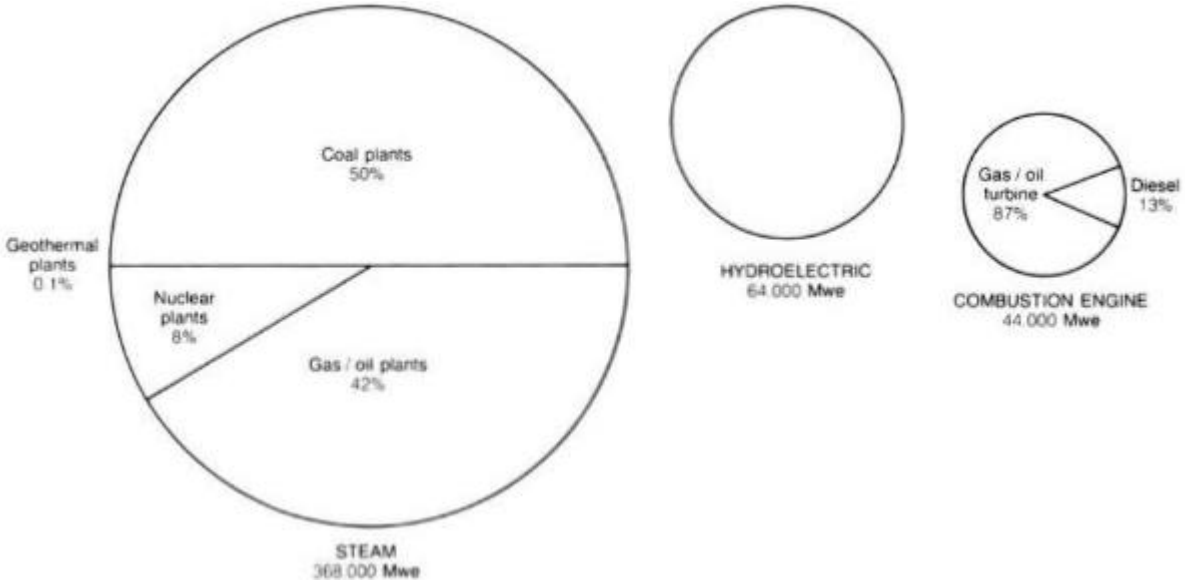

FIGURE 8-16 U.S. electric utility generating capacity. The total utility owned capacity is 476,000 electrical megawatts. Private industrial plants total an additional 19,000 megawatts. (Data are for January 1, 1975, from U.S. Department of Commerce.)

the hottest parts of the flame; solid particles (containing ash and such heavy metals as lead and cadmium); trace-element vapors (such as mercury); and carbon dioxide (CO_2) and water vapor (H_2O), the normal products of complete combustion of hydrocarbon fuels. Because power-plant furnaces are designed to give very complete combustion of the fuel, emission of pollutants arising from incomplete combustion--that is, carbon monoxide (CO) and unburnt hydrocarbons--is small. (This is not true of automobile engines.) The actual quantities and control of the effluents from fossil-fueled power plants are discussed in this chapter; their effects on human health and on the environment are considered in Chapter 10 and Chapter 11.

Two kinds of fossil-fueled thermal power plants other than those relying on steam cycles are in widespread use. One is the diesel generator, in which a diesel internalcombustion engine drives an electric generator. Because of their high capital costs, such units have not been able to compete economically with the steam cycle in very large sizes (more than a few megawatts), but they are very suitable for emergency power and for service in isolated and sparsely populated areas where electricity needs are not as large. The thermal efficiency of a modern dieselelectric unit is around 33 percent. Less expensive but also somewhat less efficient than diesels are gas turbines. Gas turbines for electric-power generation are very similar to those that power jet aircraft; the hot combustion products themselves turn the turbine, which is directly connected to a generator, and virtually all the waste heat is discharged directly into the atmosphere in the exhaust. These devices are also called *combustion turbines*--combustion gases turn the turbine, but the fuel can be liquid and often is. Even coal could be used, except that its dirty combustion products would erode the turbine blades too quickly. Gas turbines today are most widely used for *peak power*--that is, for helping meet demand for electricity at the hours of the day and on the days of the year when that demand is highest. Gas turbines are used this way because of both their rapid start-up and their low capital cost. Better gas-turbine design is improving the efficiency and operating lifetime of these devices, and their future substitution for steam turbines in large, baseload thermal-power plants has been envisioned.

The most promising avenue toward increasing the thermal efficiency of fossil-fueled power plants in the near future is to marry gas-turbine and steam-turbine technology in what is called a *combined cycle*. There, the hot exhaust of the gas turbine goes to a boiler where it raises steam for a steam turbine; in this role, the gas turbine is called a *topping cycle*. The system combines the good performance of gas turbines at very high temperatures with the ability of a steam cycle to extract energy down to low temperatures, resulting in overall thermal efficiencies of between 45 and 55 percent. Several such installations were planned or were under construction in

the mid- 1970s for commercial use by electric utilities. The composition of the electricity-generating capacity in the United States in the mid-1970s is shown in Figure 8-16. The nuclear, geothermal, and hydroelectric components are discussed later in this chapter.

Air pollution control for power plants. Considerable ingenuity and expense have been applied to the task of reducing the air pollutants emitted by fossil-fuelburning electric power plants. Inasmuch as coal is both the most abundant of the conventional fossil fuels and the worst polluter, it is treated most thoroughly here. Some comparisons with oil and gas are made at the end of the discussion.

The most visible air pollutant from coal-burning power plants is particulate matter. The simplest and least expensive methods for reducing particle emissions are settling chambers, in which the exhaust gas is slowed down enough to let heavy particles fall out by gravity; cyclone separators, in which swirling the exhaust gas throws particles to the edges of the separators for collection; and spray towers, in which water is sprayed head-on into the exhaust gases, from which it scrubs out some of the particles. [70] These techniques are not effective for removing particles smaller than about 10 microns in diameter (1 micron = 10^{-6} meter), which are the most troublesome

environmentally. Increasingly tight emissions regulations have therefore required the widespread application of a more complicated and expensive technology, the *electrostatic* precipitator (Figure 8-17). In such a device, electrons are pulled off a central conductor by a very strong electric field. The electrons tend to be captured by gas molecules passing through the device in the exhaust stream, and the charged molecules in turn attach themselves to particles. So charged, the particles are attracted to the positively charged or grounded surrounding wall, on which they collect. Modern electrostatic precipitators under favorable circumstances can collect between 97 and 99.5 percent of the mass of particles in the stack gases from a coal-burning power plant, but the uncollected fraction consists mainly of the

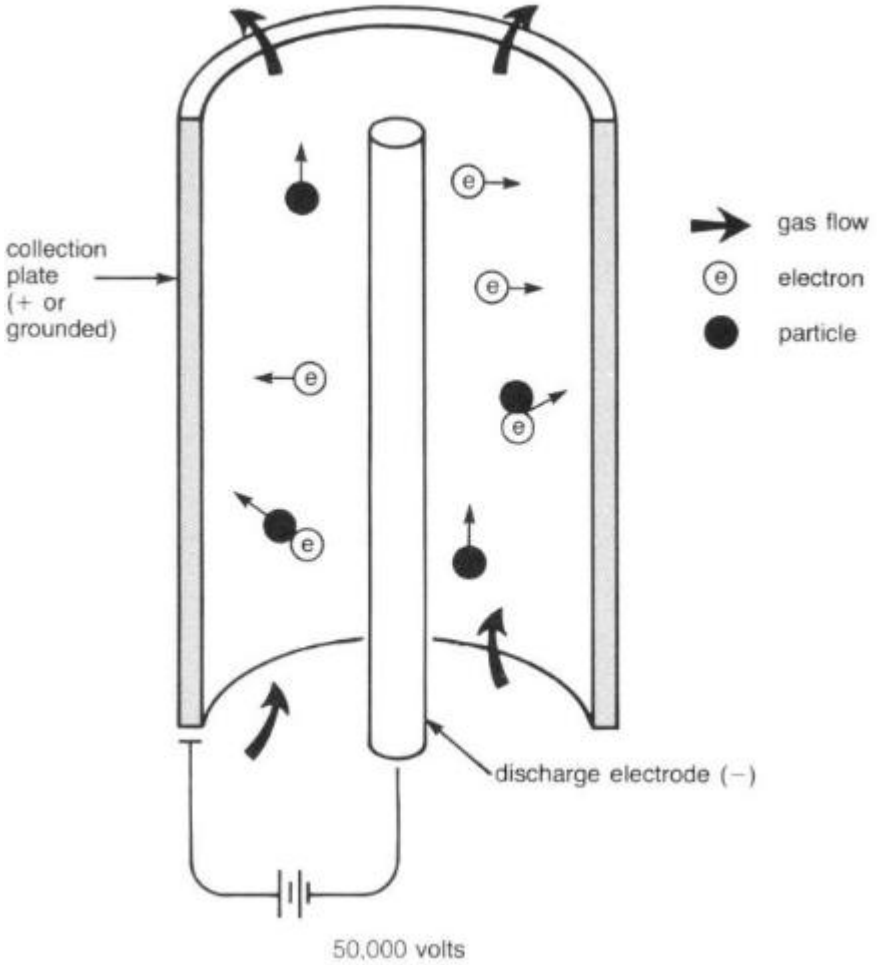

FIGURE 8-17 An electrostatic precipitator. Electrons drawn from the discharge electrode attach themselves to the particles, and the charged combination is drawn to the collector plate.

light and especially dangerous particles smaller than 1 micron in diameter. Breakdown of the precipitators, which is not infrequent, causes substantial additional emissions in practice.

The substance widely regarded as the most dangerous air pollutant emitted by coal-burning power plants is sulfur, in the form of sulfur dioxide (SO_2) and the more oxidized sulfur trioxide

(SO_3). Many techniques have been tried in the attempt to reduce emissions of sulfur oxides. We summarize some of the more important approaches here.

It would be convenient to find coal that is naturally low enough in sulfur to meet emission standards. (The 1975 U.S. standard for new coal plants was 0.6 pounds of sulfur per million Btu of thermal energy, which corresponds to 0.7 percent sulfur in bituminous coal containing 12,000 Btu per pound or 0.4 percent sulfur in lignite

[70] For more detail on these and other pollution-control techniques, see G. M. Masters, *Introduction to environmental science and technology*, chapter 10.

containing 7000 Btu per pound.) [71] Unfortunately, only a small fraction of U.S. recoverable coal reserves contain so little sulfur -- only about 16 billion out of 200 billion tons of recoverable reserves as of 1970, according to Rieber. [72] The amount of coal that could meet the 1975 standard after washing might be as high as 45 billion tons, but the amount would plummet to almost nothing if the standard were changed by the mid-1980s to 0.2 pounds of sulfur or less per million Btu. Such a change would certainly be desirable from the environmental point of view, and many think it will be made. [73]

An approach to sulfur control that has been especially popular in the United Kingdom is the use of unusually tall stacks to disperse the material more effectively. This, of course, is not really control at all; it merely alleviates acute problems near a plant by spreading out the damage. Scandinavians, who have reason to believe some of their problems with acidic rainfall (see Chapter 11) partly originate in sulfur oxides blowing over from the United Kingdom, do not perceive much merit in this approach, and they are right.

A large amount of effort has been invested, in the United States and elsewhere, in developing technology for removing sulfur oxides from stack gases before the gases reach the atmosphere. Indeed, the practicality of such technology for commercial application in electric utilities has been the subject of a prolonged and bitter controversy between the utilities and the U.S. Environmental Protection Agency in the early to mid-1970s.

The most highly developed of the technologies for cleaning stack gases is *wet scrubbing*, in which the exhaust gases are treated with a slurry of lime (CaO) or limestone ($CaCO_3$). (A slurry is a thick suspension of solid particles in water.) The oxides of sulfur react with the calcium to form insoluble calcium sulfites and sulfates, which are collected and eventually disposed of as a sludge. A definitive report on the subject in 1975 indicated that lime and limestone scrubbers on units up to 175 electrical megawatts had achieved 90-percent control of the sulfur oxides produced from low-sulfur coal (less than 1 percent sulfur). [74] For medium-to-high-sulfur coal, 90percent control was reported on 100-megawatt units burning coal that was low in chlorine, but high-chlorine coal was posing problems. [The chlorine forms hydrochloric acid (HC1), which corrodes the equipment and makes the sludge acidic.]

The largest coal-fired units being built in the mid1970s were about 750 electrical megawatts (a single power plant may have more than one unit). The report estimated installation costs of lime and limestone scrubbing at $60 to $130 (1974) per electrical kilowatt of capacity; equipping a 750-Mwe plant at $100 per kilowatt would cost $75 million-perhaps 20 percent of the cost of the power plant. Taking this expense and the costs of operating the scrubbers into account, the study computed an increase in electricity cost because of sulfur control of 0.3 to 0.6 cents per kilowatt hour, compared to total costs of electricity from coal in the range of 1.5 to 2.5 cents per kilowatt hour. When scrubbers are retrofitted to existing plants, rather than being built into new plants, the cost of sulfur control increases to 0.4 to 0.8 cents per kilowatt hour.

Aside from the expense and (according to U.S. utilities) the still-questionable reliability of the scrubbers, their most serious drawback is that they produce very large quantities of sludge. This can amount to more than a million metric tons per year for a 1000-Mwe plant, burning coal with 3 percent sulfur. The sludge is capable of causing serious water pollution, and disposing of the production of just one plant can consume around 1.5 square kilometers of land for sludge piles per year. [75] Using sludge for landfill or as foundation for highways has been suggested, but it is doubtful whether the United States (at least) really needs much more of either.

To avoid the waste problems of such throwaway stack-gas-control processes as wet scrubbing with lime and limestone, regenerative processes can be used. They produce sulfur or sulfuric acid, which can be sold, and recycle the catalysts (such as vanadium oxide) and scavengers (magnesium oxide, sodium sulfite) that are

---

[71] The notion that much "low-sulfur" Western coal does not deserve to be included among the reserves capable of meeting the 1975 standard, because its low energy content more than compensates for its low sulfur content, was slow to be appreciated. The paper most responsible for the awakening was Michael Rieber's *Low sulfur coal: A revision of reserve and supply estimates*. The English system of measure is used here because those are the official units used by the EPA.

TABLE 8-13
Air Pollution from Fossil-Fuel Electricity Generating Plants (million kg pollutant / billion kwh generated)

	Sulfur oxides		Particles		Nitrogen oxides		Hydrocarbons	
Uncontrolled coal *	16.0	(0.03)	6.7	(0.5)	3.0	(0.04)	0.39	(0.02)
Controlled coal (97% particles, 90% S)	1.6	(0.03)	0.2	(0.5)	3.0	(0.04)	0.39	(0.02)
Residual fuel oil (no controls)	6.5	(0.2)	0.22	(0.03)	2.9	(0.2)	0.53	(0.3)

	Sulfur oxides		Particles		Nitrogen oxides		Hydrocarbons	
Gasified coal (combined-cycle)	0.37	(0.03)	0.026	(0.5)	0.079	(0.04)	0.10	(0.02)
Natural gas	0.003	(0.1)	0.059	(0.002)	1.54	(0.3)	0.10	(0.002)

Note: A 1000-Mwe plant running at a typical average of 75 percent of its theoretical capacity generates 6.57 billion kilowatt hours per year. In each category, the first number is emissions from power plant itself. The number in parentheses represents the emissions from associated fuel-processing.

*2.6% sulfur, 12.5% ash, 28 MJ/kg.

Sources: Pigford et al., *Fuel cycles*; Smith et al., *Evaluation*.

used to extract the sulfur dioxide from the stack gas. [76] Regenerative processes have suffered from high costs and from the fact that their widespread implementation would quickly saturate the sulfur and sulfuric acid markets.

One other approach to sulfur control worth mentioning is drastic modification of the furnace and boiler in ways that would allow capturing the sulfur essentially at the time of combustion. The most promising technology of this type relies on gasifying the coal in a fluidized bed at the base of the boiler, instead of in a separate gasification plant. [77] Like the other forms of gasification, the fluidized-bed boiler may offer one of the better hopes for lowering sulfur emissions from coal combustion in the long term.

In practice, technologies for controlling sulfur and particles must be coordinated, not merely because the effects of the two pollutants on health are most severe when the two are present in combination (see Chapter 10), but also because one control technology may help or hinder the other. Some desulfurization steps require that very efficient particle control precede them or they do not work. Some electrostatic precipitators do not work well with low-sulfur coal. Some wet scrubbers extract particles as well as sulfur quite efficiently.

Unfortunately, the methods and combinations that succeed in controlling sulfur and particles do essentially nothing about nitrogen oxides. Those too, are dangerous to health and to the broader environment, but one hears little about nitrogen-oxide control for power plants because there are few promising techniques for doing it. Modifying burner and furnace design and operations to lower peak flame temperatures can provide an improvement of only around a factor of 2. [78] Burning in oxygen instead of air would not be worth its considerable cost, because there is enough nitrogen in most fossil fuels to keep emissions high despite this measure. Approaches like the catalytic converter, being used to control nitrogen oxides in automobiles, seem impractical or hopelessly expensive when applied to the sizable gas flows of a large electric power plant.

Carbon dioxide is produced in direct proportion to the carbon content of the fuel that is burned. Although it has no direct significance for health, the carbon dioxide can influence climatic processes globally. The quantities of carbon dioxide produced are much too large to catch and contain -- 2 to 3 tons of CO_2 per ton of coal. One report has proposed concentrating as much of the world's fossil-fuel conversion as possible at central coastal sites and discharging the carbon

dioxide produced deep underwater to hasten uptake of some of it by the ocean. [79] This scheme is burdened with practical and economic difficulties so great that it cannot be considered a serious alternative for many decades, if ever.

Table 8-13 summarizes the air-emissions characteristics of the major fossil-fueled thermal technologies for electricity generation. The last one listed, natural gas, appears primarily as a yardstick. This cleanest of the fossil fuels is really too valuable to be burned in electric power plants and will almost certainly be reserved in the future for direct uses, where its portability and clean burning are essential.

Substances and Physical Units

Ci	curie
D	deuterium
MPC	maximum permissible concentration
MWD	megawatt day (virtually always thermal)
Mwe	megawatt (electrical)
Mwt	megawatt (thermal)
Pu-239	fissile isotope of plutonium,

	Development Administration		produced from U-238
GAO *	General Accounting Office	RCG	radioactivity concentration guide (euphemism for MPC)
IAEA	International Atomic Energy Agency	T	tritium
ICRP	International Council on Radiation Protection	Th-232	naturally occurring fertile isotope of thorium
NAS/ NAE	National Academy of Sciences/ National Academy of Engineering	U-233	fissile isotope of uranium, produced from thorium
NFS	Nuclear Fuel Services, Incorporated	U-235	naturally occurring fissile isotope of uranium
NPT	Nonproliferation Treaty		
NRC *	Nuclear Regulatory Commission	U-238	naturally occurring fertile isotope of uranium
NRDC	Natural Resources Defense Council		
UCS	Union of Concerned Scientists		

*Denotes federal agency.

Nuclear Fission

The physics of releasing energy from the fission of uranium, thorium, and plutonium is not terribly complicated, aside from some details (refer to Box 8-2), and it is now thoroughly understood by nuclear scientists. By contrast, the technology of harnessing this energy reliably, economically, and on a very large scale is very complicated, and there are some not-so-unimportant details that nuclear engineers and analysts have not yet worked out completely. Some of the important problems with nuclear fission, moreover, are not technological at all -- or even environmental in a narrow sense -- but social. In the space available here we can only touch on some of the main characteristics of fission technology and the questions that surround it, while guiding the reader to some of the larger and often more technical literature that exists on the subject. Abbreviations for quantities, units, technologies, and organizations mentioned frequently in this section and in the section on fusion, following, are summarized in Box 8-3.

Some basic information about radioactivity and radiation that will be useful in this discussion of nuclear technology appears in Box 8-4. The behavior of radioactivity in the environment and its effects on human health are considered in Chapters 10 and 11.

The nuclear fuel cycle associated with electricity production from fission is represented in Figure 8-18. Some reactors have fuel cycles different in certain respects from this one, which is for reactors using enriched uranium and plutonium as fuel. Those differences will be pointed out as we consider the stages of the fuel cycle individually.

Mining and milling. Uranium is mined on the surface in open-pit mines and underground by room-

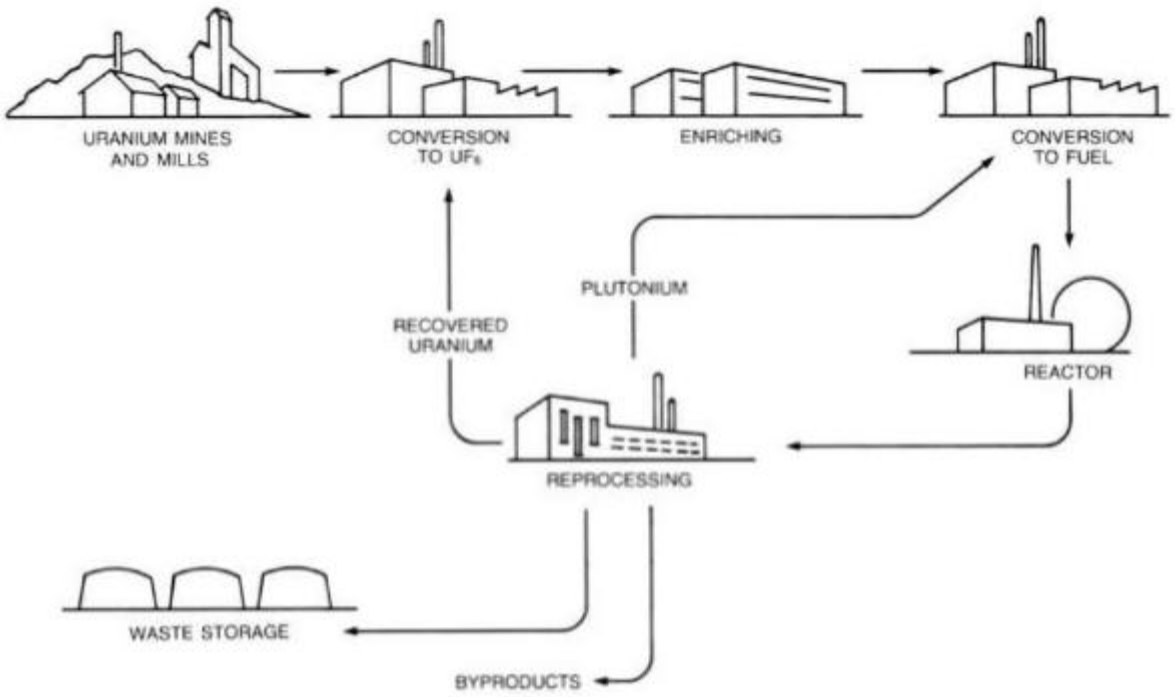

FIGURE 8-18 The nuclear fuel cycle for light-water reactors. Reprocessing, recycle of uranium and plutonium, and final waste-storage steps were not yet in regular operation as of early 1977. (From U.S. Energy Research and Development Administration, 1975.)

and-pillar methods. Production in the mid- 1970s in the United States was split about half and half between surface and underground mining. [80] The problems in both cases are similar to those of coal mining: scarred landscapes, disposal of removed materials, revegetation in the dry climate of the Colorado plateau where the ore is found, poor working conditions and dangers in the underground mines. In place of the coal miner's exposure to black lung, the underground uranium miner is exposed to radon gas, a member of the radioactive decay chain leading from uranium-238. The radon seeps from the walls into the air in the mine, where it is inhaled. As a gas, it is exhaled again, but the radon atoms that happen to undergo radioactive decay while in the lungs deposit there the solid radioactive daughter polonium-218. Polonium-218 and its daughter lead-214 are both called radon daughters, and have been responsible for lungcancer rates among uranium miners about 4 times higher than in the rest of the population. [81] Present U.S. standards for permissible exposure for uranium miners allow about twentyfold less exposure than those that prevailed when miners now dying of cancer were exposed. If the standards are complied with in practice -which involves good mine ventilation and strictly limiting miners' time underground -- the risk will be much reduced. Whether the standards are yet strict enough is controversial.

In comparing all the problems of uranium mining with those of coal mining, it is important also to note that uranium requires considerably less material to be mined per electrical kilowatt hour actually generated. About 0.2 percent by weight of the sandstone ore mined in the Colorado

plateau is recoverable uranium oxide (U_3O_8), 85 percent by weight of the U_3O_8 is uranium, and at most

[80]For technical details and descriptions of some of the environmental impacts of this and other stages of the nuclear fuel cycle (excepting reactors themselves), see U.S. Atomic Energy Commission, *Environmental survey of the nuclear fuel cycle*. An excellent critical review is D. Ford, et al., *The nuclear fuel cycle*.

[81]F. Lundin, et al., *Mortality of uranium miners in relation to radiation exposure, hardrock mining and cigarette smoking 1950-1967*. A most interesting part of the results reported is that the cancer rates of nonsmokers and the much higher cancer rates of smokers are *multiplied* by the same factor for the uranium miners--that is, the effects of smoking and radon are not simply additive. (See the discussion of synergism in Chapter 10.)

BOX 8-4 Radioactivity and Radiation

Radioactive atoms are atoms that undergo spontaneous transformations of the structure of their atomic nuclei. *Spontaneous* means the transformations take place without being stimulated by any event or force external to the atom. In the course of such a transformation, the nucleus emits energy. That energy is carried by particles that leave the nucleus or by electromagnetic radiation or both. The particles are generally either *alpha particles* (each a helium nucleus consisting of 2 protons and 2 neutrons) or *beta particles* (either electrons, arising from the disintegration of a neutron into a proton and an electron, or positrons, which are like electrons but positively charged and arise from the disintegration of a proton into a positron and a neutron). Less commonly, individual neutrons are emitted. The electromagnetic radiation emitted during nuclear transformations is called *gamma rays*; gamma rays are virtually identical to X-rays but often more energetic (hence, more penetrating). For reasons both historical and physical, the particles and the gamma rays are all termed *radiation*.

The spontaneous nuclear transformations that make up radioactivity always change the nuclear properties of the atoms involved and often change the chemical properties. If only the nuclear properties change, the atom involved becomes another isotope of the same element; if the chemical properties change, the atom involved becomes another element. Because the initial substance in any case is disappearing (by being changed into something else) the process is often termed *radioactive decay*.

Radioactive decay proceeds in such a way that a *fixed percentage* of the number of radioactive atoms present at the beginning of a specific period of time (a year, a day, a minute) undergo nuclear transformation during that period. Such a process (which also occurs with certain physical phenomena other than radioactivity) is the exact opposite of exponential growth, in which something increases by a fixed percentage of its initial value in a specified time. Whereas exponential growth at a given rate can be characterized by a doubling time, an exponential decay process such as radioactivity can be characterized by a *half-life* -- the time required for half of a given initial quantity to disappear (or to be transformed into something else).

Suppose, for example, that we have a barrel of 1000 apples, which become rotten with a halflife of one week. This means that, after the first week, half of the 1000 apples have rotted, leaving 500 good ones. After another half-life -- another week -- half of the remaining 500 apples have rotted, leaving 250 good ones. After a total of three weeks -- three half-lives --125 apples, or one-eighth of the initial 1000 remain in good condition.

The pattern for any exponential decay process is as follows:

Elapsed half-lives	Fraction remaining	Elapsed half-lives	Fraction remaining
0	1	4	1/16
1	1/2	10	1/1,024
2	1/4	20	1/1,048,576
3	1/8	N	$(1/2)^N$

Each radioactive substance has its own unique and unchanging half-life (abbreviated *t*1/2). For some substances the half-life is a fraction of a second; for others it is billions of years. A short half-life means the material is soon virtually gone, but nuclear transformations occur initially at a great rate. Broadly speaking, the associated hazard is short-lived but initially intense. A longer half-life means a proportionately slower initial rate of nuclear transformations. The associated hazard is initially less intense than that of a like number of atoms of a substance with a shorter half-life, but the hazard lasts much longer.

When we say a substance is highly radioactive, we mean many nuclear transformations occur within it each second. The yardstick by which radioactivity is measured is the radioactivity of 1 gram of radium-226, which undergoes about 37 billion nuclear transformations per second. That amount of radioactivity is called a curie (Ci). After radium's half-life of 1622 years, an initial gram will have diminished to half a gram, and the rate of nuclear transformations within the radium will be 18.5 billion per second, or half a curie.

For an isotope with a half-life much longer than radium (for example, uranium-235, with *t*1/2 = 713 million years), the amount needed to make a curie is much larger than a gram. It takes 476 kilograms of uranium-235 to produce the 37 billion disintegrations per second that make a curie. * For an isotope with a much shorter half-life than radium, a curie is a much smaller amount than a gram. Only 8 micrograms of iodine-131 (*t*1/2 = 8.06 days) make a curie.

The isotope formed by the radioactive decay of another may itself be radioactive. For example, the decay of radium-226 produces radon222, a gas that is radioactive with a half-life of 3.83 days. The decay of the radon produces polonium-218, which is radioactive with a half life of 3.05 minutes. This is called a decay chain, and members of the chain are called *parents* and *daughters*, radium-226 is the parent of radon222, which is the parent of polonium-218; polonium-218 is the daughter of radon-222. Radium is itself the sixth member down that

particular chain, which begins with uranium-238 and ends with stable (nonradioactive) lead-206. Such chains are characteristic of the decay of radioactive isotopes higher than lead in the periodic table. Many isotopes lighter than lead produce stable daughters upon decay. For example, tritium, which is another name for hydrogen-3, decays to stable helium-3. [**]

Whereas curies measure the amount of radioactivity present, *rads* and *rems* measure the doses of radiation the radioactivity delivers. The rad is a measure of the amount of energy deposited per unit mass of absorbing material. (One rad equals 100 ergs of energy -- 10 millionths of a joule - deposited per gram of absorber.) Rems equal rads multiplied by a factor called relative biological effectiveness (RBE), which measures how effective the deposited energy is in doing damage. RBE is dependent on the particular biological system and effect being measured, as well as on the specific conditions of the exposure. The *quality factor* (QF) is a rough measure of the relative effectiveness of a particular type of radiation and is used for general discussions of radiation effects. It corresponds to the high end of the range of measured RBEs for a given type of radiation. The QF is 1.0 for gamma rays and most beta particles, but it is usually considered to be 10 for alpha particles. Doses most commonly encountered are measured in millirems. (One millirem equals 0.001 rem). For example, the average whole-body dose delivered to individuals in the United States from natural sources of radiation is between 100 and 200 millirems per year. (A whole-body dose means much more energy is deposited than if the dose were confined to a single part of the body, as sometimes happens; remember that the deposited energy is the product of the dose multiplied by the mass of tissue receiving that dose.)

The complicated connection between radiation dose and health is discussed more fully in Chapter 10. Here we mention only two figures to serve as yardsticks: (1) a whole-body dose of about 350 rems delivered suddenly would result in the deaths of half the people so exposed within thirty days (this is the LD_{30}^{50}); [†] (2) the wholebody dose -- beyond that which comes from natural sources and medical exposures -- that U.S. regulations deem permissible for individual members of the public is 500 millirems per year (3 to 5 times the dose from natural sources and about 0.001 of the acute LD_{30}^{50}. The maximum permissible concentrations (MPCS) of various radioactive substances in air and water to which the public is exposed are generally determined on the basis of this guideline of 500 millirems per year. MPCs are measured in microcuries per cubic centimeter ($\mu Ci/cm^3$), which is the same as curies per cubic meter (Ci/m^3).

---

[*] Note that there is no direct connection between the radioactive half-life of an isotope and whether the isotope is suitable fuel for fission or fusion. There are over 1400 radioactive isotopes, but only a few are fissile, and those that are have quite varied half-lives. Most of the fusion fuels are not radioactive at all. Indeed, radioactivity, on the one hand, and fission and fusion, on the other, represent quite different kinds of nuclear energy; fission and fusion release energy stored in what is known as the *strong nuclear force*; radioactivity releases energy stored in the *weak nuclear force*.

[**] One of the best introductions to radioactivity and radiation appears in John Harte and Robert H. Socolow, *Patient Earth*.

[†] LD^{50} is the most common statistic used in measuring lethal doses of anything (such as insecticides); its use is not confined to radiology.

1 percent by weight of the uranium can actually be fissioned (at 79,000 MJ/g) in the present-day nonbreeder reactors. Hence, one mines 1 kilogram of uranium ore to yield the same thermal energy at the power plant as about 50 kilograms of bituminous coal. This advantage would diminish to a ratio of 3 kilograms of uranium ore to 5 kilograms of coal if it became necessary to use the very low-grade uranium resources in the Chattanooga shales before the advent of more efficient reactors.

The uranium mill is the facility that extracts from each 1000 kilograms of sandstone ore its 2 kilograms or so of U_3O_8, producing in the process a large quantity of chemically toxic and mildly radioactive liquid wastes and a sandlike solid residue called tailings. The handling of the wastes through the early years of the nuclear industry (the 1950s and early 1960s) provides one of the examples of corporate and regulatory irresponsibility that have made informed citizens cynical about the management of nuclear energy. Liquid wastes were discharged into the streams of the Colorado plateau, producing higher than permissible concentrations of radioactivity in the drinking water of residents downstream. The tailings, which contained radium, were merely piled near the mills, exposed to leaching and erosion by rain and wind. Incredibly, some of the tailings eventually ended up as landfill in Grand Junction, Colorado, on which some 5000 homes and commercial buildings (including several schools) were built. Radon gas, produced by the decay of the radium in the tailings, diffuses readily through the porous concrete-slab foundations used in such construction. Uranium miners exposed to radon concentrations comparable to those found in buildings built over tailings show twice the normal incidence of lung cancer. [82] The tailings hazard in homes and commercial buildings was first discovered in 1966. In 1976 some of the affected buildings were still occupied, and many claims for compensation for lowered property values or repair work undertaken remained unsatisfied.

Piles of accumulated tailings in the United States amounted in 1975 to about 70 million cubic meters, with much of the material from uranium mined for bomb manufacture. Under United States Atomic Energy Commission (USAEC) projections of nuclear power growth, the accumulation would reach almost 500 million cubic meters in the year 2000. [83] Current regulations do not appear adequate to assure the safe management of those materials, although there is no obvious technical obstacle that would make that impossible. [84]

Fuel preparation. Most nuclear reactors cannot use natural uranium as fuel, because the fissile isotope uranium-235 is present at a concentration of only 0.71 percent. The uranium is therefore subjected to isotopic enrichment, in which the fraction of uranium-235 atoms present in the fuel is increased above its natural level and some of the uranium-238 atoms are discarded. This is an intrinsically difficult enterprise, because there is no chemical difference between uranium-235 and uranium238 to aid in the separation. Most separation procedures therefore rely on the small difference in mass between the two isotopes (only about 1.3 percent) to distinguish them. The output of isotopic enrichment plants consists of one stream of uranium containing uranium-235 in an amount ranging from 2 to 94 percent, depending on the kind of reactor for which it is intended, and a tails stream, in which the uranium-235 content has been depleted to between 0.2 and 0.3 percent. The tails (not to be confused with tailings from uranium mills) are stored for anticipated use in breeder reactors, which will be able to convert the uranium-238 to fissile fuel.

The most widely used technique for isotope separation is *gaseous diffusion*, in which uranium in the form of gaseous uranium hexafluoride (UF_6) is made to pass under pressure through a series of thousands of porous barriers. Being slightly less massive, the UF_6 molecules that contain uranium-235 instead of uranium-238 diffuse through the barriers slightly more readily; after each stage, therefore, the concentration of uranium-235 is slightly enhanced in comparison to that of uranium-238.

[82] U.S. Congress, Joint Committee on Atomic Energy (JCAE), *Hearings on use of uranium mill tailings for construction purposes*, pp. 272-273.

[83] J. Blomeke, C. Kee, and J. Nichols, *Projections of radioactive wastes to be generated by the U.S. nuclear industry*.

[84] An excellent review of the whole tailings problem is T. C. Hollocher and James J. MacKenzie, *Radiation hazards from the misuse of uranium mill tailings*. For a discussion of the possible impact of emissions from tailings on future generations, see D. Comey, *The legacy of uranium tailings*.

Gaseous diffusion plants are enormous, very expensive industrial facilities. Being impractical in small sizes, they have been inaccessible to any but the largest industrial nations. (This inaccessibility has been considered a benefit by people preoccupied with avoiding a nuclear war, because the enriched uranium these plants produce can be used to make atomic bombs. The fewer nations with this capability, the better.) Gaseous diffusion plants also use large quantities of electric power, amounting to 3 to 5 percent of the quantity of electricity that nonbreeder reactors can deliver from the enriched uranium the plants produce. [85] The entire U.S. uranium-enrichment capacity in the mid-1970s consisted of three large gaseousdiffusion plants in Oak Ridge, Tennessee; Paducah, Kentucky; and Portsmouth, Ohio. These plants were constructed between 1943 and 1955 at a cost of $2.3 billion for the purpose of making enriched uranium for bombs. The enrichment capability of the three plants combined, operating at their full power consumption of about 6000 electrical megawatts, would feed about 120 water-cooled nuclear reactors of the kind in heavy use in the United States. Somewhat ironically, the power needs of the U.S. diffusion plants have been supplied in the past by plants burning strip-mined coal.

The production of gaseous UF_6 required by the diffusion plants from the U_3O_8 concentrate (yellow cake) produced at the mills takes place at separate *conversion plants*. Two were in operation in the United States in 1974. The environmental effects of these plants include routine discharge of small amounts of fluorine and uranium to the environment -- apparently well within the levels permitted by regulations and less hazardous than emissions elsewhere in the nuclear fuel cycle.

Natural uranium is considerably less dangerous, gram for gram, than most other radioactive substances, because of the long half-lives and the correspondingly slow rates of emission of radiation of its constituents. In fact, of the roughly 100 radioisotopes for which maximum permissible concentrations (MPCs) are specified by national and international organizations, uranium is the only one whose chemical toxicity (as a kidney poison) exceeds its radiological toxicity. This is not to say, of course, that natural uranium is innocuous; but it is enough less

hazardous than many other materials circulating in the nuclear fuel cycle that accidents and emissions at facilities handling only natural and low-enriched uranium are not of overriding concern in relation to other nuclear hazards. As recycling of uranium becomes more commonplace (that is, feeding conversion plants not only with freshly milled uranium but also with uranium recovered from spent reactor fuel at reprocessing plants) and as more complicated fuel cycles are developed, contaminants more dangerous than uranium-235 and uranium-238 (specifically, U-232, U-234, U-236) will appear in conversion and/or enrichment plants in growing quantities. [86] The hazards of those facilities must then be reexamined.

Alternatives to gaseous diffusion for isotope enrichment exist and are being used or tested around the world. The main ones are ultra-high-speed centrifuges, a related "nozzle" technique, and laser separation. The first two technologies rely on the tendency of gas molecules containing uranium-238 to be thrown more readily to the outside of a gas stream traversing a curved path than molecules containing the less massive uranium-235. [87] Centrifuge installations are in commercial use in Europe, are feasible in smaller sizes than gaseous-diffusion plants, and require only about one-tenth the energy per unit of separation performed. The nozzle technology is also feasible in installations of modest size but requires almost twice as much energy as gaseous diffusion.

Laser separation relies on an entirely different physical distinction between uranium-235 and uranium-238. In somewhat oversimplified terms, the idea is as follows. A carefully tuned laser, beamed through a gaseous compound of natural uranium, can add some energy to the uranium-235 atoms without adding any to the uranium238 atoms. Provided with this head start in internal energy, the uranium-235 atoms can be ionized (stripped of an electron) by a second laser beam or by an electric

---

[85] For a more detailed description of the process and of the facilities in the United States, see USAEC, *Environmental survey*; V. Abajian and A. Fishman , *Supplying enriched uranium*; R. Levin, *Conversion and enrichment in the nuclear fuel cycle*.

[86] See, for example, the discussion in T. Pigford, *Environmental aspects of nuclear energy production*.

[87] See Abajian and Fishman, *Supplying enriched uranium*; R. Gillette, *"Nozzle" enrichment for sale*.

field too weak to ionize the uranium-238. Then the molecules containing the positively charged uranium235 can be separated easily by electrical means from those containing the uncharged uranium-238. [88] This process, when perfected, may use less energy than even the centrifuge method.

Important details of all isotope-enrichment processes historically have been kept secret, because those technologies can be used to enrich uranium to make bombs. That the improvements in enrichment technology are making this capability accessible to many more nations is among the most serious adverse consequences of nuclear technology in general. [88a]

Breeder reactors produce their own fissile fuel (plutonium-239 and uranium-233) from abundant, fertile uranium-238 and thorium-232 (Box 8-2). They therefore do not need the isotopic enrichment of uranium-235 in natural uranium to provide them with the needed concentration of fissile material, except when not enough plutonium-239 or uranium-233 is available from stockpiles or other breeder reactors to provide for the initial loading of nuclear fuel. If most or all fission power came from breeder reactors, and if the total number of reactors were not growing too rapidly, the need for enrichment would be eliminated entirely. This could not eliminate the link between nuclear power and nuclear bombs, however, because the plutonium-239 and uranium-233 relied upon by breeder reactors are even more suitable as bomb material than uranium-235. Yet another kind of reactor, the nonbreeding heavy-water reactor (HWR), described below in the discussion of reactor technology, can use unenriched and unadulterated natural uranium as fuel. Like the breeder, then, the HWR bypasses the enrichment step of the fuel cycle; but because it unavoidably produces some plutonium-239, it too cannot entirely eliminate the link between electricity and bombs.

Once fissile material of suitable quality for the type of reactor in question is in hand, the next step in the nuclear fuel cycle is to fabricate the fuel. The fuel material may arrive at the fabrication plant as gaseous UF_6 from an enrichment plant, or as liquid plutonium nitrate or uranyl nitrate from a fuel reprocessing plant, or as the various solid uranium concentrates that come from uranium mills. The first step in fabrication is to convert those materials into solid oxides or carbides (for example, UO_2, PuO_2, UC). Those compounds are the raw material for the fuel elements, which take different forms, depending on the type of reactor. For contemporary LWRS, UO_2 is pressed into solid pellets about 13 millimeters (0.5 inch) long and 10 to 13 millimeters in diameter. The pellets are then loaded into thin, cylindrical, zirconiumalloy (Zircaloy) tubes, which are welded shut at the ends. About 3.7 meters (12 feet) of the length of the fuel rods is occupied by the pellets (the rods extend somewhat beyond the pellets).

The effluents associated with fuel-fabrication plants have been modest, and no operations likely to pose great risk of accident to the public have been involved. (Of course, in all manipulation of enriched uranium, care must be taken to avoid bringing togther the amount and configuration needed to initiate a nuclear chain reaction, but even if that happened the possible accidents could do little damage outside the plant.) Much more serious problems of public health and safety -- and of occupational damage to the health of fuel-fabrication workers -may arise when and if the routine recycling of plutonium in reactor fuel commences. Plutonium is vastly more dangerous radiologically than uranium-235 and uranium-238, and even very small discharges of it cannot be tolerated (see Chapter 10). It could also be vulnerable in the fabrication plant to theft for use in bomb manufacture. The theft problem will also exist at fuel-fabrication plants serving reactors that use very highly enriched uranium, as does one type of reactor that seemed on the verge of commercialization in the mid 1970s.

Types of reactor. A typical nuclear-fueled electric power plant is similar in many respects to the fossilfueled power plants already discussed. A heat source is used to produce steam at high pressure, which drives a steam turbine, which turns an electricity generator. The main difference is, of course, in the heat source, which can be any of several types of nuclear reactor.

The main components of the reactor itself are the fuel, the control rods, the coolant, and (depending on the type of reactor) the moderator.

The function of the moderator is to slow down

[88]R. N. Zare, *Laser enrichment of isotopes*.
[88a]B. M. Casper, *Laser enrichment: A new path to proliferation*.

neutrons released by the fissioning fuel nuclei. This is necessary in most reactors because of a fundamental property of fissile materials: an encounter between a fissile atom and a neutron is far more likely to cause the atom to fission if the neutron is moving slowly than if it is moving rapidly. Each fission event produces an average of about 2.5 neutrons, and, if the chain reaction is to be maintained, one of those neutrons must cause another fission event before it escapes or is absorbed unproductively (in a way that does not cause fission). In other words, sustaining a chain reaction requires a 40-percent (1/2.5) probability that a given neutron will cause a fission. But neutrons unavoidably start out with very high speeds -- they are "born" that way -- so they have only a small chance *per encounter* of producing another fission. The only ways to get the overall probability of fission up to 40 percent per neutron are (1) to slow the neutrons down (moderate them), thereby increasing the probability of fission per encounter with a fissile atom, and (2) to increase the density of fissile atoms (higher enrichment and/or more compact fuel), thereby increasing the number of encounters. Reactors employing strategy 1 are generally called *thermal reactors*, because they use a moderating material to slow the neutrons down to speeds corresponding to the temperature of their surroundings. [89] Reactors employing strategy 2 have no moderators and are called *fast reactors*, because the neutrons are fast. Thermal reactors are technically easier to design, to construct, and, in the view of most reactor experts, easier to operate than fast reactors. (Fast reactors share strategy 2 with bombs; a fast reactor is not the same as a bomb, but the separation in terms of physics is not as great as with thermal reactors.) [90]

To be a suitable moderator for a thermal reactor, a material should have low atomic weight (when a neutron hits a heavy nucleus, it bounces off without losing much speed), little tendency to absorb neutrons (a neutron absorbed by the moderator cannot cause a fission), and a reasonably high number of nuclei per unit of volume (gases are no good -- they put too few moderator nuclei in a neutron's way). The best moderators are ordinary water and heavy water (D_2O,where *D* stands for deuterium, the stable heavy isotope of hydrogen with 1 proton and 1 neutron in the nucleus) and carbon in the form of graphite.

The materials for reactor control rods, by contrast, are chosen for their strong tendency to absorb neutrons. Cadmium and boron are widely used. To increase the power level in a reactor, the control rods are partly withdrawn from the *reactor core*, where the fuel and the moderator are interspersed, so that fewer neutrons are absorbed and more are available to cause fissions. To slow a reaction, the control rods are moved deeper into the core, making fewer neutrons available. In the event of a malfunction or a shutdown for maintenance, the control rods are pushed all the way into the core to quench the chain reaction by neutron starvation.

The function of the coolant is to carry the heat of fission and radioactive decay away from the core and deposit it where it can be used to generate electricity. Even when the chain reaction is shut down and no electricity is being generated, the coolant is needed to carry off the heat of radioactive decay of fission products in the core, which cannot be turned off. After a reactor has been operating for some time, the magnitude of the power associated with radioactive decay at the moment the chain reaction is shut down is 6 to 7 percent of the reactor's full rated power. Thus, a reactor rated at 3000 thermal megawatts (Mwt) would have a decay power at shutdown of as much as 210 Mwt. [91] (This is as much as the full power of fossil-fueled power plants considered large a few decades ago.) A full day after shutdown, the decay power is still a considerable 0.5 percent of full power, or 15 Mwt in a large plant (easily enough to melt the core if no coolant were present). The requirements on coolants and cooling systems are therefore not only high heat-removal capability during reactor operation but also high reliability long after the reactor has been turned off.

Reactors are generally classified and named according to the coolants and moderators they employ. Thus the

---

[89] From the branch of physics called statistical mechanics, one finds that the average speed, v, of a particle of mass, m, in equilibrium with surroundings at absolute temperature, T, is given by the relation $mv^2/2 = 3kT/2$, where k is Boltzmann's constant.

[90] A good introduction for the material in this paragraph is Reynolds, *Energy*, chapter 7; for more detail, see D. R. Inglis, *Nuclear energy: Its physics and its social challenge*; a definitive technical text is S. Glasstone and A. Sesonske, *Nuclear reactor engineering*.

[91] See, for example, USAEC, *The safety of nuclear power reactors and related facilities, National Technical Information Service*, Springfield, Va., 1973 (WASH-1250).

light-water reactors (LWRs) in widespread commercial use in the United States and elsewhere are so named because ordinary water (light water, in contrast to heavy water) is used both as coolant and as moderator. Heavywater reactors (HWRs) use heavy water as moderator, but generally light water or organic liquids as coolants because heavy water is expensive. (It is produced from seawater by isotope separation.) Most gas-cooled reactors (GCRs) use helium as a coolant, although some older designs use carbon dioxide; they are generally moderated with graphite. The liquid metal fast breeder reactor (LMFBR), of which there are many designs and a few operating prototypes, is cooled by liquid sodium; there is no moderator, and *fast* refers to the neutrons, not to the breeding (which may or may not be fast). Other kinds of breeder reactors being investigated are the gas-cooled fast breeder reactor (GCFBR) and molten-salt breeder reactor (MSBR).

An inventory of the world's power reactors as of late 1975 is given in Table 8-14. They accounted at that time for about 6 percent of the world's electricity generating capacity and 8.5 percent of that of the United States. Various studies have projected that the world's nuclear generating capacity will be between 2.5 and 3.5 million megawatts in the year 2000 -- more than 30 times the 1975 total in Table 8-14. Of course, this scenario is not inevitable. [92]

Our attention in the remainder of this section of text is confined mainly to four important types of reactor: the LWR of U.S. design, the Canadian HWR known as CANDU, the U.S. GCR known as the high-temperature gas reactor (HTGR), and the LMFBR under intensive investigation in the USSR, western Europe, and the United States. Some of the principal technical characteristics of these reactor types are summarized in Table 8-15.

LWRs of U.S. design are of two basic types: boilingwater reactors (BWRs) and pressurized-water reactors (PWRs). In a BWR the water serving as coolant and moderator is turned to steam in the reactor core, and the steam drives the steam turbine. In a PWR the water in the core is kept under such great pressure (about 150 atmospheres) [93] that it cannot boil and turn to steam; this hot, pressurized water instead is passed through a heat exchanger outside the reactor core, where its heat is used to make steam from water circulating in a separate closed cycle. The BWR and PWR steam cycles are presented schematically in Figure 8-19.

Indicated there are two of the main barriers against the release of the radioactive fission products from those reactors: the steel pressure vessel surrounding the core, and the steel-reinforced concrete containment structure surrounding the pressure vessel. The other main barriers are the solid matrix of the fuel pellets themselves, which contain most of the solid fission products, and the Zircaloy cladding that surrounds the fuel pellets. The core of a large LWR contains roughly 40,000 fuel rods encasing a total of about 100 tons of uranium oxide fuel. Enrichment is 2 to 4 percent uranium-235. About a third of the fuel is removed and replaced each year -- a process that requires the reactor to be temporarily shut down. The steel pressure vessel of a PWR is about 13 meters high, 4 meters in diameter, and 20 centimeters (8 inches) thick. The pressure vessel of a BWR is about twice as large in outside dimensions, but with slightly thinner (15 cm to 18 cm) walls. [94]

LWRs of both types convert heat to electricity with an efficiency of about 32 percent -- significantly less than the best fossil-fueled plants, although about equal to the national average for all thermal electricity generation. A second kind of efficiency sometimes discussed in regard to nuclear reactors is the fraction of the energy theoretically available in uranium that the reactor is capable of harnessing. This is between 0.5 percent and 1 percent for LWRS, 1 percent for HWRS, 1 to 2 percent for HTGRs, and probably 50 to 70 percent for LMFBRs. [95]

In addition to the safety questions discussed below, many of the large LWRs installed by utilities in the United States through the mid-1970s have been plagued by a variety of technical difficulties that have led to much poorer records of electricity production than expected. [96]

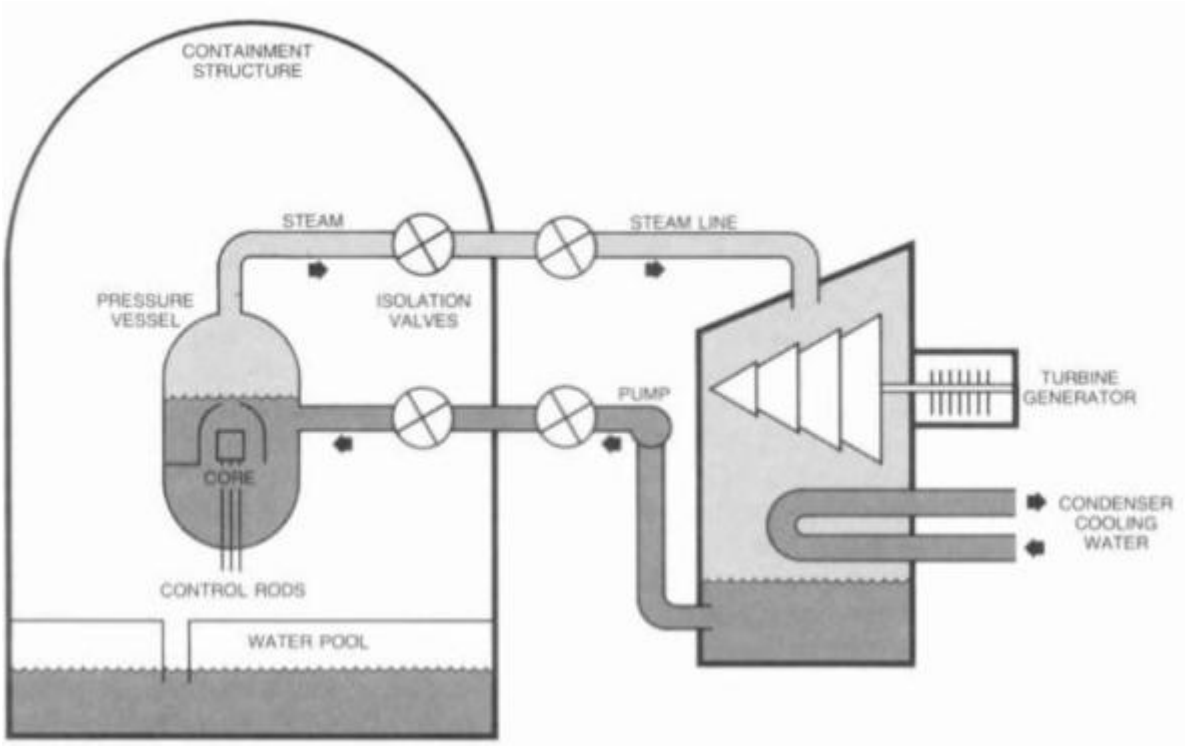
TABLE 8-15
Technical Characteristics of Reactors

	LWR	HWR	HTGR	LMFBR
Initial fuel *	3% U-235	0.7% U-235 (natural U)	94% U-235	40% U-235
Possible recycle fuel *	3% Pu/U-235	same as above	94% U-233/U-235	25% Pu
Annual consumption of natural uranium (1000 kg)	160	85-110	70	1.5
Pu or U-233 leaving reactor per year (kg)	220	270	190	500
Thermal efficiency	32%	29%	39%	39%
Power density in core (Mwt/m^3)	50-90	5-9	8	400
Operating pressure in core (atmospheres)	70-150	100	45	1-2
Peak coolant temperature (°C)	320	310	750	540

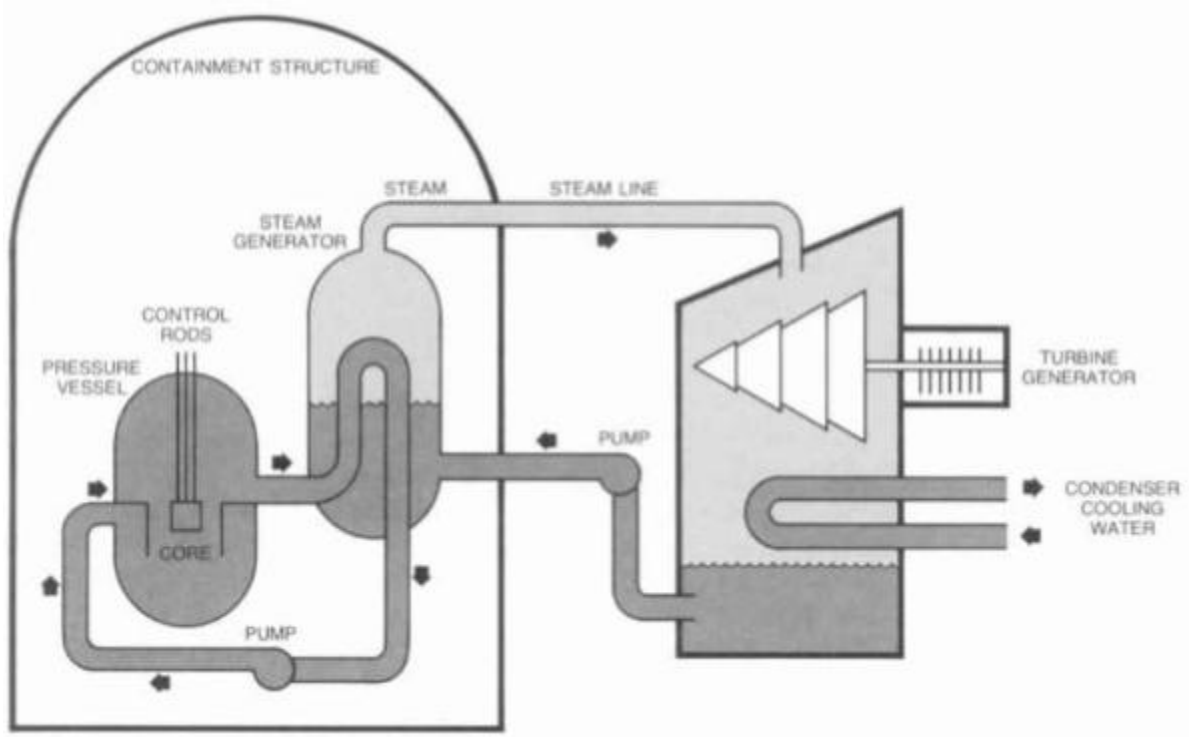
Note: All reactors are assumed rated at 1000 Mwe, averaging 75 percent of that year-round.

*Percentage denotes mass fraction of fissile material in fuel.



Sources: USAEC, *Potential nuclear power growth patterns*; McIntyre, *Natural uranium heavy-water reactors*; Nero, *A guidebook to nuclear reactors*.

Whether the difficulties will be ironed out with more experience or whether they will worsen as the reactors grow older remains to be seen.



The heavy-water moderated CANDU reactor has not enjoyed the commercial success of LWRs, probably for reasons unrelated to technical merit. Among its advantages are its ability to use natural uranium as fuel, thus dispensing with the need for expensive, energyconsuming enrichment, and its ability to permit refueling without shutting the reactor down. The first feature results from the extraordinarily good properties of heavy water as a moderator; the second, from a design that has each fuel element in its own individual pressure tube, instead of having all fuel elements in one large pressure vessel. Ordinary water flows through the tubes, serving as the coolant, and the tubes are immersed in a large tank of the unpressurized heavy-water moderator. Many believe this design has important safety advantages. [97]

The HTGR is also widely held to have safety advantages over LWRS, mainly because of its low power density and the very large capacity of its graphite moderator to absorb excess heat in an emergency. The HTGR core consists of blocks of graphite with passages for the helium coolant and control rods, and compartments filled with fuel that looks like black sand [microspheres of highly enriched uranium carbide (UC_2) and thorium oxide (ThO_2), coated with graphite.] The HTGR fuel cycle uses the thorium-232--to--uranium233 fertile/fissile conversion scheme (see Box 8-2). The core and the heat exchangers, where the hot helium is used to convert water to steam, are embedded in what amounts to a solid concrete rub laced with steel cables.

[97] McIntyre, *Natural-uranium heavy-water reactors*.

A. BOILING-WATER REACTOR (BWR)

B. PRESSURIZED WATER REACTOR (PWR) FIGURE 8-19 Schematic diagrams of boiling-water and pressurized-water reactors. The PWR core (B) is more compact and the pressure about twice as high as in the BWR (A). (From Science and Public Policy Program, University of Oklahoma, 1975.)

Among the advantages claimed for the HTGR are that it stretches uranium resources by relying partly on somewhat more abundant thorium, and that it has a thermal efficiency comparable to the best fossil-fueled plants -nearly 40 percent. It would lend itself to use with advanced gas turbines in place of or in addition to the steam cycle, to gain further increases in efficiency. There has also been considerable interest in using the hightemperature heat from HTGRs directly in industrial applications, without going through conversion to electricity. [98] This seems unlikely to see significant use before the 1990s, at the earliest. The only manufacturer of HTGRs in the United States announced in 1976 that it would not continue to market them, presumably because of slow sales and technical difficulties that plagued the demonstration plant at Fort Saint Vrain, Colorado.

If fission reactors were to become a mainstay of civilization's energy supply, breeder reactors would eventually be needed, because they can harness so much more of the potential energy in uranium and thorium than nonbreeders. It is worth emphasizing that a breeder does not get something for nothing -- it does not create new fuel out of thin air, as certain advertisements might lead one to believe. It merely transforms a material that would not otherwise be usable as fuel (U-238 or Th-232) into usable (fissile) form. (This is not entirely unlike what a refinery does with crude petroleum.) All nuclear reactors actually perform this transformation to some extent, but, to be a breeder, a reactor must have the specific property that fertile-to-fissile conversions are taking place faster than fissions. Under those circumstances, the inventory of fissile material

builds up as time goes on, and the excess can be drawn off to start new breeder reactors or to fuel nonbreeders. The time it takes a breeder reactor to produce an excess of fissile material equal to its initial inventory is called its doubling time; this quantity depends not only on the characteristics of the reactor itself but also on the losses of material and processing times elsewhere in the fuel cycle. The doubling time tells how rapidly breeder reactors could reproduce themselves if society wished to increase the number of such reactors, and it also tells (indirectly) what the ratio of breeders to nonbreeders would be in a steady-state situation, where fissile material was being consumed just as fast as it was being produced. [99]

On the assumption that breeders would be the surest way to secure a long-term energy supply, several of the world's most industrialized nations poured substantial fractions of their energy research efforts in the 1960s and 1970s into developing one particular kind of breeder, the sodium-cooled LMFBR.

The LMFBR is in many respects a much more difficult technology than the nonbreeding LWR, HWR, and HTGR. For one thing, to sustain a chain reaction using fast neutrons rather than slow (thermal) ones requires a very compact core with a high fraction of fissile material. This combination means a very high power density and very intense neutron flows in the core; the resulting high temperature and neutron damage make the weakening of fuel cladding and structural materials a difficult problem. The high power density also places severe demands on a coolant's ability to carry so much heat from so small a volume. Sodium has the advantage of being able to do this -- even at low pressure (see Table 8-15). But sodium also has the disadvantages of becoming highly radioactive itself, of burning upon contact with air or water, and of being opaque (making maintenance especially difficult). To minimize the possibility of radioactive sodium's coming in contact with water, most LMFBR designs have an intermediate sodium loop to transfer the heat from the radioactive loop to the water loop, where steam is produced for the turbine (see Figure 8-20).

The doubling times of various LMFBR designs have been matters of some controversy. Proponents had hoped for a time not much longer than the historical doubling time of electricity consumption -- say, 12 to 15 years. Some competent skeptics think a doubling time closer to 50 or 60 years is more likely. [100] This uncertainty has produced increased interest in alternative breeders: a gas-cooled fast breeder with a short doubling time

[99] Studies of the "optimum" mixtures of breeder and nonbreeder reactors are reported in USAEC, *Potential nuclear power growth patterns*, and W. Haefele and A. Manne, *Strategies for a transition from fossil to nuclear fuels*. (This may well be a classic example of what philosopher/economist Kenneth Boulding has called suboptimization -determining the best way to do what should not be done at all).

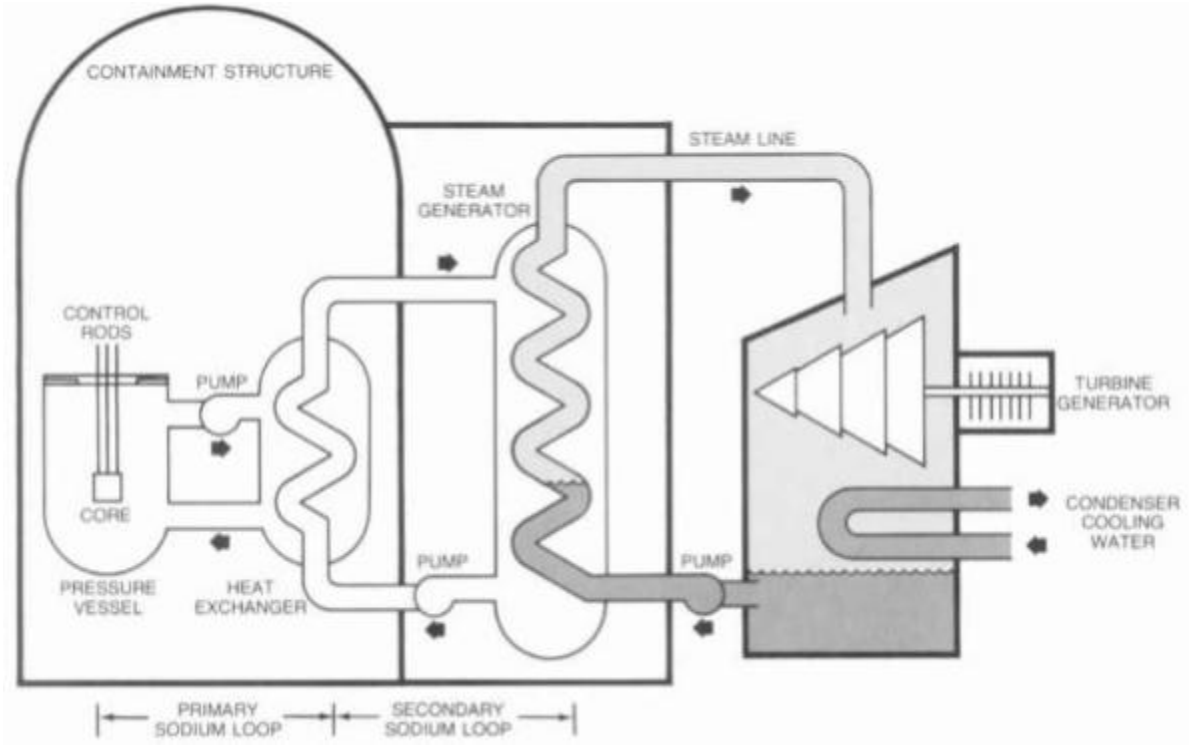

FIGURE 8-20 Schematic diagram of liquid metal fast-breeder reactor. The LMFBR core is smaller than that of a light-water reactor, and the power density is higher. Shown is the loop design favored by U.S. designers. (From Science and Public Policy Program, University of Oklahoma, 1975.)

(because the gas coolant gobbles up fewer neutrons, needed for breeding, than sodium), and a molten-saltcooled breeder (in which the fuel is actually a constituent of the molten salt), using the thorium -- to -- uranium-233 conversion with thermal neutrons. The latter has a very long doubling time -- perhaps it will barely breed at all -- but it could have important safety advantages over the fast-neutron breeders. [101] A closely related question is: under what circumstances does deployment of LMFBRs make economic sense? It seems likely -- even setting aside all issues of safety and environmental and social impact -- that the answer is that such circumstances will not arise before 2015 or 2020, if ever. [102]

Reactor hazards. Radiological hazards arising from the nuclear reactors themselves can be divided into three categories: (1) routine and accidental radiation doses to workers in nuclear power plants; (2) radiation doses to members of the public resulting from routine emissions of radioactivity from reactors in normal operation; (3) radiation doses to members of the public from accidents or sabotage at reactors.

Radiation doses to workers have received little public attention compared to the other two categories of hazard, but they are not negligible. The total occupational dose per nuclear power plant per year in the United States rose steadily from 188 person-rems in 1969 to 404 personrems in 1973. [103] (The person-rem count is the result of adding the individual doses received by all persons exposed. Statistically, one would expect 1 cancer death to result from each 5000 to 10,000 person-rems -- see Chapter 10.) Whether this increase is due to greater

[101]A brief review of breeder options is found in Hammond, Metz, and Maugh, *Energy and the future*, chapter 7. See also D. J. Rose, *Nuclear eclectic power*; and Cornell University, *Report*.
[102]For an introduction to the two main sides of this convoluted controversy, see T. Cochran, *The LMFBR: An environmental and economic critique*; U.S. Energy Research and Development Administration, *Final environmental statement, liquid metal fast breeder reactor program*. Also I. C. Bupp, *The breeder reactor in the U.S.: A new economic analysis*.
[103]K. Z. Morgan, *Effects of radiation on man: Now and in the future*.

power-plant size, growing laxity of practices, growing requirement for maintenance with age, or some combination of these and other factors is not clear. Neither is it clear whether the trend will continue.

Following a vigorous controversy in the United States in the early 1970s concerning the consequences of low-dose radiation the public might receive from routine emissions in an expanded nuclear-power program, the USAEC tightened the guidelines for emissions from LWRs a hundredfold. [104] This had the effect of lowering the "design target" maximum dose delivered to a member of the public by routine emissions from an LWR of 5 millirem (mrem) per year. LWRs built after the mid1960s apparently were able to meet the new guidelines handily. [105] In early 1977 the U.S. Environmental Protection Agency (which by then had secured jurisdiction over setting standards for radiation exposure) promulgated standards applicable not just to LWRs but to all reactor types and to other nuclear facilities as well, limiting exposure to any member of the public to 25 millirem per year. [105a] (See also Chapter 10.) This is a regulation, in contrast to the earlier 5 millirem "design guideline" for LWRs. It can be assumed that LWRs and probably other reactor types can meet the new standard more easily than, say, reprocessing plants (see below). To the extent that they can, routine emissions from the reactor become one of the least objectionable characteristics of fission power. It should be emphasized, however, that meeting such standards over the operating life of a reactor may prove more difficult than meeting them for the first few years, and that vigilant monitoring and enforcement will be required in any case to assure performance.

Accidents and attempted sabotage at nuclear power plants can have a wide range of consequences, from minor equipment damage and no release of radioactivity from the plant site, on one extreme, to a catastrophe with tens of thousands of people killed and tens of billions of dollars' worth of property damage, on the other. Since many people are rightly concerned about the worst thing that could happen as a result of putting a given reactor in a given location, we treat mainly the consequences and probabilities of the largest accidents here. The nuclear industry and its regulators call these Class IX accidents (the mildest accident is Class I). Their occurrence depends on a sequence of several equipment failures and/or errors, all deemed highly improbable (but see our discussion of probability, below). [106]

Deferring the question of probability for a moment, consider first the potential for harm in a very large accident. The main relevant questions are: (1) How much and what kinds of radioactive substances are inside a reactor? (2) How much could be released in the worst conceivable event? (3) Where would it go? (4) How many individuals and what kinds and quantities of territory

would receive what doses as a result? (5) What pattern of deaths, injuries, and property damage would be caused by those doses? The amount of scientific uncertainty about the answers increases as one goes down the list, but reasonable estimates seem possible for all five. These questions have been studied in varying degrees for all the major reactor types, although probably most thoroughly for the LWRS.

A 1000-Mwe LWR after sustained operation contains about 12 billion curies of fission products, more than 3 billion curies of the heavy radioactive elements called actinides (the uranium fuel and its derivatives, including plutonium, thorium, and neptunium), and around 10 million curies of activation products (radioactive materials produced by the interaction of fission neutrons with the reactor structure). [107] Quantities of curies, by themselves, are not very enlightening measures of hazard (see Chapter 10), so it has become customary to define a crude measure of relative hazard as the number of curies of a given isotope divided by its maximum permissible concentration (MPC). The resulting number is the volume of air or water that would be required to dilute that material, uniformly mixed, down to the MPC. Also

Chapter 1, Part 20, Standards for protection against radiation, Government Printing Office, December 1975.

relevant is the half-life of the isotope, which indicates how quickly the needed amount of dilution diminishes.

The inventories of a few of the most dangerous radioactive isotopes in an LWR at the instant the chain reaction is shut down appear in Table 8-16, along with their half-lives, their MPCs in air, and their relative hazards (measured in thousands of cubic kilometers). A somewhat more meaningful measure of potential hazard can be obtained by multiplying the inventory by the fraction of a material thought to be capable of becoming airborne in the worst conceivable accident, and then computing the volume of air required to dilute that smaller amount to the MPC. Such corrected relative hazards are tabulated in Table 8-17. The volumes are still very large; the releasable iodine-131 alone is sufficient at shutdown to contaminate the atmosphere over the forty-eight contiguous United States up to an altitude of 10 kilometers (the tropopause) to more than twice the MPC. (This is not to suggest that the material would actually be uniformly dispersed that way, but only to communicate some feeling for the magnitude of the problem.)

Potential contamination of surface water and groundwater by radioactivity released in a reactor accident is another measure of the hazard, and relative hazard figures analogous to those for air can be computed for water. For example, half the strontium-90 in a reactor at shutdown is enough to contaminate the annual freshwater runoff of the forty-eight contiguous states to 6 times the MPC (although, again, it would certainly not be distributed that way).

TABLE 8-17
Adjusted Relative Hazards of Radioactive Isotopes in a 1000-Mwe LWR at Shutdown

Isotope	*Fraction releasable**	*Adjusted relative hazard(km^3)*
Iodine-131	0.70	600,000,000
Ruthenium-106	0.50	65,000,000
Strontium-89	0.10	31,000,000
Tellurium-132	0.70	21,000,000
Cesium-134	0.50	9,500,000
Xenon-133	1.00	570,000

Isotope	*Fraction releasable*[*]	*Adjusted relative hazard(km^3)*
Neptunium-239	0.005	400,000
Plutonium-238	0.005	290,000

[*]Fractions releasable to air in the worst-case accidents, according to U.S. Nuclear Regulatory Commission, *Reactor safety study*.

It is physically impossible for an LWR or any thermal-neutron reactor to blow up like a nuclear bomb. The only way a reactor could release to the environment the large amounts of radioactivity being discussed here is in an accident that caused much of the nuclear fuel to melt. Such a chain of events could involve steam explosions and releases of chemical energy that would break open the containment building above the ground; and almost certainly any large-scale fuel melting would lead to penetration by the molten mass through the steel and concrete layers into the ground below. These possibilities are mentioned further in the discussion of probability, below. For now, it suffices to emphasize that the concern is not with a reactor's blowing up like a bomb, but rather with its cracking open like an egg.

In some respects, however, such an event could be worse than a "typical" nuclear bomb. A large reactor's inventory of long-lived radioactivity is more than 1000 times that of the bomb dropped on Hiroshima. Moreover, the portion of the radioactivity that would issue from a cracked-open containment building would not be blown directly into the stratosphere -- as was much of the bomb's radioactivity -- but instead might be trapped by atmospheric conditions near the surface (where the people are).

The number of immediate and long-term human casualties and the amount of property damage resulting from a given release of radioactivity depend on the distribution of population around a site, the degree of evacuation that proves possible, and, especially, on weather conditions at the time. Several specific published estimates deserve mention. The first is a 1957 study conducted by the USAEC and commonly known by its document number, WASH-740. [108] It considered an LWR of about 500 Mwt (160 Mwe) about 30 miles from a major city, and concluded that the greatest consequences in the worst case would be about 3400 persons killed (to a distance of 15 miles), about 43,000 injured (to a distance of 45 miles), with maximum property damage around $7000 million. The report stated that, in most circumstances considered, the consequences would be considerably less than that (that is, "assumed losses would not exceed a few hundred million dollars"), and that the probability of any such major reactor accident was exceedingly low. At about the same time a less widely distributed study was published, concerning potential consequences of hypothetical accidents at a specific experimental LMFBR power plant -- the 300Mwt Fermi plant being built near Detroit. [109] It concluded that the worst event, which the authors termed "incredible," could kill as many as 133,000 persons.

The nuclear industry, the USAEC, and the Joint Committee on Atomic Energy (JCAE) of Congress were unhappy about the wide attention given to the maximum-casualty figures in WASH-740, and members of those groups increasingly disparaged that report, asserting that it

used unduly pessimistic assumptions. In 1964 another study of LWR accidents was initiated by the USAEC and also performed at Brookhaven National Laboratory. The idea was to take into account the improved scientific information that had become available since 1957, and it was hoped that more realistic assumptions made possible by that information would more than compensate for the increased reactor size (up to 2000 Mwt, or about 600 Mwe) which by then had to be considered. After the preliminary results in 1965 indicated an increase in the potential consequences over those published in WASH-740, the project was canceled and the working papers locked up. They were released in 1973 as the result of a lawsuit brought under the *Freedom-of-Information Act* by conservationist organizations. The preliminary investigation had indicated, for the worst case, 45,000 short-term fatalities and land contamination in an area equal in size to Pennsylvania. [110] No attempt was made to assign a numerical probability to that event, but it was deemed highly unlikely.

The most recent and largest USAEC study of accidents in LWRs (WASH-1400) was released in draft form late in 1974 and in final form in October 1975. [111] It was performed over three years by USAEC staff (later part of the Nuclear Regulatory Commission) and outside consultants under the direction of a nuclear engineering professor at Massachusetts Institute of Technology, Norman Rasmussen. It is popularly known as the Rasmussen report. The report addressed itself to both the probability and the consequences of major accidents at LWR power plants. It did not address other types of reactors or other parts of the nuclear fuel cycle. The maximum accident considered, which was assigned a probability of one in a billion per reactor per year, would lead (in the study's estimation) to the consequences shown in Table 8-18. The uncertainty factors given in the table are those stated in the Rasmussen report itself. The multiplicative uncertainty of from 1/4 to 4 about the

"best estimate" of 3300 prompt deaths means that the actual value would fall in the range of from 825 to 13,200, in the view of the report's authors. The total of prompt deaths plus delayed cancer deaths has the very large range of from 8325 to 193,200. These deaths would take place in a total exposed population of 10 million people, according to the report.The best-estimate casualty figures in the final draft of the Rasmussen report, as reproduced in Table 8-18, represent significant increases over the figures in the earlier draft. The upward revisions were made as the result of correcting a number of errors that were uncovered in several external and internal reviews of the report. [112] Specific responses to parts of these reviews are given in Appendix XI of the report's final draft.It remains controversial whether the best-estimate casualty figures in the final draft now really represent the most realistic estimates that can be made. A critique of the final draft performed by the Environmental Protection Agency suggested that the Rasmussen best estimate of cancer deaths may still be too low by a factor of between 2 and 10. [113] This critique indicated that early deaths and illnesses were also underestimated in the final draft, but EPA was unable to estimate by how much because of inadequate documentation in the Rasmussen report's treatment of that topic. Other reviews of the calculations used by the Rasmussen group to estimate early casualties have revealed enough dubious assumptions and internal inconsistencies that it is clear the true uncertainty range is greater than indicated in Table 8-18. [113a] No one disputes that extensive engineering precautions have been taken in an attempt to make reactor accidents of such magnitude very unlikely. [114] But how meaningful are the tiny probabilites computed in the Rasmussen study, representing the chance of a reactor accident that kills 1000 persons as being less than the chance of a catastrophe from a large meteorite's striking a city? It is difficult indeed to ascribe much credibility to such numerical values, for several reasons.First of all, there are at least four categories of potential failure modes (in no implied order of likelihood):

human error and/or mechanical failure internal to an installation;

human error and/or mechanical failure external to the installation (such as a plane crash);
natural catastrophe (earthquake, tornado, tsunami);
malicious human activity (war, sabotage, terrorism).

The Rasmussen report's treatment of accident probability was based essentially exclusively on random internal mechanical failures -- that is, on some of the failure modes in Category 1. It could not account for many kinds of

human error, for certain kinds of disasters such as large earthquakes, or for malice.

Reactor systems themselves are extraordinarily complex, and neither the probabilities of component failure nor the possible failure modes of the systems are known with sufficient assurance to permit a meaningful calculation even of the probability of a catastrophic event of Category 1, listed above. Although there has been no major accident to date (in loss of human life) at a commercial power reactor, there have been enough serious malfunctions to confound the calculators of such probabilities. For example, a fuel meltdown at the Fermi LMFBR in Detroit in 1965 exceeded the "maximum credible accident" for that installation. [115]

As of mid- 1975, there had been little more than 1000 reactor years of power-reactor experience worldwide. [116] Therefore, *on the basis of experience alone*, no one can be sure that the probability of a catastrophic accident is not as high as 1/1000 per reactor-year (although so high a figure seems unlikely). Moreover, much of the early experience was with much smaller or otherwise much different reactors from, say, the very large LWRs that are coming into service today. It is not apparent, therefore, how much of the earlier experience is relevant to assessing accident probabilities now. Unfortunately, even the most careful theoretical analysis cannot entirely evade the pitfalls created by the lack of extensive operational experience--for example, uncertainty about the reliability of individual components of a system and the possibility of overlooking a combination of events more probable than those considered.

Moreover, an extended controversy in the early 1970s over emergency systems for LWRs in the United States revealed major gaps and apparent mismanagement in the USAEC reactor-safety

program. [117] It is difficult to escape the impression that, in the event of a loss-ofcoolant accident, the emergency core-cooling systems for contemporary pressurized-water reactors and boilingwater reactors of United States design might not be able to prevent the melting of a reactor core and a subsequent catastrophic release of radioactivity. The Rasmussen report *assumed* high reliability for those emergency systems; it did not prove it.

Notwithstanding this and other defects in the Rasmussen report's probability analysis, the study computed the probability of a complete core meltdown in an LWR of contemporary design (the event previously assumed to define a catastrophic accident) as 1 in 20,000 per reactor per year. This figure is much higher than any with which the USAEC had previously associated itself. It would indicate (if it still applied to the 1000 reactors widely projected to be in operation in the United States before the year 2000) a probability of 1 chance in 20 per year that such an accident would take place in this country. This result is only transformed into a reassuring one in the Rasmussen study by calculations and assumptions indicating that the consequences of a meltdown, once it occurred, would be much abated by retention of the radioactivity in soil and rock under the reactor, by meteorological factors, and by evacuation of the threatened population. This line of argument suddenly and drastically changed the official position--from "it won't happen" to "it's not so bad if it does." Those revised contentions in the Rasmussen report provide the basis for its disagreement with the two previous, more pessimistic USAEC-sponsored studies of the consequences of reactor accidents. The revised arguments therefore require the closest critical scrutiny. Reliance on evacuation seems particularly suspect. [118]

Of course, it may be possible in principle to design reactors that are inherently very safe against internal accidents, even if some present-day LWRs are not. Gas-cooled reactors may represent the direction in which such safe reactors are to be found, because the enormous heat capacity of the graphite moderator provides an extended period of grace following an accidental loss of coolant before the fuel begins to fail. (If the heat of radioactive decay after shutdown is not removed by primary or emergency coolant, the rate of heat generation

is sufficient to initiate the melting of the fuel in an LWR within about 60 seconds. [119] In a high-temperature gascooled reactor, however, the graphite moderator can soak up the decay heat for well over an hour before the graphite coating of the fuel particles begins to sublime.)

Whether LMFBRs will prove to be significantly less safe than LWRs (or safer) is not entirely clear. The high power density and high enrichment of the fuel are negative features in terms of

safety, as is the chemical reactivity of the sodium coolant. On the other hand, the low pressure of the coolant is an advantage for the LMFBR, and at least some designs have the characteristic that natural convection in the sodium can remove the decay heat fast enough to prevent core melting, even if all the coolant pumps should fail. One of the most important questions is how much energy could be released in a "nuclear excursion" in an LMFBR--the sort of nearbomb behavior that is strictly limited to fizzles in LWRs by the basic properties of the fuel. Some reactor experts believe that properly designed LMFBRs will not be capable of much more than a fizzle, either; they assert that the maximum possible nuclear-energy release is small enough to be contained within the layers of steel and concrete surrounding the core. Other equally qualified specialists insist that the possibility of excursions too large to be contained cannot be ruled out. [120]

Although some of the engineering approaches to assuring reactor safety against internal accidents apply also in some measure to external events (Categories 2-4, above) there are important differences. To an even greater extent than is true of internal accidents, for example, it is possible for the cause of an externally imposed disruption to disable the emergency systems as well as the primary reactor functions. The nature of natural catastrophes such as earthquakes is such that it is virtually impossible to guarantee the integrity of a system against the strongest conceivable event, although it may be possible to reduce the probability of failure to a very low level by careful construction and siting. Society may find it difficult, however, to decide on what is an acceptably low probability for an almost completely unacceptable event.

It is possible, although not yet certain, that the probability and/or magnitude of major releases of radioactivity that might be associated with events of Categories 1-3 at reactors can be reduced to tolerable levels by siting the reactors under several hundred feet of rock or earth fill. Preliminary studies indicate that the construction-cost penalty of this approach would not exceed 10 percent. [121] Thus, isolation from events of Category 2 would be virtually assured, and in Category 3 only earthquakes would still be of consequence. The degree of containment against major releases of radioactivity by any catastrophes that might befall an underground reactor remains to be thoroughly investigated. Placing reactors underground, however, would seem to have considerable advantage over surface siting.

Perhaps the most troublesome events of all, potentially, are those in Category 4--the malicious disruption of reactor systems through acts of war, insurrection, sabotage, or terrorism. The possibilities are obvious, and we will not dwell on them in detail. Suffice it to say that in the event that a determined and knowledgeable saboteur gains access to a nuclear power plant, all theoretical calculations concerning reactor reliability become meaningless. A study by the General Accounting Office of the U.S. government in 1974 confirmed the reality of that possibility. [122]

Spent fuel. Neither the technology nor the environmental impact of nuclear energy ends with the generation of electricity at the reactor. The nuclear fuel must eventually be removed from the reactor core--not so much because the fissile component would be used up but because the accumulating fission products "poison" the chain reaction by absorbing neutrons. Most reactors are operated on a three- or four-year cycle; that is, once a year, one-fourth to one-third of the fuel is removed and replaced with a fresh batch. The material removed is called spent fuel. It is first stored at the reactor site so

some of the most intense but short-lived radioactivity can decay before further handling. Then the fuel is shipped to a reprocessing plant, where as much as is practical of the useful uranium and plutonium isotopes are separated from the fission products and other radioactive wastes. The uranium and plutonium are then stored or recycled, and the wastes are stored, pending adoption of a plan for their permanent management or disposal. All these steps together are often called the "back end" of the nuclear fuel cycle. They present some of the greatest technical and environmental problems associated with nuclear power.

Cooling the spent fuel elements immediately after removal from the reactor core takes place in pools of water provided for that purpose at the reactor site but outside the main containment building. At that point, then, the barriers against the release of radioactivity that were provided in the reactor by the reactor vessel and by the main concrete-and-steel containment building are no longer present. In these respects, the spent fuel is more vulnerable to dispersal by external events, such as sabotage or earthquakes, than the fuel in the reactor core. However, probably less radioactivity could be widely dispersed by such events than by the meltdown of a reactor core. During the 150-day cooling-off period that is customary for LWR fuel, the radioactivity in a 40-ton annual batch of spent fuel drops from about 5 billion curies to 135 million curies. (The complete lack of commercial fuel-reprocessing plants in the mid-1970s in the United States has led to the retention of fuel in storage pools for much longer than 150 days, creating the problem for reactor operators of where to put the overflow. [123]) The economics of the LMFBR fuel cycle will require that the spent fuel be discharged more frequently and in smaller batches, which will be cooled for only 30 days. [124] The shorter cooling period means that radioactivity about 3 times greater than that of LWR fuel will have to be handled in shipment and processing, posing significant additional problems.

Shipment of the intact spent-fuel elements from the storage pool to the reprocessing plant takes place in heavily shielded casks. The heat of radioactive decay after 150 days of cooling amounts to about 20 kilowatts per metric ton of fuel, requiring continuous cooling in the cask to prevent the fuel from melting. Spent-fuel casks shipped by truck weigh up to 35 metric tons; those shipped by rail, as much as 100 metric tons. [125] The casks are designed and tested to withstand severe impacts, fire, and immersion in water. The main question is the probability of there being a shipping accident severe enough to rupture such a cask. The chance would seem to be low if the casks are as good as claimed.) There will be ample opportunity to learn the answer by experience; the largest casks must make about 10 trips a year to service a 1000-Mwe LWR. This means there will be more than 1000 cask-trips per year for the 100 reactors expected to exist in the United States before 1985.

Once at the reprocessing plant, the fuel elements are chopped into pieces and the contents dissolved in acid for chemical separation. At that point the barriers between the concentrated radioactive material and the environment are at their lowest, for then the protection afforded by the metal cladding and the ceramic matrix of the individual solid fuel elements is gone. Virtually all of the operations at the reprocessing plant must be conducted by remote control because of the intense radiation emanating from the wastes. Many of the gaseous and liquid effluents are controlled by using scaled-up versions of the systems used at reactors. (A single, large reprocessing plant of the future may serve as many as fifty reactors, so the amount of radioactivity handled will be very large indeed--about 7 billion curies per year after the 150-day cooling periods.) Under present practices, all of the radioactive gas krypton-85 ($t_{1/2}$ = 10.8 years) goes up the reprocessing-plant stack, and all of the tritium ($t_{1/2}$ = 12.3 years) is released to air or water. Traces of other radioactive isotopes are released, but most are concentrated in the residual liquid high-level waste-some 1200 liters of it per metric ton of spent fuel processed (around 40,000 liters per reactor per year), containing 12,000 curies of fission products per gallon. BOX 8-5 Radioactive Wastes: An Aspirin Tablet per Person?

It is not uncommon to hear from the publicrelations arm of the nuclear industry that the radioactive wastes from nuclear power are equivalent in size to only an aspirin tablet per year for every person whose electricity is provided by nuclear plants. [*] Probably the most misleading

aspect of this analogy is that *toxicity*, not volume, is the important characteristic of those wastes. If a tablet were to be an apt comparison, it would have to be a cyanide tablet--and even that would not do justice to the actual toxicity of the fission products.

It turns out, moreover, that 1 tablet per person is far from a correct figure, even in respect to volume. If the high-level radioactive wastes from a reprocessing plant were to be solidified in their most concentrated form (the form to which the aspirin-tablet view presumably refers), the resulting volume per 1000-Mwe LWR per year would be 2.5 to 3 cubic meters. [**] Since such a plant, running at a generous average of 75 percent of full capacity, could meet the full electricity demand of 750,000 Americans in 1975 (this includes not only their homes but also the associated commerce and industry), the volume of high-level solid waste per person served would be 3.3 to 4 cubic centimeters. The volume of an aspirin tablet is about 0.4 cubic centimeters, so the solidified high-level wastes would be about the size of 10 aspirin tablets per person.

That, however, is only the tip of the iceberg. Most high-level wastes have not been solidified yet, and federal law requires only that such solidification take place within 10 years of the creation of the wastes. The volume of the liquid form before solidification is 10 times greater than that of the solid (therefore, we would have 100 aspirin tablets per person). Additionally, there are the highly radioactive remains of the fuel cladding (2 cubic meters per reactor year, or 5 more aspirin tablets per person).

There is still more. The reprocessing plant also produces annually for every 1000-Mwe reactor about 25 cubic meters of intermediatelevel liquid wastes (contaminated to between 10,000 and 1 million times the maximum permissible concentration) and 1200 cubic meters of low-level liquid wastes (10 to 10,000 times the MPC). Those wastes would amount to 60 and 3000 additional aspirin tablets per person, respectively. Low-level solid wastes from the reprocessing plant and from the reactor itself amount to between 80 and 160 cubic meters per year (200 to 400 more aspirin tablets per person). Those wastes contain alpha-emitting radioisotopes of very long half-life.

All this adds up to a volume equal to that of between 3300 and 3600 aspirin tablets per year per person served. If the Nuclear Regulatory Commission (NRC) were to approve the routine recycling of plutonium in LWRs, an additional 340 cubic meters of plutonium-contaminated wastes per reactor per year would appear at the fuel-fabrication plants--another 850 aspirin tablets per person served. Dismantling the reactor and other radioactive fuel-cycle facilities at the ends of their operating lifetimes would add more waste to the total, amounting to perhaps 500 cubic meters per year of operation, or 1250 aspirin tablets per person. [†] The total would still perhaps not be an overwhelming volume, around 2000 cm^3 of waste per person per year. But remember, the toxicity of this material is what is really important.

It is disquieting, in any case, to find persons in the nuclear industry--so quick to complain about what its representatives consider to be irresponsible statements from environmentalists--glibly dispensing information that is both qualitatively misleading and quantitatively wrong by a factor of thousands.

Less intensely radioactive, but still dangerous wastes are also produced as intermediate- and low-level liquids and solids (see Box 8-5).

The release of tritium and krypton at reprocessing plants is the largest routine emission of radioactivity in the nuclear fuel cycle. Krypton eventually becomes thoroughly mixed with the global atmosphere, and tritium with atmospheric and surface water [127] At that point, their contribution to human exposure to radiation is small compared to those of natural sources of radiation (this is not to say it is entirely harmless--see Chapter 10). This will remain true even if the use of nuclear power grows rapidly for another thirty years. The increasing releases, especially of tritium, could cause relatively severe local problems before then, however, and they would presumably have to be controlled if such nuclear power growth materialized.

The only commercial fuel-reprocessing plant to operate in the United States before 1977 was the Nuclear Fuel Services, Inc. (NFS), plant near Buffalo, New York, which was in service from 1966 to 1971 before being shut down for expansion and repairs. Its peak rated capacity was around 300 tons of fuel per year, corresponding to the output of fewer than ten large reactors. Emissions from the plant have been studied by several groups; the plant occasionally operated very close to the permissible limits and could not have come close to the much tighter emissions guidelines that have since been applied to the reactors themselves. [128] (Reprocessing plants were

excluded from those revised guidelines.) What this plant's emissions might be if it came back into service at 3 times the old rated capacity--originally scheduled for 1978-remains to be seen. The plant's operators announced in 1976 that it might not reopen at all. A second commercial reprocessing plant built by the General Electric Company near Morris, Illinois, was to have come into service in 1974. It did not work and was shut down without reprocessing any fuel, after an investment of about $65 million. [129] A reprocessing plant large enough to serve almost fifty large reactors was scheduled to begin commercial operations near Barnwell, South Carolina, in 1977 or 1978, but has been delayed.

It has been claimed that the technology exists, and will be implemented, to make routine emissions very modest, even at such large reprocessing plants. [130] This may prove to be true. If it does, the serious question that will remain about such plants, with their large inventories of radioactive poisons and the relative paucity of solid barriers against the release of those poisons, is their vulnerability to such hard-to-predict disruptions as fires, earthquakes, tornadoes, and the intervention of saboteurs.

As with operations at the reactors and the reprocessing plants, the need for actual long-term management of radioactive wastes from reprocessing plants confronts society with a situation in which the routine impact perhaps can be made very small, but the consequences of conceivable nonroutine events are very great. In the case of managing the wastes, moreover, the necessity for ironclad safeguards extends far beyond the life of the reactors, the people who build them, and the people who

use the electricity they produce. Table 8-19 lists the half-lives of some of the most dangerous long-lived radioactive wastes, along with the number of curies of each that would be present for each year of operation of one large LWR, after various periods of decay. The amount of waste produced annually in an economy of 1000 large reactors, of course, would be 1000 times as much of each of the isotopes listed, in addition to others not in the table.

A 1974 study of waste-management alternatives published by the USAEC calculated the hazard of the total waste inventory the USAEC expected to have accumulated in the United States by the year 2000. That is, the study divided the anticipated inventory of each isotope by its MPCs in air and water, to obtain what were termed an inhalation hazard and an ingestion hazard. [131] The magnitude of those hazards at intervals up to 1 million years later (counting only wastes produced in the United States until 2000) were then computed. The results are summarized in Table 8-20. The huge volumes of air and water that would be required to dilute the waste material down to the MPCs, even tens and hundreds of thousands of years after it was produced, testify to the degree of control that must be achieved.

Many proposals have been put forward for providing such safeguards for radioactive waste materials. The suggestions include burial in salt deposits, in deep bedrock, in the deep trenches on the ocean floor, at the bottom of the Antarctic ice cap, and in underground cavities blasted for the purpose with nuclear explosives. They include ejecting the wastes from the solar system in rockets, letting them ride into Earth's interior at subduction zones where tectonic plates collide, or merely storing them in concrete-and-steel bunkers under surveillance until someone thinks of a better way. [132] Some of the schemes have defects that are easily identified (wastebearing rockets could blow up on the launching pad) and other have defects that have been pointed out by specialists in the fields involved (the future of the Antarctic ice cap is too uncertain for us to rely on it, and even now there is evidence of significant melting and of fast pathways to the open ocean at its base). [133] Some have promise. The option of separating out the long-lived actinides and breaking them up into shorter-lived fission products by bombarding them with fast neutrons, either in a fast breeder reactor or a fusion reactor, may have merit as a way of changing a million-year problem into a thousand-year problem. [134] Whether this is really practical is not known. Indeed, no scheme yet proposed is free of substantive uncertainties and/or controversy within the technical community. Certainly, any approaches that require maintenance or continuing surveillance of storage facilities must be regarded as temporary expedients and not solutions, since the continuity of society even over 500 years can hardly be guaranteed. And, whereas some existing or future proposal involving fission *may* be satisfactory, it is hard to be complacent about the use of fission with no solution actually in hand. [134a]

The record of the handling of radioactive wastes produced so far, moreover, is not especially encouraging. Pending the beginning of U.S. commercial operations to solidify high-level waste,

it is still being stored as liquid in steel tanks at the reprocessing plants. This is the method used by the USAEC to manage the radioactive wastes from its bomb-building programs, from which

[131]USAEC, *High-level radioactive waste management alternatives*, p. A-9.
[132]Notable surveys of the high-level waste problem and various proposed solutions are T. Hollocher, *Storage and disposal of high level wastes*; A. S. Kubo and D. J. Rose, *Disposal of nuclear wastes*; USAEC, *High-level radioactive waste*.

[134a]For a provocative and insightful study of ethical as well as technical dimensions of the problem, see G. I. Rochlin, *Nuclear waste disposal: two social criteria*.

there have been several leaks totaling hundreds of thousands of gallons of high-level liquids at both the Hanford, Washington, and Savannah River, Georgia, sites. [135] It is believed that essentially all the radioactivity from those spills has been confined by absorption by soil particles in the immediate vicinity of the tanks.

In the early 1970s, the USAEC announced that a solution had been chosen -- burial in abandoned salt mines, as in fact is practiced in both the Federal German Republic (West Germany) and the Democratic Republic of Germany. Unfortunately, the USAEC picked a particular mine in Lyons, Kansas, that was quite literally full of holes (from drilling for oil and gas decades before). The agency abandoned its plans for this "national repository" after the Kansas Geological Survey identified the site's defects. [136] In 1974, the USAEC announced that a new official solution was to be retrievable surface storage facilities -- an interim plan until something better came along, of course -- and that three potential sites in the western United States were under scrutiny. The draft environmental impact statement for the project reflected so slipshod an approach that complaints were received from utilities and manufacturers of nuclear equipment, as well as environmentalists, and that plan was sheived. [137] USAEC's successor, ERDA, in 1975 was investigating salt deposits again, that time in New Mexico.

Management of intermediate- and low-level wastes has received less scrutiny by the technical community at large, but it also poses significant problems (see Box 8-5). Those materials typically have been placed in oil drums and stacked on the surface on government sites or buried under a few meters of earth at those sites and at various commercial burial grounds. A study by the National Academy of Sciences of radioactive-waste management in the late 1960s concluded that management practices were "barely tolerable . . . on the present scale of operations" and "would become intolerable with much increase in the use of nuclear power." [138] At the Hanford, Washington, government nuclear facility, so much liquid waste contaminated with plutonium was dumped into a single trench over a period of twenty-two years that a genuine and serious danger of an explosive nuclear chain reaction arose (it was estimated that 100 kg of plutonium was contained in about 50 m3 of soil). [139]

A final waste problem is the question of what to do with the reactors themselves (and, for that matter, the reprocessing plant) after their twenty- to forty-year service lives are over. The facilities are intensely radioactive and are not as easy to chop up and dissolve in acid as individual fuel elements. So far, only a few small plants have been decommissioned, and neither the costs nor adequate techniques for large ones are known with certainty. [140]

The weapons connection. Perhaps the most troublesome of all the environmental and social risks of nuclear power is the connection between nuclear-power systems and nuclear weapons -- specifically, the possible diversion of fissionable and toxic material, produced in civilian power programs, for illegitimate and destructive uses.

The knowledge needed to construct fission bombs (popularly called atomic bombs), for example, is relatively widespread and accessible. [141] The principal obstacle to bomb-building until now has been the restricted availability of suitable fissile materials, which only large industrial nations have had the technical resources to obtain. The spread of fission reactors is now changing this situation, because *all* such reactors produce materials suitable for bomb-making, and some reactors even require such materials as input. The idea has been widely propagated that the form of plutonium produced in LWRs is not usable in making bombs, but that is

---

[137] USAEC, *Management of commercial high-level and transuranium contaminated radioactive waste*. The most comprehensive and telling critique was T. Lash and J. Bryson, *Comments of the Natural Resources Defense Council Inc., and the Sierra Club on the USAEC WASH-1539*.

[138] Summarized in National Academy of Sciences/National Research Council, *Resources and man*, p. 8.

[139] USAEC, *Contaminated Soil Removal Facility: Richland, Washington*.

[140] One of the few relevant official documents is USAEC, *Elk River dismantling. Environmental statement*. See also S. Harwood et al., *The cost of turning it off*.

[141] A good popular introduction to the problem is J. McPhee, *The curve of binding energy*. The book is built around a biographical sketch of T. B. Taylor, formerly an accomplished designer of fission bombs, who is as responsible as any individual for calling wide attention to the risk of clandestine bomb production.

incorrect. Use of LWR plutonium presents some additional difficulties in design and renders the explosive yield somewhat unpredictable, but devastating nuclear explosives *can* be made with it. [142]

The problem has both international and national components. Internationally, the main concern is nuclear proliferation -- the spread of nuclear weapons into the hands of governments that did not previously possess such weapons. The Nonproliferation Treaty, signed in 1968 and officially reviewed in 1975, was aimed at ameliorating this threat, but it has many defects: Many nations have not signed it; the safeguards provided by the treaty and administered by the International

Atomic Energy Agency (IAEA) may be able to detect governmental diversion of fissile material from peaceful uses into weapons programs, but they cannot physically prevent it; and the sanctions that can be invoked against governments that are detected violating the treaty are weak. [143] India's nuclear explosion in May 1974, which brought the official membership of the "nuclear club" to six (the others: U.S., USSR, United Kingdom, France, China), was accomplished with the aid of materials from a reactor supplied by Canada. It is widely surmised that Israel has fission bombs or the capacity to assemble some quickly -- again, with raw materials from reactors. The Federal Republic of (West) Germany agreed in 1975 to sell Brazil a complete nuclear fuel-cycle "package," including the reprocessing technology needed to extract plutonium from spent fuel. [144] Brazil has not signed the Nuclear Nonproliferation Treaty.

Perhaps as threatening as international proliferation of nuclear weapons is the possibility of the theft and misuse of nuclear materials by subnational groups -- terrorists, blackmailers, or organized or individual black marketeers who would sell to the highest bidder. (Fissile material is worth about $10,000 per kilogram as nuclear fuel; what it might bring on the black market for use in weapons is anyone's guess.) The bidders, of course, might include governments still lacking their own nuclear facilities or wishing to avoid the risk of being caught at diversion by IAEA safeguards. The theft of nuclear materials by subnational groups could be done by stealth or by force, and of course the possibility of an inside job is especially difficult to exclude. [145] The explosion of a "homemade" nuclear bomb of the sort within the reach of small, technically literate groups could kill tens of thousands of people -- in the worst case, hundreds of thousands -- and injure even more if it took place in a major city. Even a fizzle by such a bomb could be devastating. [146]

All this is not to suggest that it would be easy to steal fissile material and manufacture a fission bomb with it. In fact, it would be quite difficult and extremely dangerous for the conspirators. But it does not have to be easy; if it is possible at all -- and it is -- this is a risk from nuclear power that needs far more public attention. How many nuclear explosions in major cities are too many? One per decade? One per century? One ever? How can one compare this sort of risk with the impacts of fossil fuels? These questions must be answered by society as a whole, not by technologists alone.

The problem of the theft of fissile materials -- especially plutonium and secondarily uranium-233 -- is compounded by the great radiological toxicity of those materials. Bungled attempts at theft, leading to dispersal of the materials, could have serious consequences for public health. Table 8-21 lists the MPCs for the main fissile isotopes and tells how many grams of each makes a curie. The mixtures of plutonium isotopes that come from reactors are about 5 times as dangerous, gram for gram, as pure plutonium-239. The most dangerous pathway for plutonium intake is inhalation. The amount needed to produce a 50-percent chance of lung cancer when deposited in the lung following inhalation is somewhat controversial, but it is probably in the range of from 10 to 100 micrograms of plutonium-239, or one-

---

fifth as much reactor-grade plutonium. [147] This enormous toxicity suggests the possibility of large-scale radiological terrorism using plutonium -- an enterprise that may be considerably easier than manufacturing a clandestine bomb. [148]

The full magnitude of the problem becomes apparent when one compares the quantities of fissile material involved in nuclear fuel cycles with the amounts needed for nuclear malevolence. The critical masses of fissile material needed to make nuclear bombs are listed in the right-hand column of Table 8-21 ; they range from 4 to 25 kilograms. Even smaller amounts might be used effectively for radiological terrorism. As indicated in Table 8-15, a single large power reactor produces an annual output of fissile material in the range of hundreds of kilograms. (Some of the material produces fissions in the reactor before the fuel is removed for reprocessing and so is not counted as output.) In a reactor economy of 1000 large plants, the flow of fissile material would amount to hundreds of thousands of kilograms per year. Historically, the nuclear industry has been unable to keep track of its fissile materials with an accuracy of better than about 99 percent per year. [149] The missing 1 percent or so, known as material unaccounted for (MUF) might only be mixed up with various radioactive wastes; the point is, there is no way to be sure.

The vulnerability of fissile material to theft varies greatly from point to point in the fuel cycle. Spent reactor fuel is not very vulnerable because there the fissile isotopes are mixed up with fission products whose penetrating radiation makes the mixture impossible to handle without the

most elaborate equipment. Fresh reactor fuel is not very radioactive, but for most reactors the fissile material is mixed up with fertile or inert material and is too bulky for convenient theft. The greatest points of vulnerability are probably at the reprocessing plant after the fissile material has been separated from the fission products, at the fuelfabrication plant before the fuel elements are assembled, and in any transportation and storage links between those two steps. A study by the government General Accounting Office in 1973 showed that theft of multibomb quantities of fissile material from U.S. storage facilities would not have been difficult. [150] Safeguards have been tightened up since then, but by what means is classified and by how much is impossible to assess.

One proposal for reducing the risk of nuclear theft is to consolidate the facilities of the commercial nuclear fuel cycle into fewer sites. This could consist of merely putting reprocessing and fabrication plants together, or of adding ten or more large reactors to a reprocessingfabrication complex in a well-guarded "nuclear park" or "nuclear energy center." [151] If adopted, the latter strategy would require substantial reorganization in the utility industry to organize, finance, and otherwise cope with

---

[147]Notable in the large literature of this subject, which incorporates but is not limited to the hot-particle controversy, are: National Academy of Sciences, *The effects on populations of low levels of ionizing radiation*; USAEC, *Generic environmental impact statement: Mixed-oxide fuel*; A. Tamplin and T. Cochran, *Radiation standards for hot particles*; W. J. Bair, and R. C. Thompson, *Plutonium: Biomedical research*; International Atomic Agency, *Inhalation risk from radioactive contaminants*. See also Chapter 10.

the generation of 10,000 Mwe or more at a single site. Concentrating the environmental impacts of so much activity at one site might also pose problems.

The idea that the way to guard against nuclear theft is to use more guards, more thorough investigation of industry employees, more surveillance, and so on, has been challenged as a major threat to civil liberties. [152] And the nuclear industry has vigorously opposed many proposed safeguard methods as causing unwarranted expense and disruption of their activities.

Nuclear Fusion

The difficulty in harnessing fusion as a practical energy source is associated with three conditions essential to the process: (1) the fusion fuel must be heated to a temperature of tens of millions to billions of degrees; (2) the fuel must be dense enough to yield a significant reaction

rate; (3) the fuel must be confined under those conditions for a time long enough that the energy output from fusion reactions exceeds the energy input for heating and confinement. A quarter-century of research on fusion has developed many ingenious approaches to the problem, but none has yet attained the combination of conditions needed for a fusion reactor to produce more energy than it consumes. If this break-even set of conditions is achieved in the late 1970s or early 1980s, as many scientists now think likely, the first commercial fusion reactors might be ready for service around the year 2000.

At the temperatures where fusion can take place, all substances are in the fourth state of matter, or plasma. That is, if solid iron (for example) is heated to 1535° C, it becomes a liquid; if it is heated further, to 3000° C, the liquid boils and becomes vapor -- literally, a gas consisting of iron atoms. If the gas is heated still further, to 10,000° C and more, the increasingly energetic collisions between the iron atoms begin to knock electrons loose.

When there are enough free electrons flying around in the gas of iron atoms that the gas begins to display electrical properties (for example, becoming a good conductor of electricity), the mixture is called a plasma. Atoms that have lost one or more of their electrons are called ions, and a plasma that is hot enough will consist entirely of electrons and ions; no neutral atoms will remain. Although relatively rare on Earths surface, plasma is by far the most common state of matter in the universe -- the sun and all other stars are made of it.

The reason the fusion reactions that fuel the stars run only at the very high temperatures where plasma prevails is simple; two light nuclei can fuse into a heavier one only if they are brought extremely close together. At ordinary temperatures, nuclei are held far apart by the shell of electrons that surrounds each of them. With the electrons gone, as in a "low-temperature" plasma of a few tens of thousands of degrees Celsius, two nuclei still cannot be made to come together because, being both positively charged, they repel each other with enormous force. Temperatures of tens of millions of degrees and more are needed to give the nuclei the tremendous speed required for them to crash together despite their strong electrical repulsion. Fission reactions, by contrast, are initiated by neutrons; a neutron penetrates an intact electron shell and crashes into the nucleus inside without encountering any electrical force at all, so fission can work at room temperature.

In the sun and other stars, the fusion plasma is held together by the gravitational force of its own tremendous mass. This will not work on Earth's surface. Nor can one hold the fusion plasma with any conventional container. Either the plasma would melt the container, or the container would cool the plasma to well below the kindling temperature of fusion. (Usually it is the latter -the container cools the plasma; the plasma, although hot, is too dilute to melt through much metal.)

There are two approaches capable of releasing fusion energy on Earth's surface. One is to heat the fuel so rapidly to fusion temperatures that fusion reactions take place before the hot gas has time to blow itself apart. This is called *inertial confinement*, because inertia holds the atoms together for the fraction of a second needed to get a substantial amount of fusion energy. An extreme case of inertial confinement is what happens in a hydrogen

---

[152]J. G. Speth, A. R. Tamplin, T. B. Cochran, *Plutonium Recycle: The fateful step*; R. W. Ayres, *Policing plutonium: The civil liberties fallout*. For a discussion in the British context, see Sir Brian Flowers, Chairman, Royal Commission on Environmental Pollution, *Nuclear power and the environment*.

bomb. It may also be possible to make a fusion reactor this way, using lasers or intense beams of electrons or heavy ions as the initial energy source. (In a hydrogen bomb, a fission bomb serves as the trigger that provides the initial heating.)

The second approach is to take advantage of the electrical properties of the plasma to heat it and confine it, using electromagnetic fields. This approach is called *magnetic confinement*. This has had the longer history of the two approaches in the controlled-fusion field (bombs, although intentional, are uncontrolled in this terminology), and we therefore treat it first.

Magnetic confinement. The heart of the matter is that electrically charged particles -- namely the electrons and positively charged ions -- cannot move very far perpendicular to the direction of a strong magnetic field. The stronger the magnetic field, the more tightly the particles are constrained. One can think of magnetic fields, in fact, as exerting a pressure on plasma; and by arranging magnets cleverly it is possible to produce a set of magnetic fields that push in on a plasma from virtually every direction. Such an arrangement is often called a "magnetic bottle." Of course, Newton's laws should remind us that if the magnetic field is pushing on the plasma, the plasma must be pushing back. It does, and the magnetic field transmits its push to the magnet's structure. Thus the system "knows" it is containing something, but the hot plasma itself is held away from the magnets and all material structure.

Unfortunately, it is not quite so easy in practice. Roughly twenty-five years of effort in laboratories around the world have revealed a dismaying tendency for the plasma to leak from the magnetic bottles faster than anticipated. (The enterprise has been compared to trying to hold watery Jello in a cage of rubber bands.) There are two main ways in which the plasma escapes. One is when collisions among ions knock them across the magnetic field and eventually into the walls or otherwise out of the machine. (Remember, particles that hit the wall lose most of their energy and with it the capacity to react.) The motion by interparticle collisions is called *classical diffusion*, and it is slow enough that a fusion reactor can work in spite of it. The second escape mechanism is called *instabilities*. These may involve large-scale, coherent motion of the plasma (macroinstabilities), in which the magnetic field is systematically deformed by the plasma itself in ways that bring the plasma into contact with the walls. Alternatively, instabilities can take the form of interactions of certain groups of ions and electrons (that is, those in a particular speed range) with each other and with the magnetic field in such a way that the rate of diffusion of plasma across the magnetic field is greatly enhanced. These are called microinstabilities. Most of the effort in controlled-fusion research has been devoted to cataloging, analyzing, and trying to circumvent those instabilities.

Three types of magnetic bottle have received most of the attention in recent fusion research and are widely believed to represent the best hopes for success among the many approaches to

magnetic confinement that have been invented. The three are the theta pinch, the mirror machine, and the tokamak. They are illustrated schematically in Figure 8-21.

In the theta pinch, the plasma takes the shape of a long rod. It is held away from its tubular container by a magnetic field whose direction is parallel to the axis of the rod. The plasma is compressed to high density and temperature by suddenly increasing the strength of that magnetic field. A fusion reactor using the theta pinch would operate in pulses, since the very strong field required cannot be maintained for long. To reduce or eliminate the escape of plasma out the ends of the rod, the theta pinch must either be made very long (a kilometer or more for a reactor) or bent into a doughnut shape (torus) that closes upon itself.

Mirror machines operate with the plasma at somewhat lower densities and would be capable, in theory, of running more or less steadily, rather than in pulses. The name *mirror* comes from the tendency of the moving charged particles to reverse direction (hence, "reflect") if they move into a region where the strength of the magnetic field increases very sharply. The earliest mirror machines contained basically cylindrical plasmas and looked like a section of a theta pinch but with very strong fields at the ends forming the "mirrors." Those plasmas were unstable, and ways were subsequently found to produce more complicated magnetic-field shapes with the basic desirable properties of mirrors but without the strongest instabilities. The high temperatures achieved

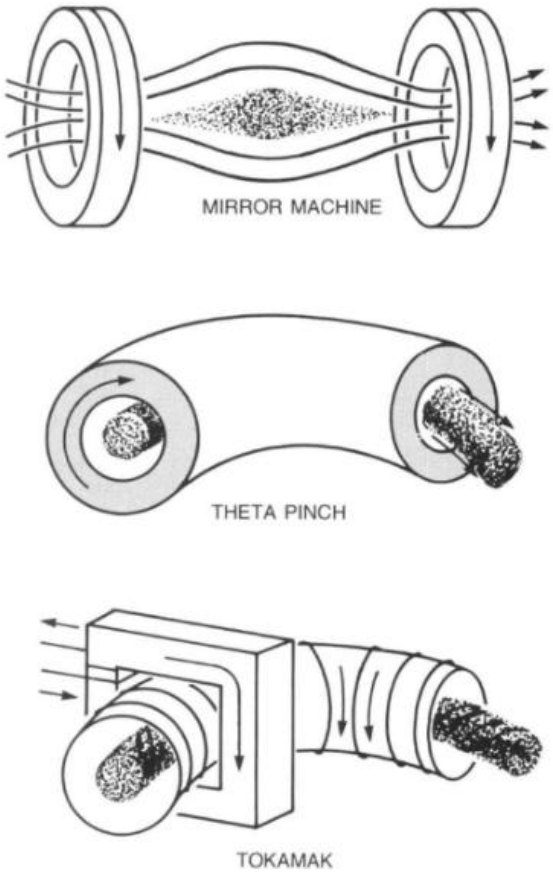

FIGURE 8-21 Schematic diagrams of three concepts for fusion reactors. From bottom to top are the tokamak, the theta pinch, and the mirror machine. The tokamak and theta pinch diagrams show one-quarter of the full toroidal device. (After Gough and Eastlund, 1971.)

TABLE 8-22 How Close Is Magnetic Confinement to Energy Break-Even?

Device, country	**n** *(sec)* × τ*(ions/cm^3)*	*Temperature (million° C)*
Mirror (U.S., 1975)	10^{11}	100
Theta-pinch (U.S., 1972)	3×10^{11}	20
Tokamak (USSR, U.S., 1972)	10^{12}	5
Advanced tokamak (USSR, U.S., 1977?)	10^{13}-10^{14}	10-100
Lawson condition (D-T plasma)	10^{14}	50
Lawson condition (D-D plasma)	10^{16}	500

Source: R. Hirsch and W. Rice, *Nuclear fusion power and the environment*.

in modern mirror machines are produced by injecting high-energy beams of neutral fuel atoms across the magnetic field and into the plasma. The atoms in the beam ionize as soon as they hit the plasma, they become part of it, and they deposit their energy there.

Tokamaks are toroidal (doughnut-shaped) devices of medium plasma density, in which a strong current is made to flow along the tube of plasma itself. This current heats the plasma and produces a magnetic field that helps to suppress instabilities. Tokamaks surged to a position of dominance in world fusion research after important successes were achieved in the USSR with this approach in 1969. (Magnetic-confinement fusion research was declassified by international agreement in 1958, and the field has been a model of international scientific information-sharing ever since.) Large tokamaks that are expected to approach fusion break-even conditions are scheduled for operation in the late 1970s in several parts of the world. Sad experience in the fusion field, however, makes most experts wisely reluctant to count those chickens before they hatch.

The elusive break-even point, which would conclusively demonstrate the scientific feasibility of fusion-although by no means the engineering practicality -- is the achievement of plasma density and average time of confinement such that the product of those quantities (with density measured in ions per cubic centimeter and time in seconds) equals 10^{14}. This must be done while the plasma temperature is 50 million° C or more. This set of requirements is known as the Lawson condition, after the British physicist who showed in 1957 that its achievement would permit a fusion machine running on the deuterium-tritium (D-T) reaction to produce more electricity than it consumed. The performance of past and future fusion machines is compared to the Lawson condition in Table 8-22. [153] Note that the break-even conditions for the D-D reaction are considerably more difficult to attain.

[153] Particularly good expanded coverage of the material treated here is offered by W. Gough and B. Eastlund, "The prospects of fusion power"; R. F. Post and F. L. Ribe, "Fusion reactors as future energy sources"; R. Hirsch and W. Rice, "Nuclear fusion power and the environment". For readers with strong technical backgrounds, the basic physical principles are well covered

in the classic D. J. Rose and M. Clark, *Plasmas and controlled fusion*.

Laser fusion. Although it was conceived in 1961, the idea of using lasers to produce fusion miniexplosions in pellets of fusion fuel had to await the development of the very powerful lasers of the late 1960s and early 1970s before experimentation could begin in earnest. In the late 1970s, the performance of lasers (and of high-energy beams of electrons or ions, which could serve the same function) remain the principal limitation holding back this approach to controlled fusion.

In laser fusion, the Lawson condition still applies, but the aim is to meet the condition the same way a fusion bomb does -- not by confining a low density for a long time, but by creating enormously high densities in a plasma held together for the tiniest fraction of a second by its own inertia. In magnetic confinement, the highest densities that can be considered are around 10^{16} ions per cubic centimeter (around 1000 times less dense than the air we breathe), requiring confinement times of about a hundredth of a second for energy break-even. (The limit on density comes from the maximum pressure the magnet structure can withstand; at 100 million° C, 10^{16} particles/cm3 exert a pressure of about 130 atmospheres -- a ton per square inch.) By contrast, the breakeven conditions for laser fusion are a density of 10^{26} particles per cubic centimeter and a confinement time of 10-12 (a millionth of a millionth) second. This density is from 1000 to 10,000 times that of normal liquids and solids, and the process by which it is achieved is *implosion*. [154]

To produce implosion, tiny fuel pellets must be irradiated symmetrically from all sides by precisely synchronized, precisely focused laser beams. These beams are pulsed; that is, they deliver their energy in bursts, each of very short duration. Probably, the required spherical symmetry will be obtained by splitting a single powerful laser beam with mirrors and then focusing the components of the beam on the fusion combustion chamber. To build a successful laser-fusion reactor based on the D-T reaction would require a laser that could deliver a pulse of 1 nanosecond duration containing 0.3 megajoule of energy (1 nanosecond = 10^{-9} second). The laser must also have an efficiency of 10 percent in converting electric energy to laser energy. The best lasers available in 1974 had energies around 0.001 megajoules per pulse and efficiencies between 0.1 and 2 percent. Nevertheless, the science and technology of lasers is changing rapidly, and it is not inconceivable that the improvements needed to make laser fusion break even energetically will be made. A laser capable of delivering 0.01 to 0.05 joules in a pulse of less than a nanosecond is scheduled for operation in 1977. [155]

Assuming that a suitable laser were available, a laser-fusion reactor of 100-Mwe generating capacity would operate by detonating about 100 pellets of D-T fuel per second. Each of those implosions would produce about 30 megajoules -- 100 times as much energy as the laser deposits in the pellet to detonate it. (Thirty megajoules is about the amount of energy released in the explosion of 7 kilograms of TNT.) The high repetition rate needed for a large plant might be accomplished by using several split-beam lasers, each with its own combustion chamber. The combustion chambers would have to be lined with materials capable of withstanding the rapid-fire explosions inside and of transferring the energy outward in a form suitable for conversion to electricity. A diagram of a laser-fusion power plant is shown in Figure 8-22.

Engineering aspects. Whether controlled fusion is accomplished with magnetic confinement or with lasers, the transition from a demonstration of scientific feasibility to a practical power plant will require the solution of some difficult engineering problems. This could easily require ten or fifteen years of intensive (and expensive) work -- and with bad luck, even more.

In either scheme, for example, the D-T fusion reactions produce about 80 percent of their energy in the form of extremely fast neutrons. These are several times as energetic as the neutrons that create the very difficult materials problems in fission breeder reactors. As many of the neutrons as possible must be made to deposit their energy as heat in a solid or liquid "blanket," from which

---

[154] An excellent and detailed description of the entire laser-fusion problem by some of the pioneers of the field is J. Emmett, J. Nuckolls, and L. Wood, "Fusion power by laser implosion". A shorter and less technical description appears in Chapter 14 of Hammond, Metz, and Maugh, *Energy and the future*.

[155] Emmett, Nuckolls, and Wood, "Fusion power", p. 31.

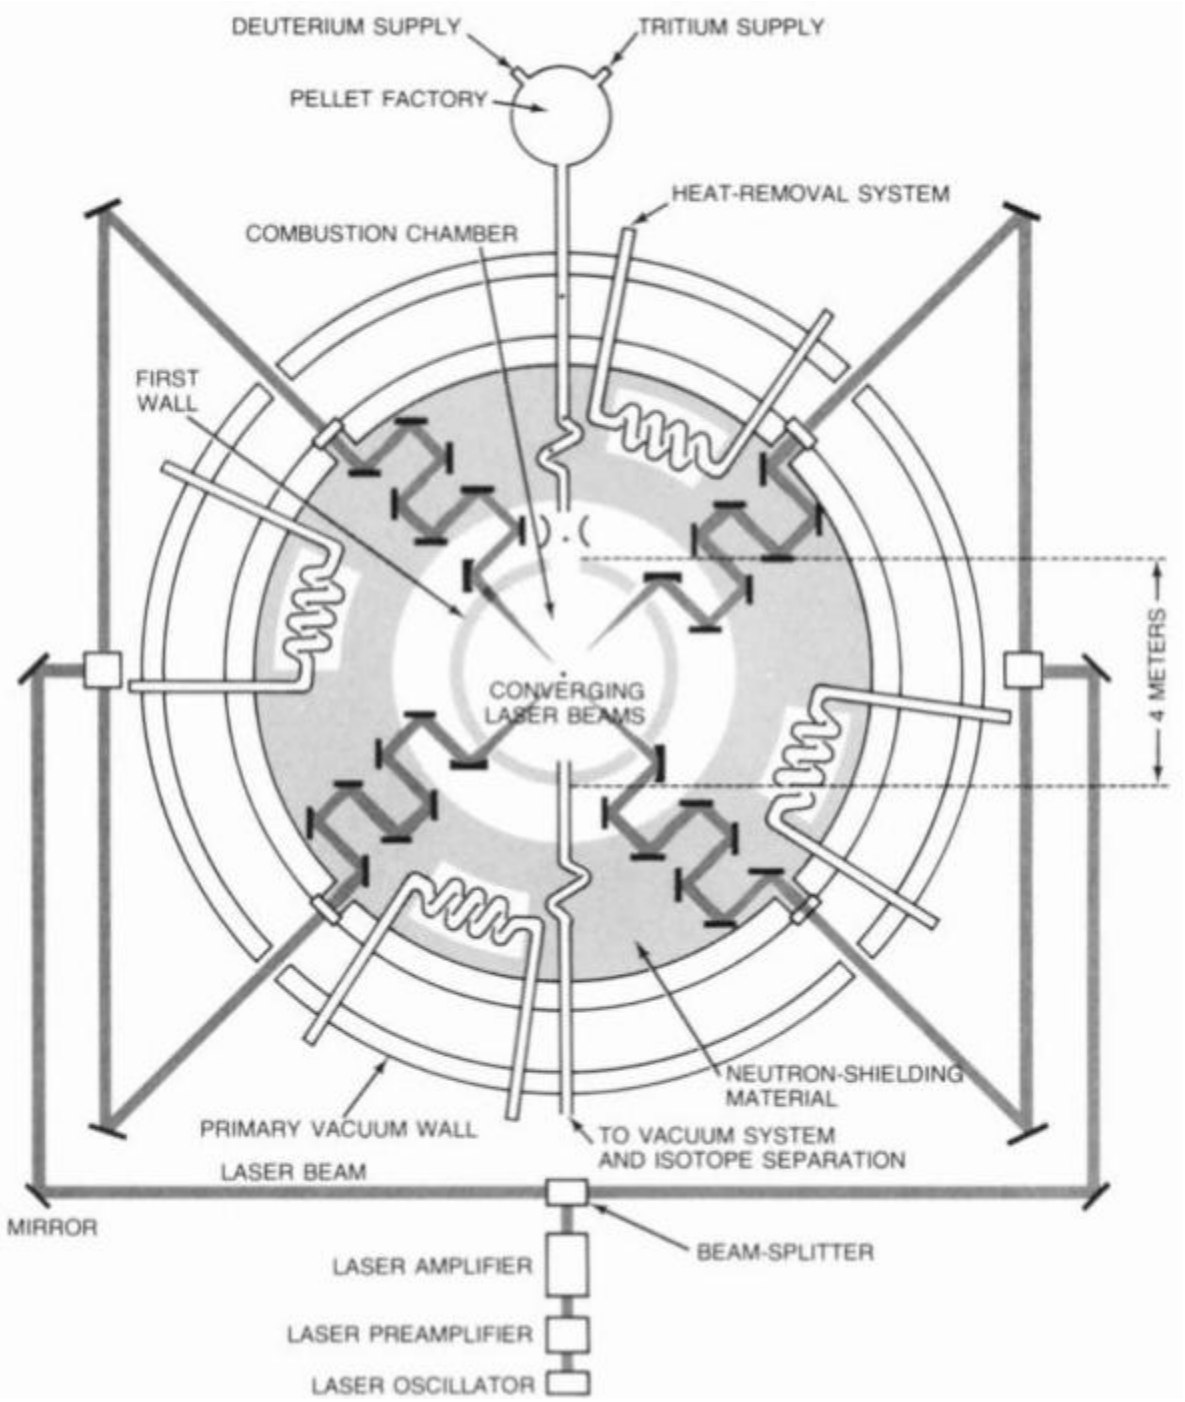

FIGURE 8-22 Schematic diagram of a laser fusion power plant. (From Emmett et al., 1974.)

the heat can be extracted for generating electricity. It is desirable that the neutrons end up being absorbed by lithium, which thereby breeds tritium to replace that which reacts. Neutrons that get absorbed in structural materials instead of in lithium do great damage and convert the elements that absorb them into radioactive isotopes, many with long half-lives. Under fusion conditions,

large quantities of X-rays and stray ions of various kinds are also produced, and they, too, bombard the inner structure of the reactor.

Even if a laser with the required performance for laser fusion can be built, making laser components that will *last* under the stresses of handling huge pulses of energy many times a second for years on end will be extremely difficult, perhaps impossible. The lenses and mirrors that handle the laser beam close to the combustion chamber will be especially hard to protect from neutrons and X-rays.

In magnetic-confinement fusion, the magnets are like the lasers in laser fusion: they are the cornerstone of the system, very expensive, and vulnerable to damage by overheating from their own circulating energy or from energy deposited by neutrons and X-rays. The problem is especially difficult because most magnetic-confinement schemes appear feasible only with superconducting magnets -- special materials whose resistance to electric current drops to zero when they are cooled to the temperature of liquid helium, a few degrees above absolute zero. These magnets must be very close to the fusion plasma they are containing; if they were far away, the confining field would be too weak. Thus, the fusion engineer faces the remarkable task of maintaining a temperature of about 4 degrees above absolute zero, at most a meter or so away from a fusion plasma of 100 million degrees Celsius, releasing energy at a rate of thousands of megawatts. When all the machinery needed to create, confine, heat, shield, and replenish the fusion plasma is taken into account, together with the devices needed to convert its energy into electricity, a fusionreactor system will be a very complicated enterprise.

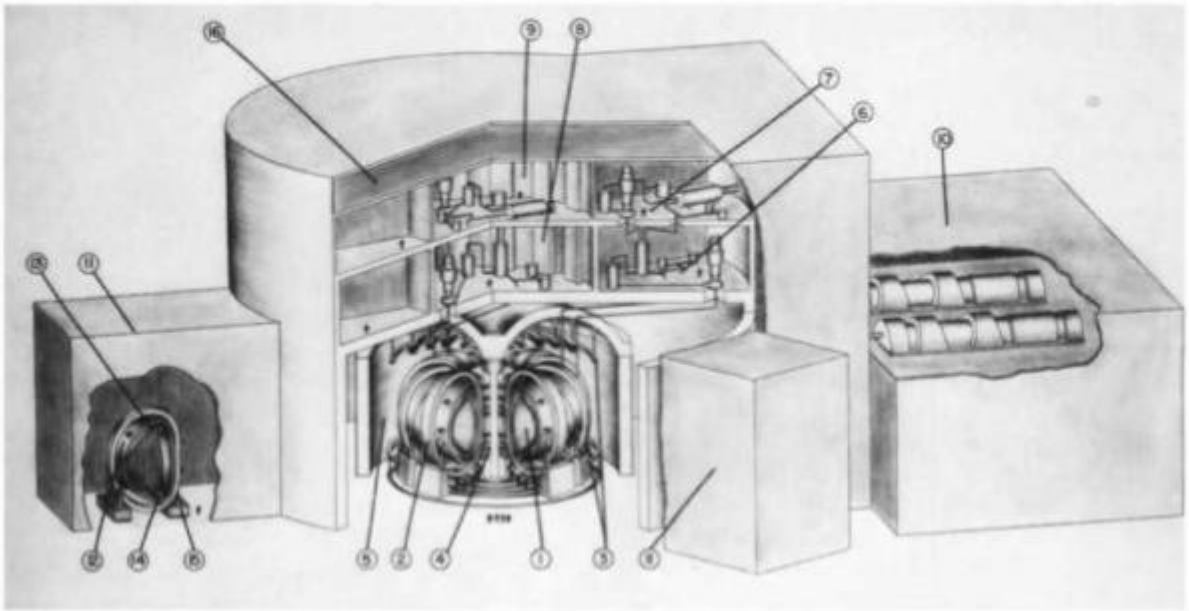

FIGURE 8-23 Conceptual design of a tokamak fusion reactor. The great complexity likely to characterize fusion reactors means they will not be cheap. 1, Plasma; 2, Toroidal field coil (12); 3, Retractable divertor coil (8); 4, Transformer coil (10); 5, Evacuated primary containment

building; 6, Li primary system (one for each of 12 modules 7, Na secondary system (one for each of 12 modules); 8, Divertor Li primary system; 9, Divertor Na secondary system; 10, Turbine-generator building; 11, Hot cell repair area; 12; Magnet shield, 13, Blanket; 14, Divertor collection area; 15, Motorized module support vehicle; 16, Auxiliary equipment area. (From Badger, et al., 1975.)

This is illustrated for magnetic confinement by the conceptual tokamak-reactor power plant presented in Figure 8-23.

Environmental aspects. Fusion offers the potential for significant environmental and safety advantages, compared to fission, in three main respects. First, the fuels and reaction products of fusion are nonradioactive, except for tritium. Being a fuel, it can be burned up and need not become a waste-management problem. Second, there is no chance of a runaway reaction that could release more energy than intended. The conditions under which fusion flourishes are so extreme and so difficult to attain that any malfunction merely causes a departure from those conditions and thereby quenches the reaction. (A good deal of the essence of this situation has been summed up in the only partly humorous statement, "Fusion must be safe, because it doesn't work.") Third, fusion does not automatically produce materials needed to make nuclear explosives; hence, the problem of nuclear theft need not arise with fusion.

None of the foregoing potential advantages is absolute, and it would be possible to design fusion reactors with so little concern for their environmental characteristics that the advantages over fission would be minimal. This can be avoided only if optimizing the environmental characteristics of fusion reactors is given high priority and intensive effort throughout the process of reactor development and design.

The inventory of tritium in a 1000-Mwe D-T fusion reactor, for example, varies between 10 megacuries and 500 megacuries in different conceptual designs. [156] (The term *conceptual design* indicates that these are not designs for plants actually to be built. Designs for real plants will have to await more progress in basic fusion physics.) The lower figure represents a relative hazard (inventory divided by MPC) about 20,000 times less than the radioactive iodine in a fission reactor of the same size, and

[156] Most data in this section are from John P. Holdren, T. K. Fowler, and R. F. Post, "Fusion power and the environment"; G. Kulcinski, "Fusion power: An assessment of its potential impact in the USA"; Hirsch and Rice, "Nuclear fusion power".

the second figure a relative hazard 400 times less than the radioactive iodine. [This calculation assumes all the tritium (T) is incorporated into water, forming HTO instead of H_2O by replacing normal hydrogen; this HTO is much more dangerous than tritium gas and has a lower MPC. Radioactive iodine is the most dangerous substance easily releasable from a fission reactor in gaseous form.] If ingenious design can actually keep the tritium inventory near 10 megacuries or less -- about three days' fuel consumption in a 1000-Mwe fusion system -- then even successful sabotage probably could not cause a release that would lead to fatal acute radiation exposure

outside the reactor site. Great care will have to be taken in any case to minimize routine emissions of tritium, which at high temperatures is capable of diffusing rather readily through steel.

The second radiological hazard of fusion is the material in the reactor structure that becomes radioactive because of bombardment by neutrons. The size of this inventory of activation products depends on what material is used for the inner structure of the reactor. Niobium, which is a good structural material for fusion reactors in other respects, has activation products whose total relative hazard at reactor shutdown would be only 10 to 100 times less than that of the fission products in a fission reactor of the same size. If vanadium can be used instead of niobium, the initial relative hazard would be about 1000 times less than that of fission products. After a year, the margin becomes much larger -- a factor of 1 million or more -- because the half-lives of most activation products of vanadium are short.

The environmental promise of fusion relative to fission is even greater if one considers the possibility of clever designs that minimize the opportunities for neutrons to come into contact with structural materials, and the possibility of harnessing fusion reactions more difficult than D-T, which produce fewer neutrons.

That fusion reactors are incapable of nuclear excursions does not make them absolutely safe against release of whatever radioactive materials are inside, because other sources of energy may be available to break reactors open. Most conceptual fusion-reactor designs embody a great deal of liquid lithium, for example, which serves both as a coolant and as the means for breeding tritium fuel. Lithium, like the sodium used to cool the fission LMFBR, is chemically reactive; a large lithium fire is probably the maximum conceivable accident for a fusion reactor. Much attention is now being given in the conceptual design of fusion reactors to the possibility of using coolants other than lithium and incorporating the lithium needed to breed tritium in molten salt or a solid.

A few people have suggested that controlled fusion might accelerate the spread of nuclear weapons (including into terrorist hands) just as fission might, because the tritium could be diverted or stolen to make fusion bombs. [157] The analogy is inept in two respects. First, as far as is known, no one has ever succeeded in making a fusion bomb without using a fission bomb for a trigger. [158] Thus, it is the availability of *fissile* materials that limits the manufacture of nuclear bombs of all kinds. Second, the further limit on fusion bombs is lack of knowledge and technical sophistication, not lack of usable fusion fuels. A group with the knowledge to make a fusion bomb would not need tritium from a fusion reactor to do it. [159] One must ask, of course, whether the dissemination of fusion-power technology will spread the knowledge needed to make fusion bombs. The knowledge relevant to magnetic confinement is not relevant to the design of bombs, so the answer there is no. Some parts of laser-fusion research were still classified at this writing, apparently because that knowledge is related to the problem of making a fusion bomb. [159a] This connection to nuclear weaponry seems to us to be a serious drawback of laser fusion.

Fusion-Fission Hybrids

As early as the beginning of controlled-fusion research in the 1950s, the idea occurred to some people to combine fusion and fission technology in a hybrid power system. The idea kindled renewed interest in the 1970s, both in the Soviet Union and the United States. The essence of

[157]W. Haefele and C. Starr, "A perspective on fission and fusion breeders"; for detailed counterarguments, see the responses by F. von Hippel and by J. Holdren ("Comments on fission and fusion breeders") in the same journal, April 1975.
[158]Willrich and Taylor, *Nuclear theft*.
[159]See, for example, the discussion of fusion bombs in Inglis, *Nuclear Energy*, pp. 183-187.
[159a]See, for example, W. Metz, "Energy research: Accelerator builders eager to aid fusion work"; ERDA, *Final report of the special laser fusion advisory panel*.

the concept is to wrap a subcritical fission blanket around a sub-break-even fusion reactor core. (Subcritical means that the fission part has a composition and configuration such that it cannot sustain a chain reaction by itself.) The fusion neutrons then cause fissions in the blanket, from which about 10 times as much energy per fusion neutron is produced as in a pure fusion reactor. This relieves the Lawson condition for energy break-even -- the plasma containment in the fusion core can be almost 10 times less effective in a hybrid than in a pure fusion reactor and still permit the machine to produce a net energy output.

Suitably designed fusion-fission hybrids could also be used mainly to make fission fuel by arranging for the fusion neutrons to cause fertile-to-fissile conversions in the blanket. The fuel thus produced could be used in pure fission reactors elsewhere. This approach has been proposed in case pure fission breeder reactors don't work very well. Furthermore, hybrids could be used to fission the long-half-life heavy elements (actinides) produced in pure fission reactors, thus reducing their half-lives to those of fission products. The energetic fusion-reactor neutrons would be much more effective at fissioning actinides than are fission-reactor neutrons. [160]

Environmentally, fusion-fission hybrids have some of the worst characteristics of both parents. They would have somewhat fewer neutron-activation products than a pure fusion system, but almost as large a quantity of fission products as a pure fission system. There would be less tritium than in a pure fusion reactor, but still a lot, and there would be essentially the same risk of nuclear theft as in a pure fission system. The principal advantage would seem to be a much smaller chance of an accident than in a pure fission breeder reactor, *if* it is shown that breeder reactors are as dangerous as some of their critics think. It seems unlikely that hybrids will be as attractive as pure fusion systems, once those work; and, because hybrids combine the considerable complexity of both fusion and fission technology, they could easily be extremely expensive. [161]

Geothermal Technology

The character and environmental impact of geothermal energy technology depend strongly on the kind of deposit being tapped. The five main kinds are: (1) vapor-dominated (dry) steam, in which little or no liquid water comes to the surface with the steam; (2) hot water and wet steam,

in which the resource is actually hot water under high pressure, some of which "flashes" to steam as the water is brought to the surface; (3) hot, dry rock, in which the water that serves a heat-transfer medium must be pumped in from the surface; (4) "geopressure" resources, consisting of hot brines present in combination with methane gas under pressure; (5) magma (see Chapter 2), for which no harvesting technology has yet been worked out. Harvesting technologies corresponding to the first three categories are illustrated schematically in Figure 8-24.

The technology of dry-steam geothermal fields is the simplest. Wells are dug into steam reservoirs, typically at depths of 200 to 3000 meters. [162] The dry-steam electricity generating plant at The Geysers, California, requires about fourteen such wells, each supplying 150,000 pounds of steam per hour, for each of its 110-Mwe units. The steam comes up the well under its own pressure and is directed through valves and pipes to a low-pressure turbine. The steam enters the turbine at about 175° C and 7 atmospheres pressure. Those values, much lower than those for fossil-fueled or nuclear generating plants, lead to a turbine efficiency of about 22 percent. The overall plant efficiency is about 15 percent. The steam passes from the turbine to a condenser, and then about three-fourths of the water produced there from the steam (condensate) is evaporated into the atmosphere in a wet cooling tower. The remainder of the water is reinjected into the steam-bearing underground formation.

Hot-water technology differs from that for dry steam in requiring separation of the hot water from the associated steam before the steam enters the turbine. The hot brine, whose salinity may approach 100 times that of seawater, meets one of three fates: it may be discharged at the surface to mix with fresh water runoff (as happens in

---

[160] A good, although technical, review of hybrid possibilities is L. M. Lidsky , "Fission-fusion system: Hybrid, symbiotic, and Augean"; see also U.S. Energy Research and Development Administration, *DCTR fussionfission energy systems meeting*.

[161] For a more detailed examination of the environmental and cost questions, see J. P. Holdren, The relevance of environmental concerns in contemplating development of fission-fusion hybrids, in ERDA, *DCTR*.

[162] Most data in this section are from Science and Public Policy Program, University of Oklahoma, *Energy alternatives: A comparative analysis*. A shorter review is Hammond, Metz, and Maugh, chapter 9.

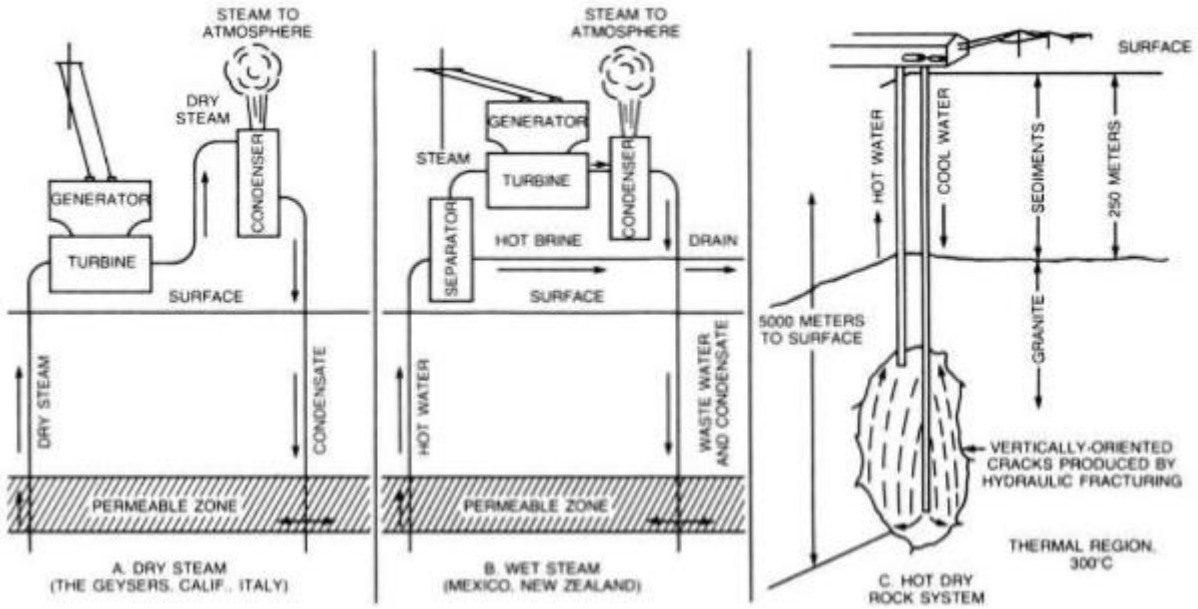

FIGURE 8-24 Three ways to harness geothermal energy. (After Science and Public Policy Program, University of Oklahoma, 1975.)

the hot-water fields in New Zealand); [163] it may be reinjected into the ground (Japan); or it may be treated to remove the minerals for possible sale, rendering the water usable for agricultural or other use (as planned for some future installations in southern California and elsewhere). As with dry-steam systems, much of the condensate is evaporated in cooling towers. Advanced hot-water power plants will probably eventually use a closed cycle, in which the hot water transfers its energy to an organic fluid such as isobutane and then is reinjected into the ground. The organic fluid is vaporized in the heat exchanger, drives a turbine, is recondensed, and then returns to the heat exchanger. (Turbines that use organic fluids are more efficient at temperatures below 200° C than steam turbines, but there is an energy loss in the water-to-organic-fluid heat exchanger.) The overall steam-to-electricity efficiency of hot-water plants is only around 11 percent.

Technology for harnessing the geothermal energy in hot, dry rock had not been perfected as of the mid-1970s, but encouraging experiments were underway. [164] The basic idea is to drill to depths between 2000 and 10,000 meters, where rock temperatures between 300' and 700° C are encountered (depending in detail on the proximity of upward intrusions of magma from deeper in Earth, as described in Chapter 2). Water is pumped down the well under great pressure to fracture the hot rock at the bottom, producing a large cracked volume in which the rock can give up its heat to water that is subsequently circulated. A second well is drilled into each fractured area to complete the path for this circulation; the circulating water flashes to steam when it reaches the lower pressures near the surface, and the steam drives a turbine. As in the other schemes, there must be a condenser and a means of discharging the waste heat at the surface.

At a few locations around the world, geothermal steam is available in close proximity to human settlements and is used directly for heating buildings and greenhouses, rather than for producing electricity. Such applications will probably remain of strictly local importance.

[163]R. Axtmann, "Environmental impact of a geothermal power plant".
[164]A. L. Hammond, *Dry geothermal wells*.

Geothermal-energy technology is not without significant environmental problems, most of them arising from the high mineral content of the underground deposits of steam and hot water. The contaminants include sulfur, arsenic, mercury, fluorides, ammonia, radon gas, and a variety of salts that corrode equipment and that can pollute surface water if the brines are not reinjected into the underground deposits. Sulfur emissions (in the form of odorous hydrogen sulfide) from The Geysers drysteam plant are roughly equal to the sulfur emissions from a fossil-fueled plant of the same size burning low-sulfur oil. [165] Sulfur emissions from open-cycle hot-water plants may even exceed those from uncontrolled burning of high-sulfur coal. Reduction of those emissions is one strong motivation for using the more expensive closed cycle with organic working fluid in these plants.

Emissions of radon gas probably vary considerably from one geothermal reservoir to the next. No definitive data are available; it is possible that the most serious associated problem will be the exposure of workers to accumulations of radon gas in geothermal-plant buildings. [166]

Because of the low thermal efficiency, the waste heat discharged to the environment at geothermal installations is several times that at fossil-fueled or nuclear power plants of like generating capacity. Additional environmental liabilities of geothermal technology

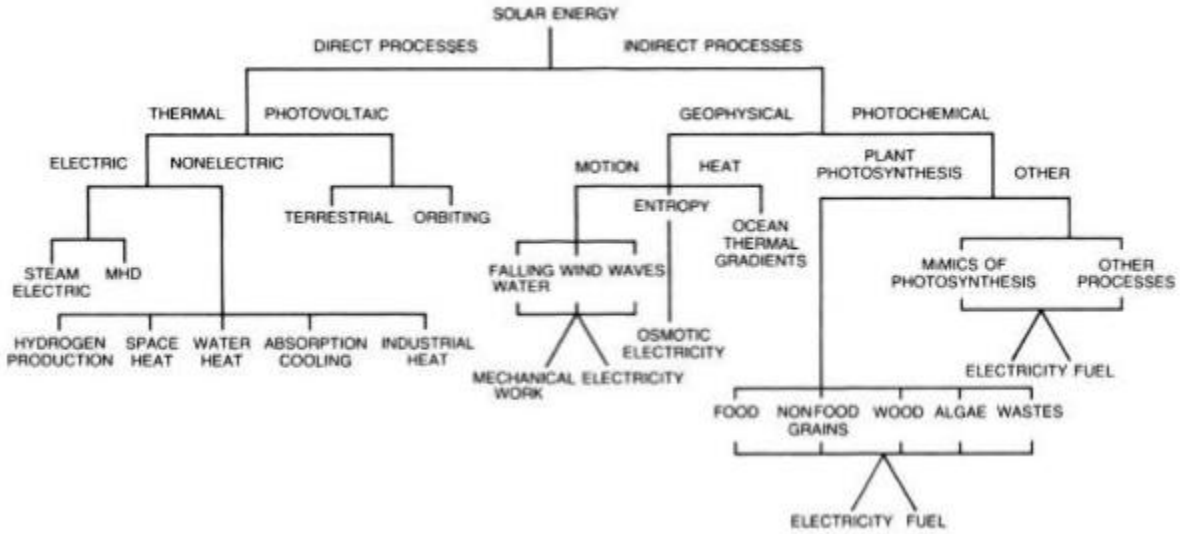

FIGURE 8-25 Options for harnessing solar energy. There are many possibilities. Excluded here are fossil fuels, which are solar energy stored in chemical form over millions of years. MHD = magnetohydrodynamics.

(mostly of only local influence) are ground subsidence, noise, and the possibility that fluid injection may trigger earthquakes.

Notwithstanding the technical and environmental problems that must be overcome or ameliorated, geothermal energy possibly has the potential to be producing 30,000 Mwe of electrical power in the United States by 1985; 100,000 Mwe by 1990; and 200,000 Mwe (about half the U.S. 1970 installed capacity) by the year 2000, according to a major study conducted by the National Science Foundation for the Federal Energy Administration. [167]

Direct Uses of Solar Energy

The abundance and long duration of the solar resource are not in doubt. The important questions are for what uses and with what technologies solar energy can be harnessed economically. There are a great many options, most of which are identified in Figure 8-25. They are

TABLE 8-23 Distribution of Solar Energy in the United States (MJ/M2-day)

	December	March	June	September	Annual average
Burlington, Vt.	5.1	12.3	20.0	13.6	12.6
Seattle	2.6	12.1	23.4	13.8	13.1
Omaha	6.8	14.6	24.6	14.5	15.3
Atlanta	8.1	14.6	21.0	18.1	15.8
Tucson	9.9	19.9	27.8	19.7	19.8

Note: Figures are average amounts of energy incident on a flat horizontal surface, in megajoules per square meter per day (MJ/m^2-day). Multiply by 11.6 to get w/m^2, or by 88.1 to get Btu/ft^2-day.
Source: U.S. Department of Commerce, *Climatological data: National summary*.

divided somewhat arbitrarily there into direct and indirect applications of solar energy. By direct we mean technologies wherein incident sunlight is converted directly into a desired form -- heat or electricity -- for essentially immediate application. By indirect we refer to processes wherein the solar energy is converted into intermediate forms -- wind, falling water, chemical energy stored by photosynthesis -- before being used. We consider the direct uses first.

Important in all such uses is the intensity of incoming solar energy and the variation of that intensity with time. At noon on a clear day on Earth's surface, a collector perpendicular to the rays receives around 1000 watts per square meter (w/m^2). As indicated earlier, the average on a continuous basis in the United States is about 180 w/m^2. (The latter, in units still commonly used in the United States, is 1370 Btu per square foot per day.) The distribution of incident sunlight in the United States in differing regions and times of year is given in Table 8-23. [168]

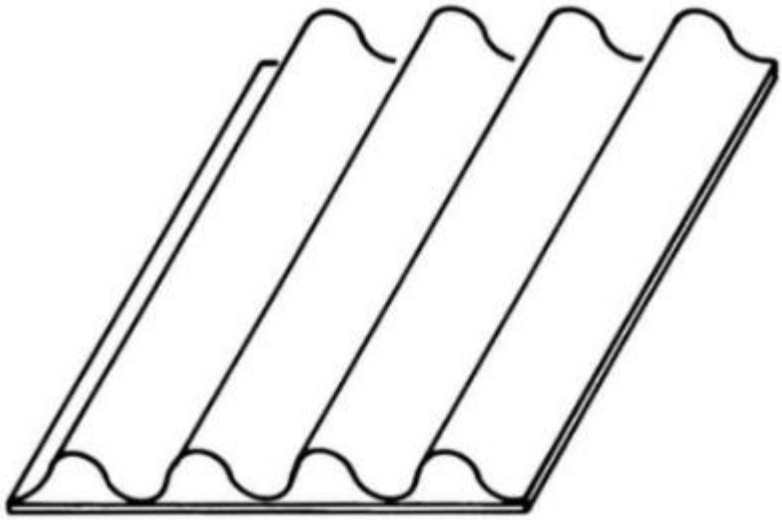
Those energy densities are lower than values typically encountered in "high-technology" energy systems -- for example, the several hundred thousand watts per square meter of heat-transfer surface in a fossil-fueled boiler. They are not low, however, compared to many kinds of needs. The rate of residential energy use in the United States in 1975 averaged 2500 thermal watts per person, which corresponds to the solar input on 14 square meters of average territory in this country.

Heat and cold. Among direct uses of solar energy, the oldest and most widespread applications have been those that used sunlight as heat: drying crops, distilling water, warming water for domestic use, warming dwellings, cooking in reflector-ovens. [169]

Solar collectors for heating domestic water have been manufactured commercially and used widely for many years in Australia, Israel, India, the USSR, and Japan. Such systems were used in Florida in the 1930s, before cheap natural gas was introduced there, and in the mid-1970s they were coming back onto the market in many parts of the United States in response to soaring prices of electricity and natural gas. Water heating is probably the simplest solar technology with the potential for replacing significant amounts of fossil fuel and electricity in this country, as it requires only a flat-plate collector and some rather simple plumbing.

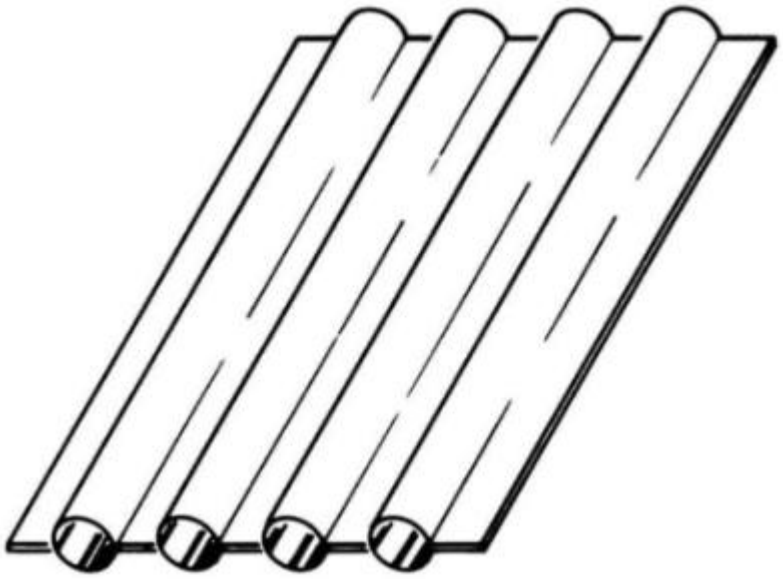
Flat-plate collectors are presented schematically in Figure 8-26. Water flows in tubes, either attached to or part of a sheet of black metal or plastic. Sunlight is absorbed by the black surface as heat warms the water, which is stored in an insulated tank. If a glass plate (or two) is placed over the collection plate to keep the wind from cooling it and to trap some of the heat that would otherwise be radiated away, and if the back of the plate is insulated to reduce heat losses there, water temperatures around 60° C (140° F) are readily attained. This is sufficient for domestic purposes. Such collectors were being marketed for about $70 to $100 per square meter

[168] More detail on the distribution of incident solar energy in the United States can be found in J. I. Yellot's *Solar radiation and its uses on Earth*.



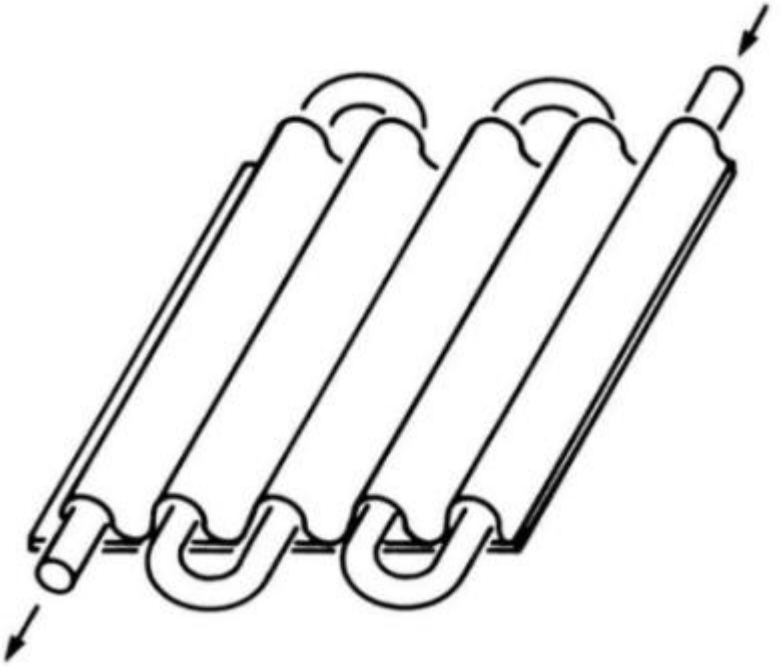
[169] The classic text, indispensable for the history of these and other uses worldwide, is F. Daniels, *Direct use of the sun's energy*. See also J. R. Williams , *Solar energy: Technology and applications*.

($10 per square foot) in the United States in 1975. Seven to ten square meters are required to meet most of the hot-water needs of a typical dwelling in the United States. (In times of prolonged bad weather, some augmentation with gas or electricity is required.) [170]



For heating swimming pools, a substantial energy-user in the United States and some other countries, the glass plates and insulation on the flat-plate collectors can be dispensed with because lower temperatures suffice. Low-temperature collectors for pool heating were being sold for around $40 per square meter in 1975 (about half the area of the swimming pool in collectors is required).

Most dwellings get a significant part of their spaceheating in winter from solar energy automatically -- that is, from sunlight entering through the windows. When special attention is paid to maximizing the winter input of sunlight and minimizing summer input, through the orientation, design, and construction of a building, this form of solar heating can greatly reduce fossil-fuel and electricity use without the purchase of special solar collectors. [171] In most climates, this basic use of solar energy cannot meet all heating needs of typical dwellings; for many years, experimenters interested in further reducing the use of fossil fuels and electricity have been constructing heating systems using solar collectors of various kinds. Most of them have used flat-plate collectors of the sort described above for water heating. [172] Use of the heated water for warming interior spaces is a more demanding enterprise than water heating for other domestic uses, however, requiring significantly more collector area for a typical dwelling (between 60 and 120 square meters). The high initial cost of such a venture, with collectors costing nearly $100 per square meter, has discouraged commercialization. [173]



Many experts believe that the price of a collector suitable for space-heating will come down to around $65 per square meter ($6 per square foot) if large quantities are produced. At that price solar systems can compete with resistive electric heating (conversion of electricity to

A. Water heater with corrugated iron soldered to sheet-metal plate

B. Tube-in-sheet water heater formed with hydraulic pressure

C. Corrugated iron soldered to metal sheet enclosing tight-fitting plastic tube FIGURE 8-26 Flat-plate solar collectors. There are many approaches to the design of flat-plate collectors, suggested by the three represented here. Economy of construction and durability are essential goals. Sheets of plastic or glass may be added to top and layers of insulation to bottom to reduce losses. (After Daniels, *Direct use of the sun's energy*.)

heat by running it through suitable wires) in some parts of the United States, and with direct use of natural gas and fuel oil if those become expensive enough. There will nevertheless be many institutional and economic barriers to the rapid spread of solar-heating technology; among them: the high initial costs, which seem to be an obstacle even where the economics over the life of the device are favorable; uncertainty among consumers

[170] A well-documented reference for these and many subsequent points in this section is P. Steadman, *Energy, environment, and building*.
[171] American Physical Society, *Efficient use of energy*.
[172] Detailed descriptions of many of the pioneering "solar houses" are in Steadman, *Energy*.
[173] A definitive study of the economics of solar heating in different climates, as of 1970, is R. Tybout and G. Löf, *Solar house heating*.

about the long-term reliability of solar systems; the thousands of building codes in the United States, many with quite different requirements that solar systems would have to meet. [174] A variety of incentive programs and demonstration projects -- including some large government buildings heated with solar energy -- were being undertaken by the U.S. government in the mid-1970s to try to overcome those barriers. [175]

In climates where air conditioning is also a significant energy-user, solar cooling can be considered, too. This is not really paradoxical -- any air conditioner requires an energy source, and there are technologies for which that source is heat, not electricity. They are called *absorption air conditioners*, and traditionally they have been designed to use natural gas as an energy source. Versions modified to run on solar energy require water temperatures of 80° to 95° C (170° to 200° F.) or more; therefore, they need better collectors than suffice for ordinary water and space heating.

The most economical way to achieve the higher temperatures needed is probably to coat the collector plate and tubes with a *selective surface*. Such coatings absorb sunlight in the visible wavelengths very efficiently but radiate energy away very inefficiently. (Ordinary black paint radiates energy away in the infrared wavelengths just as effectively as it absorbs incident visible radiation; it is *nonselective*. This sets a limit on the temperature that can be achieved, because the rate of energy loss by radiation goes up as the fourth power of the collector temperature.) Several such coatings were available on commercial flat-plate collectors in the $\$100/m^2$ range in the mid-1970s. [176] The efficiency of flat-plate collectors -- that is, the fraction of incident sunlight they deliver as heat -- is usually between 40 percent and 50 percent. Precisely opposite to a heat engine, a given flat-plate collector becomes *less* efficient as the water temperature rises, because all the losses increase with temperature. This is a price that must be paid if high-temperature water is needed, as for air conditioning.

In addition to using selective coatings, more glass cover plates, and more insulation on the back, one can also obtain higher temperatures in solar collectors by using adjustable mounts that track the sun or curved collectors that focus the collected energy on a small area. Sun-tracking and -focusing collectors may be suitable for electricity generation and specialized industrial applications, but they seem too expensive for space-heating and air conditioning. But possibly innovation and mass production will change this verdict.

The most effective use of an investment in solar collectors for residences or small commercial buildings is in a system that serves waterheating, spaceheating, and air-conditioning needs together. Such a combination is illustrated schematically in Figure 8-27. To maximize the

amount of sunlight collected for such combined summer and winter use, the collector should be tilted toward the equator at an angle from the horizontal equal to the latitude. For winter heating only, the optimum angle is latitude plus 15 degrees. [177] Energy storage for a solar heating system for a typical residence is most economically provided by several thousand gallons of water in an insulated tank. Less storage is required for cooling systems, since the heaviest demand occurs at times when the sun is shining brightly (or was a few hours earlier). The cost of storage using hot water, or alternatively, hot rocks, is around $1000 for a few days' winter reserve for a residence -- a modest fraction of the cost of the collectors. [178] It seems likely that combined solar systems like the one depicted in Figure 8-27 will be widely available in the United States in the first half of the 1980s.

In addition to its use in residences and commercial buildings, solar heat has also found application in high-temperature furnaces, which use mirrors to focus the sunlight collected over a large area onto a small volume. Temperatures greater than 3000° C have been obtained. The largest such furnace, completed at Odeillo, France, in 1970, can focus a megawatt of solar energy on a small target. [179] The potential applications

---

[174] A major study of these barriers is R. Schoen, A. S. Hirshberg, J. Weingart , and J. Stein, *New energy technology for buildings*.

[175] U.S. Energy Research and Development Administration, *National plan for solar heating and cooling: Interim report*.

[176] A good discussion of coatings is found in Meinel and Meinel, *Applied solar energy*.

[177] For more about the interesting geometry of the solar-collector, see Daniels, *Direct use*; Steadman, *Energy*; Meinel and Meinel, *Applied solar energy*.

[178] See, for example, W. Morrow, *Solar energy: Its time is near*.

[179] Steadman, *Energy*.

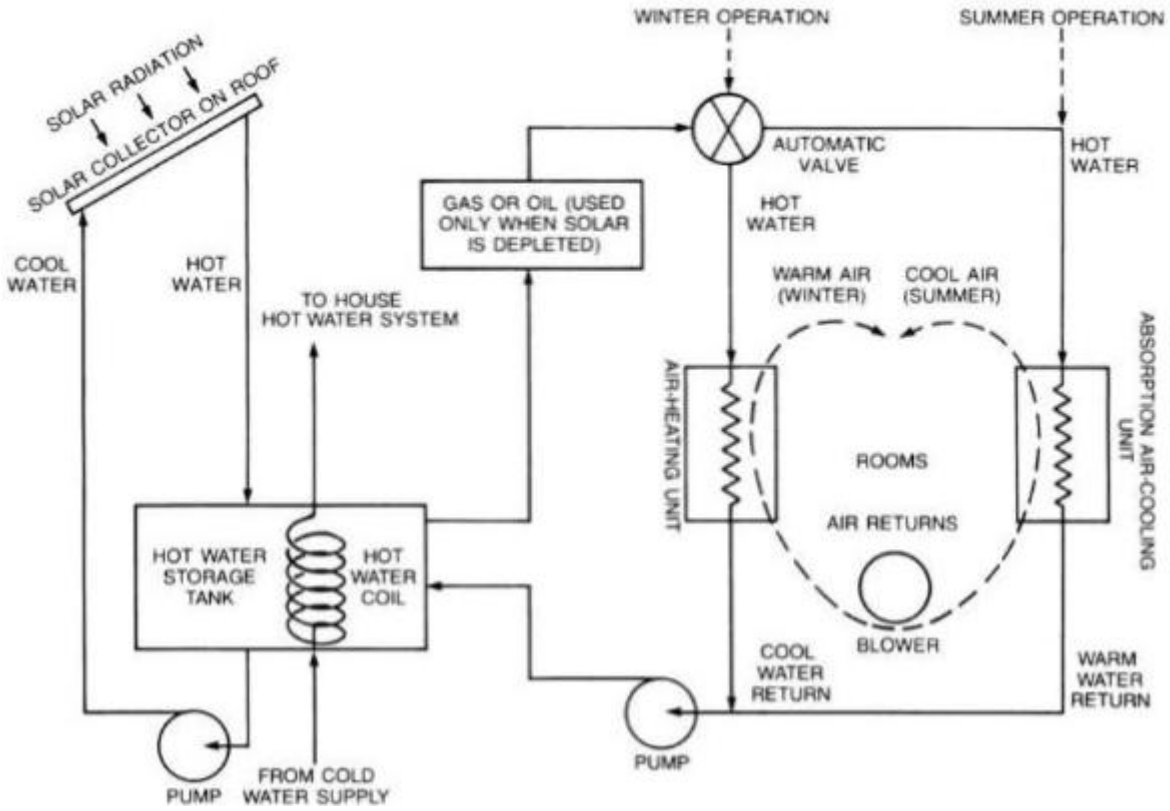


FIGURE 8-27
Solar energy system for heating, cooling, and water heating. Such multipurpose systems offer the greatest economy.

for these expensive, special-purpose devices do not make up a significant fraction of industrial energy use. Of greater interest are the possibilities for making solar energy available cheaply for processes where lowtemperature heat suffices. Relatively little work was done in this area before the mid-1970s, because the economics looked unattractive in an era of cheap fuels. [180]

Thermal-electric systems. The dispersed uses of solar heat discussed above are especially attractive because they reduce dependence on complex, centralized systems with expensive distribution networks -- the sun does the distribution. There is also interest in applying solar energy to central-station generation of electricity, however, largely because of the soaring costs and the less and less acceptable environmental impacts of other methods of generating electricity.

One way to generate electricity with sunlight is to let solar heat replace fossil or nuclear fuels as the heat source in a more-or-less conventional steam cycle. This requires collectors more sophisticated than the flat-plate collectors discussed above, since temperatures of at least 200° C are needed to make the heat-to-electricity conversion efficiency high enough to be attractive. There are at least two particularly promising approaches. One is to use steerable collectors shaped like parabolic troughs, focusing the sunlight on pipes carrying a heat-transfer fluid such as liquid sodium to a central boiler and steam turbine plant. In a version of this scheme developed by A. B. Meinel and M. P. Meinel of the University of Arizona, the design of the

collector and selectively coated central pipe allows a sodium temperature of 550° C to be achieved. Energy storage for operation at night and in cloudy weather requires 20 million cubic meters of rock for a plant with average capacity of 1000 megawatts. The total plant area would be 30 square kilometers, with an actual collector area about 16 kilometers, corresponding

[180] A few recent efforts are W. Dickenson and R. Neifert, *Parametric performance and cost analysis of the proposed Sohio solar process heat facility*; W. Read, A. Choda, P. Cooper, *Solar timber kiln*.

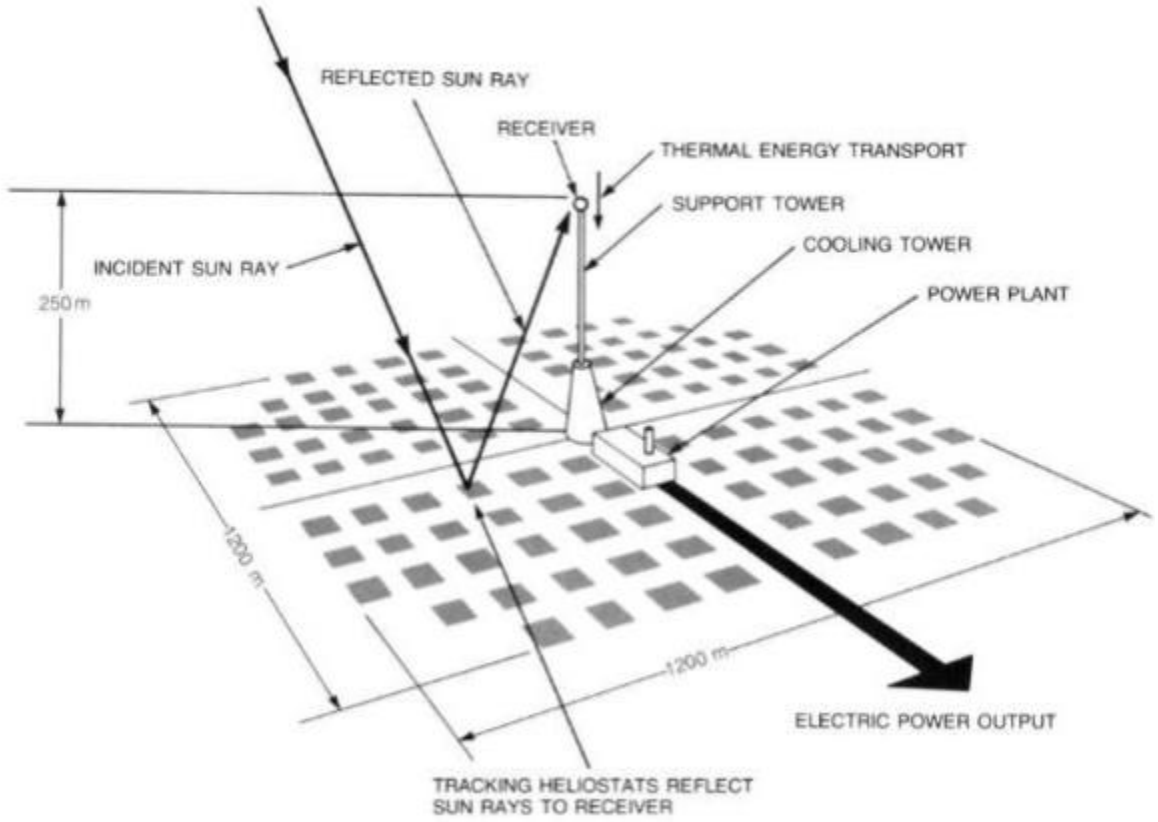

FIGURE 8-28
Solar thermal-electric plant. The central tower in a field of sun-tracking mirrors (heliostats) may be the first solar electricity-generating scheme to become economically attractive. (After JPL, *Program review*.)

to a ratio of electric energy to solar energy incident on the collectors of about 25 percent. [181] A variety of studies have placed the cost of such a plant in the range of $1000 to $2000 per electrical kilowatt. [182]

The second approach uses a field of steerable mirrors (called heliostats) focused on a single central receiver on a tower (see Figure 8-28). The central-receiver approach has an advantage over the trough-and-pipe system in that the energy travels as sunlight to the central location with little loss and no pumping. Focusing many mirrors on a small boiler can produce high

temperatures, and hence high thermal-to-electric conversion efficiency. The overall plant efficiency might easily match that of a fossil-fueled power plant -- say, 35 to 40 percent. Cost estimates again fall in the range $1000 to $2000 per average electrical kilowatt, [183] as opposed to $300 to $500 for fossil-fueled and $600 to $1000 for nuclear plants. Combined systems, where the waste heat from generating electricity is used for space-heating, water-heating, and air conditioning, have been suggested for large commercial and industrial complexes. Use of hightemperature heat from focusing solar collectors for direct production of hydrogen has also been suggested. [184]

Photovoltaic conversion. The direct production of electricity from sunlight by means of photovoltaic cells is well understood. The technology has had extensive application in the space program. The advantage of the process is its simplicity: the cells, which look like wafers of glass or plastic, are self-contained electricity generators that need only be hooked up to a load (in series, to obtain the desired voltage) -- no pipes, no liquid metals or steam, no rotating machinery. The disadvantages are low efficiency, which is limited by the physics of the process

to a theoretical maximum around 22 percent and which more commonly has been 10 percent or less, and high cost, which has been $100,000 per electrical kilowatt or more for the space applications. [185]

Photovoltaic cells used in the space program have usually been made of silicon. Silicon is abundant, but difficult to produce in the purity and single-crystal form needed to make a solar cell. Photovoltaic cells have also been made with cadmium sulfide (cheaper to make than silicon cells, but less durable and less efficient) and gallium arsenide (efficient, but gallium is scarce). Significant progress was being made in the mid-1970s on techniques of mass producing silicon cells much more cheaply than previously possible. [186] Development of a gallium arsenide cell capable of converting sunlight concentrated a thousandfold at efficiency around 15 percent (making possible great reductions in the cell area needed for a given power output) was announced in 1975 by Varian Corporation of Palo Alto, California. [187] These advances hold out the hope that the cost of electricity generation with photovoltaic cells could fall to the range of a few thousand dollars per average electrical kilowatt in the 1980s.

If solar cells become cheap enough -- say, $500 per peak kilowatt -- they will probably be used in combined systems on individual roofs, with the energy that is not converted to electricity being harnessed for heating and cooling. Such a system could produce enough extra electricity above household needs to run an electric commuter vehicle. [188]

The idea of placing large arrays of photovoltaic cells in synchronous Earth orbit to take advantage of sunlight undiluted by Earth's geometry and atmosphere has been pursued persistently by P. Glaser and colleagues at the Arthur D. Little Company, Cambridge, Massachusetts. [189] (In a synchronous orbit a satellite remains over the same spot on Earth all the time; its orbital period is synchronized with the period of Earth's rotation.) There are significant technological difficulties with this approach, not least of which are those associated with beaming the electric power produced down to Earth using microwaves -- difficulties that include endangering people and other organisms if the beam should drift. It seems likely that one of the methods of producing electricity from sunlight on Earth's surface will turn out to be more economical and less risky.

Environmental effects. The environmental characteristics of direct uses of solar energy seem preferable to those of other technologies, but the solar option will not be entirely free of significant impacts. For example, materials requirements for covering large areas with collectors will be significant; extracting and processing those materials will produce some environmental disruption. Extensive land use itself, pre-empting other uses, is a significant effect. Installation of large solarelectric plants in the sunny Southwest would probably encourage extensive industrial and residential development of fragile and scenic desert areas there. And there will be waste heat! Although much of the solar energy collected would have been converted to heat at Earth's surface by natural processes, solar technology increases the heat burden somewhat because a collector absorbs more and reflects less than the natural surface. Also, there would be a redistribution of energy insofar as energy was collected, say, in the desert and then used in cities elsewhere.

Indirect Solar Energy

Solar energy makes itself available in a variety of indirect forms as well as in the form of light striking Earth's surface. Those forms include the chemical energy stored via photosynthesis in plants, the energy of the hydrologic cycle, the energy of wind and of waves and ocean currents, and the energy represented by the temperature difference between deep and shallow ocean waters (ocean thermal gradients).

Photosynthesis. The first energy technologies, fire and agriculture, harnessed energy stored by photosynthesis. Agriculture and burning wood are still important energy technologies today, of course, but they by no

means exhaust the potential of photosynthesis. The annual net photosynthetic production of the biosphere (the amount of solar energy stored in chemical bonds by plants and not consumed by the plants' metabolic processes) is around 10 times the annual commercial energy use of civilization. [190] An estimated 5 percent of this amount takes place in agricultural ecosystems; [191] the photosynthetic energy that reaches the human population as food is only a tenth of that 5 percent, or 0.5 percent of net photosynthesis (for a fuller discussion, see Chapter 3 and Chapter 7).

The agricultural "energy system" is not only a producer of energy in the uniquely useful form of food, but it is also a consumer of commercial energy forms -mostly fossil fuels -- that subsidize the production, processing, and delivery of solar energy as food (see Box 8-6). If more of the solar energy actually captured in agriculture could be harnessed -- specifically, by using the energy in the uneaten or inedible plant parts now called *agricultural wastes* -- it is possible that agriculture could start augmenting commercial energy supplies rather than draining them.

In the United States in the early 1970s, agricultural and food wastes and manure were estimated by the U.S. Bureau of Mines to be almost 600 million metric tons of dry organic matter per year; it was estimated that only about 8 percent of this was "readily collectable." [192] (Calculations based on net photosynthesis would suggest that 600 million metric tons is much too low a figure, but we will use it here as an official minimum estimate.) The average energy content of this material is about 10 megajoules per kilogram. Most of the energy is made available as heat if the dried waste is burned directly as boiler fuel; conversion of the waste to more conventional liquid, gaseous, and solid fuels yields 60 to 70 percent of the original energy in the final product. [193] Taking an average figure of 65 percent conversion, the readily collectable fraction of U.S. agricultural and food wastes could have yielded about 300 billion megajoules per year in the early 1970s, or 0.4 percent of total U.S. energy use at that time. If modification of agricultural practices permitted collecting as much as 50 percent of the Bureau of Mines estimate, then the energy recoverable at 65 percent conversion would roughly equal the recent commercial energy inputs to U.S. food-growing (but not food processing, transportation, and so on) as discussed in Box 8-6.

Organic wastes from sources other than agriculture (urban refuse, sewage, logging wastes, industrial wastes) amounted to about 300 million metric tons in the United States in the early 1970s, of which about 30 percent was estimated to be readily collectable. [194] At 65-percent conversion, that would total 600 million megajoules per year, or 0.8 percent of the total U.S. energy use at the time. It does not seem unreasonable to suppose that, with effort, the collectable fraction of those nonagricultural organic wastes might be doubled.

The simplest and cheapest way to harness the energy of organic wastes is by direct combustion. This is now being done in devices ranging from the electric-utility boilers in St. Louis, which burn municipal wastes mixed with coal and gas, [195] to open fires and simple stoves for cooking and heating in the villages of India, where cow dung, crop residues, and wood are burned. The total energy embodied in these noncommercial fuels in India is apparently considerable. According to Makhijani and Poole, it is equal to all commercial energy use in that country. [196] Unfortunately, the efficiency with which the noncommercial energy forms are converted into

useful heat and work in India and other LDCs is very low -Makhijani's estimate is 5 percent. [197] This problem could

[190]Commercial energy use means consumption of fuels and electricity that are sold, and excludes food and other plant and animal matter gathered by the user. The global rate of commercial energy use in 1975 was around 8.4 million megawatts (that is, 265 trillion megajoules per year -- *New Scientist*, July 22, 1976, p. 181) compared to net photosynthesis around 100 million megawatts (G. Woodwell and E. Pecan, eds., *Carbon and the biosphera National Technical Information Service*, Springfield Va., 1973, USAEC CONF-720510, p. 369).

BOX 8-6 Energy and Food: "Helping" the Sun

It has been said that Americans eat potatoes made mostly of petroleum. The statement refers to the heavy infusions of fossil fuels that are used in operating the many phases of the United States food industry -- agriculture, processing, packaging, transport, marketing, storage, and preparation. Detailed studies have shown that the amount of nonsolar energy used in all those activities in the United States was almost 10 times greater than the energy content of the food consumed in 1970 (having increased from around 6 in 1960, 2 in 1930, and 1 in 1910). [a]

Where was all the energy going in 1970? About a fourth of the total for the food system was used on the farm (tractor fuel, electricity for irrigation pumps) or to manufacture things used on the farm (fertilizers, pesticides, tractors, other machinery). [b] Almost 40 percent was used to process, package, and transport the food (including the energy costs of cans, bottles, and paper wrappings). The remainder was used mainly for refrigeration and cooking in homes and businesses.

Although the food system is, strictly speaking, an energy technology, it is one with a negative energy balance -- far more commercial energy goes in than food energy comes out. This works

economically because food energy fetches so high a price. Bread at 40 cents a pound represents an "energy price" of about $75 per gigajoule (1000 megajoules), whereas gasoline at 60 cents a gallon is less than $5 per gigajoule. The massive subsidization of U.S. agriculture and food processing with cheap fossil fuel cannot be duplicated in developing countries, where under the U.S. pattern more energy would be required for the food system than is available for all purposes combined; and the prospects that such quantities could be made available in the forseeable future are decidedly dim. [c] Indeed, as the real costs of the fossil fuels and the environmental costs of the energy-intensive agricultural practices themselves become increasingly apparent, there is more and more reason to break away from this pattern even in the United States and other DCs. The amount of solar energy captured by plants on farms and then wasted, as commercial energy pours in from elsewhere, suggests the possibility of restoring sunlight to its original position as the *main* driving force of agriculture -- and perhaps even of exporting some nonfood fuel to the rest of society as well.

Some experimentation along these lines has been started in the United States and several other developed countries, notably the United Kingdom and Australia. Perhaps the best-known and most comprehensive such project in the United States is that of the New Alchemy Institute in Massachusetts. [d] This organization, which was founded in 1969 by two marine biologists, operates a small farm on Cape Cod and another in California and plans to start a third in Canada. For energy, the Massachusetts farm is dependent mainly on windmills and solar heaters. The solar heat is stored in greenhousecovered fish ponds, which also produce edible fishes and fertilizer for crops. Since all crops are produced by "organic" methods (no synthetic fertilizers, pesticides, or other chemicals), the energy costs of the chemicals are also saved. The New Alchemy Institute's water-pumping windmill design has already been exported to India; many of its other energy-saving methods and technical inventions might also be adaptable to LDC agriculture (as well as to that in DCs).

Some farmers in the United States have practiced organic farming for decades, believing that the food produced in this way is nutritionally superior and that the method preserves and builds up the quality of soil (see Chapter 7 and Chapter 11). Because no synthetic chemicals are used and mechanization is minimal, organic farms on the average use only about 35 percent as much energy as conventional farms in the United States do. [e]

be somewhat ameliorated by the use of improved -- but still simple -- stoves for burning these materials.

Unless large boilers are at hand that can burn organic wastes and capture the heat efficiently to produce steam (which makes little sense in rural India and is not necessarily the best use of the materials or the energy in the United States), the way to increase the efficiency of applying the energy in such materials is to convert them into more compact fuels. One way to do this, which was in the pilot-plant stage of development in the United States in the mid-1970s, is to produce fuel oil from the wastes by *hydrogenation*. Hydrogenation consists of treating the waste material with steam and carbon monoxide under high pressure. Complicated and sophisticated facilities are required, and the yield is about 1.4 barrels of low-sulfur fuel oil per metric ton of dry organic matter, representing a conversion efficiency around 63 percent. [198]

Less elaborate technology suffices for *pyrolysis*, which means decomposition without combustion. This is accomplished by heating the material in the absence of air. The process produces a charcoal-like solid fuel (char), a medium-energy gas (10 to 18 MJ/m^3), and combustible liquids. The efficiency is around 70 percent. Small pilot plants were subjecting municipal waste to pyrolysis at several locations in the United States in the mid-1970s, and larger installations were planned. [199] Either aproach may prove a useful way to deal with municipal waste (primarily garbage, much of which is paper) in developed countries, but this is probably not the best use of agricultural wastes anywhere.

More attractive in many respects than any of the foregoing approaches is *biogasification*, which refers to the breakdown of organic matter by anaerobic bacteria, producing methane gas (CH_4) and carbon dioxide (CO_2). The process takes place in enclosed volumes of various designs, called digesters, which can be small and cheap to serve the needs of small living groups and villages, or much larger and more elaborate to handle efficiently the larger volumes of wastes from towns, livestock feedlots, and so on. The gas, as produced, has an energy content around 20 megajoules per cubic meter, but the CO_2 can be removed with straightforward technology to produce nearly pure methane with an energy content of 38 megajoules per cubic meter. Not only is this fuel suitable for cooking, heating, and electricity generation in units of many kinds and sizes, but farm machinery can be modified to burn it in place of gasoline. [200]

Biogasification has the further great advantage that the nutrients in the waste material -- nitrogen, phosphorous, and others -- are not wasted but are retained in a compact residue much more suitable for use as fertilizer than the original material. The economics and technology of putting biogasification units into rural villages in Asia, Africa, and Latin America to provide fuel, electricity, and fertilizer have been summarized by Makhijani and Poole. A schematic diagram of one of the very promising combined-use systems appears in Figure 8-29. In the mid- 1970s in the United States, at least one commercial firm was proceeding with plans for a large biogasification plant running on the wastes of cattle feedlots in Colorado, with the product to be sold to a gas pipeline company. [201]

All the techniques described here for extracting energy from organic waste can also be applied to organic material grown explicitly for that purpose. Serious proposals have been put forward for using fast-growing trees (pines, eucalyptus) to supply wood for electricutility boilers; [202] grain

can be fermented to produce alcohol for use as fuel; and the idea of culturing algae in ponds for use directly as fuel or as fodder for biogasification has stimulated considerable research in the past few decades. [203] The same basic difficulties confront all these schemes: (1) the efficiency with which plants convert solar energy to stored chemical energy is low -rarely more than 0.5 percent (although a few percent has been claimed for some kinds of algae) -- so the required land area is large; (2) water needs are high for most of the schemes; (3) the energy cost of maintaining suitable growing conditions, supplying nutrients, and harvesting

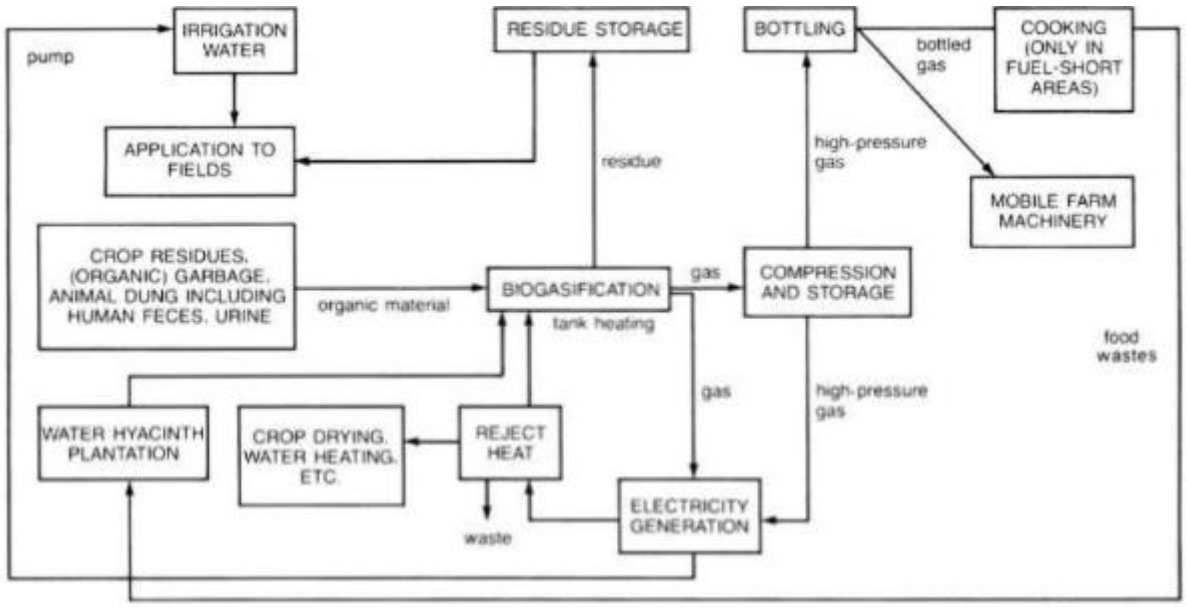

FIGURE 8-29
Village biogasification and electricity system. Energy technology tailored to the needs of developing countries is urgently needed. (After Makhijani and Poole, 1975.)

a crop can be high, so the net energy profit may not be large; (4) the economic pressure to produce high yields can lead to the same ecological problems that have been associated with high-yield agriculture and high-yield timber production (see Chapter 11); (5) photosynthetic products are likely to be more valuable as food, feed, fertilizer, or industrial raw materials than as fuels. Nevertheless, the possibility of a successful energy plantation based on a high yielding plant or alga of some kind cannot be entirely ruled out.

The use of photosynthetic materials to replace hydrocarbons from fossil fuels as raw materials for the chemical industry is of interest in itself. [204] About 6 percent of U.S. fossil-fuel use in the 1970s was for such nonfuel uses. Petrochemicals have largely replaced such photosynthetic materials as alcohol from molasses and grain, and rubber from the rubber plant *Hevea*, for strictly economic reasonS; [205] that revolution could likewise be reversed for economic reasons -- namely, the soaring costs of fossil fuels.

Finally, there is a possibility to use photosynthesis by imitating it. More specifically, some researchers hope that, by gaining sufficiently detailed understanding of the biochemical machinery of photosynthesis, they can devise nonbiological systems that use similar reactions to convert solar energy into chemical energy (in the form of hydrogen) or electrical energy, but at higher efficiency than that attained by green plants. [206] Part of the basis of their hope for higher efficiency is that plants must spend a substantial part of the energy they handle to maintain their own life-support systems and to propagate themselves. The nonbiological mimic need not perform such functions, or so it seems at first. However, all the energy costs of building such a system and maintaining it -- analogous to the plant's energy expenditures in supporting and propagating itself -- must be charged against its net efficiency.

Hydropower. Of the nonbiological processes that provide opportunities for indirect harnessing of solar energy, by far the most heavily used is the hydrologic cycle. Developed hydroelectric capacity worldwide in

---

[204] Although the energy in fossil fuels was stored by photosynthesis hundreds of millions of years ago, *photosynthetic materials* in the present context means plant matter of more recent origin.
[205] Melvin Calvin, *Solar energy by photosynthesis*.
[206] Ibid.

1974 was 307,000 electrical megawatts (Mwe), compared to an estimated potential of about 2,300,000 Mwe. [207] (U.S. hydro capacity in 1975 was 66,000 Mwe compared to a potential of 172,000 Mwe and a total electrical capacity in all forms of 505,000 Mwe. [208]) Most of the undeveloped hydro capacity is in Asia, Africa, and South America. Although the flow of rivers can be expected to be roughly constant over many millennia, much of the potential of specific hydroelectric sites is typically destroyed within one to three centuries when the reservoirs fill with silt. No real solution for this problem is yet known. [209]

Hydropower is harnessed by building a dam with water turbines and generators installed at the base. The energy that would have been dissipated as the water descended over the streambed is then stored as potential energy in the form of water that builds up behind the dam. When electricity is needed, tunnels through the dam are opened and the stored energy -- the pressure of a column of water tens to 100 or more meters high -- drives water through them and into the turbines with great force. The generators turned by the turbines are essentially identical to those in steam-electric plants. The efficiency with which hydroelectric plants convert the potential energy of the water to electricity is high -- about 90 percent in the best installations, and an average of 75 to 80 percent. [210]

Some hydroelectric installations have capacities equal to or larger than the largest fossil-fueled and nuclear power stations: there are several hydro plants of around 2000 Mwe in the United States, two of more than 4000 Mwe in the Soviet Union, and even larger plants under construction. One of them, the Itaipu Dam, which is a joint project of Brazil and Paraguay, is expected to have an eventual generating capacity of more than 10,000 Mwe. [211]

Hydroelectric plants are not without adverse environmental and social impacts. The spawning grounds of migratory fishes of commercial and recreational importance, such as salmon, are often destroyed by hydroelectric facilities, or the fishes are prevented from reaching them. Other wildlife habitat and valuable farmland may be destroyed, and long-time human residents forced to move. Seepage from reservoirs can raise a water table and bring subsurface salts with it, impairing the fertility of the soil. Stream conditions downstream from dams can be greatly altered, and estuaries and the associated fisheries can be affected. Rapid fluctuations of river levels with the intermittent operation of hydro plants -- which are especially cherished by utilities for their ability to start rapidly when the need arises -- can be especially disruptive. [212]

The reservoirs behind dams lose water by evaporation in proportion to their surface area; in dry climates this can aggravate water shortages by reducing the average flow and can increase the concentration of dissolved minerals in the water remaining. In some instances, the filling of large reservoirs has triggered earthquakes because the weight of the accumulating water has shifted the balance of stresses in the underlying crust (see Chapter 11). Perhaps more important than causing small earthquakes, however, is the vulnerability of dams to destruction in large ones. If a major dam upstream from a densely populated region should give way suddenly, tens of thousands of people could be killed. [213]

A second form of hydropower is sometimes mentioned. The source of that energy is the work done by the sun in evaporating fresh water from the surface of the salty ocean (as distinguished from the work done in lifting the evaporated water to high altitudes, which is the source of the energy tapped by conventional hydropower installations). That desalination energy ordinarily is dissipated as heat in the zones near the mouths of rivers, where fresh and salt water mix. It is possible in principle to tap this energy by means of technology based on semipermeable membranes; one analyst has suggested that an efficiency of conversion to electricity of 25 percent is attainable, at costs per kilowatt hour about 10 times higher than for producing electricity from coal. [214] The analyst has noted, however, that this technology

would be environmentally disastrous for estuaries and so could not be tolerated on a large scale.

Wind and waves. Windmills have been used to pump water and turn grindstones for centuries, and they are still in extensive use for pumping in many parts of the world today. Over the past several decades, windmills of various sizes and designs also have been used to generate electricity, generally on a one-of-a-kind basis. The peak output of such devices has ranged from around 1 electrical kilowatt, for adaptations of the pumping machines of the sort typically seen on American farms, to the 1250 electrical kilowatts of the famous SmithPutnam machine that operated from 1941 to 1945 on Grandpa's Knob in Vermont. The blades of the latter machine swept a circle 53 meters (175 feet) in diameter. [215]

The total energy in the winds is large. Estimates for the globe fall in the range of 250 million to 2500 million megawatts of average continuous power. It seems unlikely that as much as I percent of the total could actually be harnessed, but even that small fraction represents a great deal of energy -- 3 times the world's 1975 use of commercial energy, if we take the lower extreme of the range of estimates of total wind power. A study under the auspices of the National Science Foundation and the National Aeronautics and Space Administration (NASA) concluded in 1972 that wind power in the United States could deliver about 5 trillion (5×10^{12}) megajoules of electrical energy by the year 2000. [216] This is close to the *total* U.S. demand for electricity in 1972.

Why, then, has wind power not been harnessed more extensively to date? One reason is that the wind is unpredictable from hour to hour and day to day, although the average energy delivered annually in a given location is generally very consistent. Meeting electricity needs that cannot be timed to coincide with periods when the wind is blowing therefore requires a means of storing electricity, which is difficult and expensive. A second obstacle has been the high cost of building a windmill in relation to the average amount of power it can deliver and the cost of power in the past from more conventional sources. These factors have confined the use of wind power for electricity generation to locations far from electric-utility grids selling cheap power from fossil fuels or hydro dams, and to applications where a little power can be used very effectively (as for communications and lighting). [217]

The power that a windmill can produce is proportional to the area swept by its blades and to the cube of the wind speed. In other words, for a given blade, the available power goes up eightfold for every twofold increase in wind speed. Economic feasibility, therefore, depends strongly on the frequency and steadiness of high winds at a given site. At least 12 miles per hour is needed for most applications -- a fact that makes islands, coastal sites, and hilltops particularly attractive places for windmills. Since the wind speed increases with height above the ground, there is also incentive to place windmills on tall towers; this, of course, increases costs, as does designing the equipment to withstand high winds without breaking.

For basic physical reasons, windmills cannot extract all the energy that passes through the swept area. The theoretical maximum is about 60 percent for windmills with horizontal axes, and only

a fraction of that theoretical limit can actually be attained by existing machines. An efficient two-blade propeller-type windmill can get about 330 watts per square meter of swept area from a wind blowing 11 meters per second (25 mph). This is 37 percent of the power in the wind and 62 percent of the amount theoretically extractable. Conversion of the mechanical energy of the spinning shaft to electricity with a good generator can be nearly 100 percent efficient. Three types of windmills are illustrated in Figure 8-30.

Ambitious schemes have been put forward for the construction of large arrays of wind generators on seacoasts, offshore on anchored floating platforms, and over highway and railroad rights-of-way. [218] The construction costs for such installations have been estimated

[215] Good surveys of the history and technical characteristics of windmills are to be found in Steadman, *Energy*, pp. 185-211; J. McCaull, *Windmills*; Marshal Merriam, *Wind energy for human needs*; and Windmills for less developed countries. (Steadman and Merriam include lists of manufacturers.)

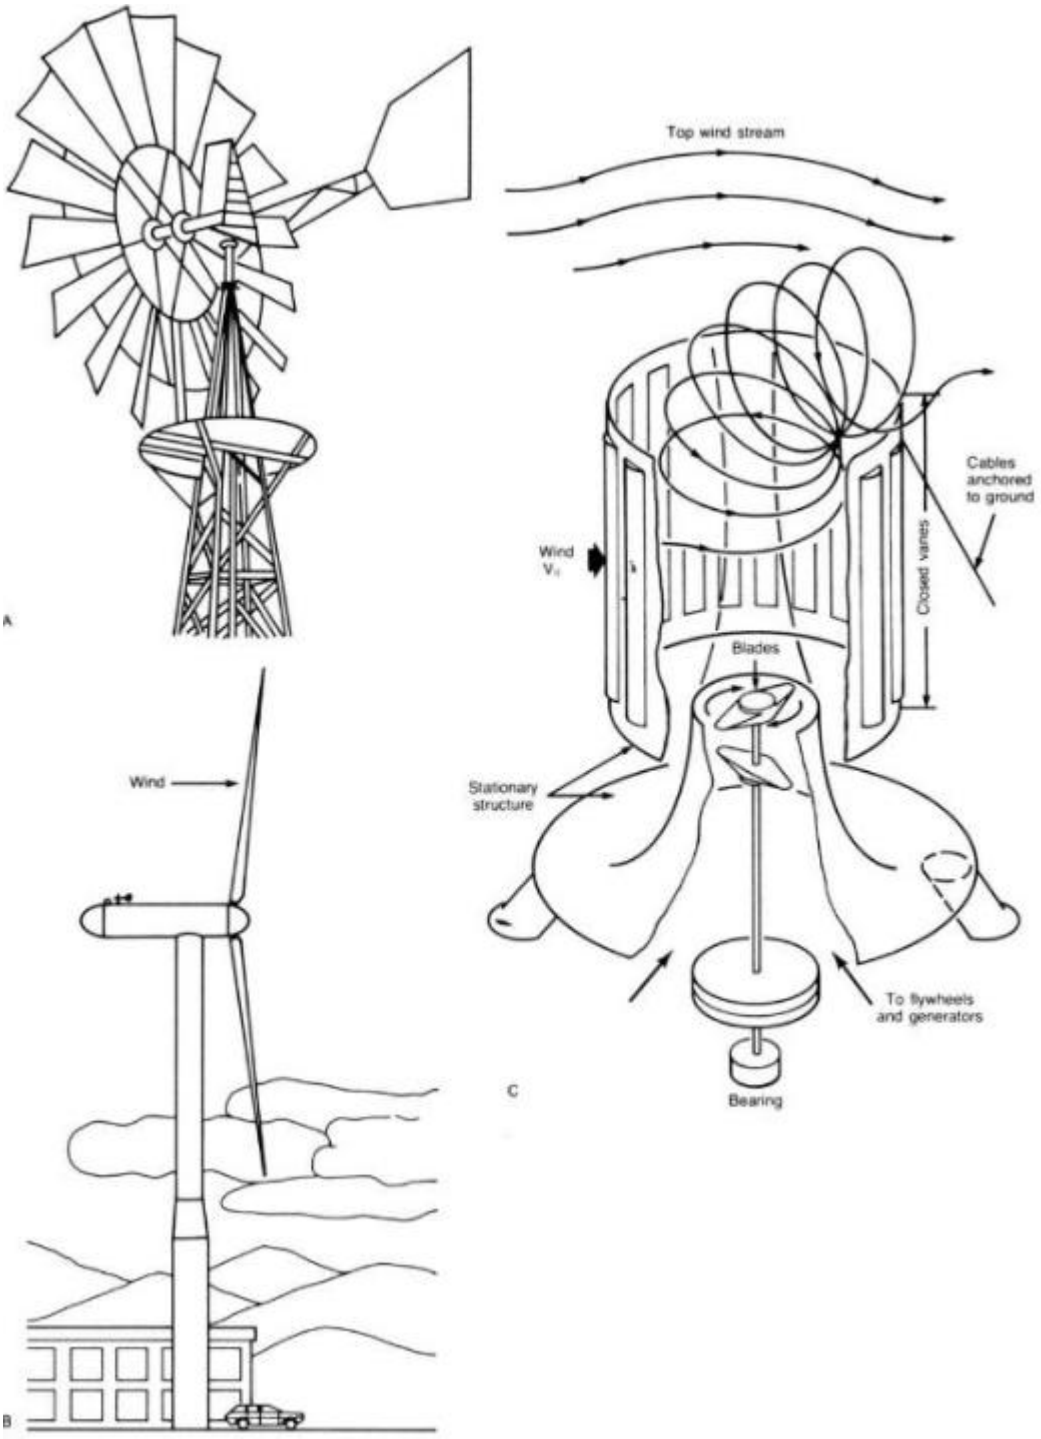

FIGURE 8-30

Some different windmills. Nontraditional designs exploiting contemporary aerodynamic science (B and C) may have significant advantages. (A and B, after Steadman, Energy, environment, and building; C, after Hammond, Artificial tornadoes.)

to be in the range of $200 per electrical kilowatt, which is much lower than achieved for smaller mass-produced windmills and larger experimental ones to date. Even if those costs are underestimates, however, harnessing the wind may prove to be a significant and attractive way to produce electricity. Adverse environmental effects would be mainly the aesthetic impact of the windmills and destruction of birds, until the amount of wind harnessed became large enough to present the possibility of largescale climatic impact. Sensible restraint can prevent the last problem, and the others are perhaps a small price to pay in comparison to the impacts of most alternatives.

When the wind blows over large expanses of water, a substantial part of its energy is transferred to waves. They can carry the energy far from the place it was supplied. There are many coastlines in the world (as well as regions far from shores) where the reliability of energy flow in waves is considerably greater than that of the wind. Over the years several kinds of devices have been constructed in attempts to harness wave power, both in deep water and in shallow. Many obstacles remain to be overcome, not least of which is the tremendous battering that wave-power systems receive in storms. Nevertheless, the possibility of successful and economical systems cannot be ruled out. [219]

Ocean thermal gradients. Solar energy is also stored in the oceans in the form of the temperature difference between warm surface water and the colder layers 750 meters to 1000 meters below. In many parts of the world, that temperature difference is between 20° and 25° C. That is enough to support the operation of a heat engine converting thermal energy to mechanical work with a maximum theoretical efficiency of around 3 percent. The efficiency likely to be attainable in practice is 1 to 2 percent. [220]

The reservoir of energy is so large that, in this respect, such low efficiency is not a serious drawback. The heat transported by the Gulf Stream alone, [221] converted to electricity at 1-percent efficiency, corresponds to an average power of 21 million electrical megawatts -- about 100 times the average electric power use in the United States in 1975. The problem with low efficiency is that enormous volumes of water and energy must be handled per unit of useful energy delivered, which makes the equipment unwieldy and expensive. Particularly troublesome in that respect would be the huge intake pipes for sucking up cold water from the deeps, and the turbines, which would have to be very large to extract significant amounts of energy at low temperature and low pressure. And, somehow, the huge structures would have to be designed to withstand the battering of the sometimes hostile ocean.

Those obstacles notwithstanding, the advocates of drawing power from ocean thermal gradients believe that it can be practical and economical -- and, like most forms of using solar energy, relatively benign environmentally. Systems that evaporate the seawater itself to provide the vapor for the turbines could produce fresh water from the condensers as a desirable side product. Other designs use an organic working fluid, such as propane, in a closed cycle. A study for the Federal Energy Administration in 1974 indicated that large sea-thermal power plants could be constructed for around $600 per electrical kilowatt of generating capacity. [222] If this were an underestimate by a factor of 3, or even 5, the approach would still be economically interesting.

Advanced Conversion: MHD and Fuel Cells

Magnetohydrodynamics (MHD) and fuel cells are not primary energy sources; they are technologies of energy conversion that may make existing and future primary sources -- such as fossil fuels, fission, fusion, or solar energy -- more efficient or more versatile.

Magnetohydrodynamics. MHD generation is a means of converting the thermal and kinetic energy of a flow of hot gas or liquid metal directly to electricity, bypassing the intermediate stage of the mechanical energy of rotating machinery. The most common approach is to seed hot combustion gases, from burning a

[221]Computed as 2200 km^3/day at a temperature 20° C warmer than the deep water below it.
[222]U.S. Federal Energy Administration, *Solar energy, task force report*.

fossil fuel, with a material such as potassium or cesium that is easily ionized (stripped of electrons) at those temperatures. The free electrons make the combustion products conduct electricity. The hot, electrically conducting gas is then expanded through a nozzle to increase its velocity and passed through a channel to which a strong magnetic field is applied. Just as in mechanical generators, the motion of a conducting medium through a magnetic field produces an electric voltage. In an MHD generator, the current is drawn off from electrodes lining the channel.

Many small experimental MHD generators have been built in various countries, but a variety of technical problems remain to be worked out before this technology is commercially available. [223] The first commercial plants will probably use MHD as a topping cycle in combination with a conventional steam cycle. A pilot plant of that kind, producing 25 electrical megawatts from an MHD generator and 50 electrical megawatts from a steam cycle, began operation in the Soviet Union around 1971. Such plants may have difficulty competing economically with gas-turbine combined-cycle plants, which yield overall plant efficiencies in the same range -- 45 to 55 percent. (The efficiency of the USSR prototype is only about 30 percent.) Pure MHD plants of the future possibly could achieve efficiencies of 60 percent or more, and there are ways to combine MHD conversion with nuclear fission and solar energy sources as well as with fossil fuels. [224] A technology closely related to MHD might be used to convert the energy of charged particles in fusion plasmas directly to electricity. [225]

Fuel cells. Fuel cells are devices for converting the stored chemical energy in natural gas, hydrogen, or other chemical fuels directly to electricity, at efficiencies as high as 60 percent or more. A fuel cell operates on the identical principle as an ordinary battery: a chemical reaction yielding electrons (oxidation) takes place at one electrode and a reaction consuming electrons (reduction) takes place at the other. The resulting deficiency of electrons at one electrode and excess at the other causes a voltage between them. The fuel cell differs from a battery only in that the reactants are continuously supplied from outside the fuel cell itself, and the reaction products are continuously removed. Fuel cells may eventually be important as electricity

generators, in both centralized and dispersed applications (perhaps, for example, in individual homes and in automobiles), and as part of a hydrogen economy -- if one materializes (that concept is discussed below). First, however, the technology must overcome present obstacles of short operating lifetime, reliance on scarce materials as catalysts, and efficiences far lower in practice than in theory. [226]

Realization of practical fuel cells for electricity generation would have considerable environmental advantages over combustion of fossil fuels -- emissions of oxides of nitrogen would be significantly reduced, and the higher efficiency would mean a much smaller burden of waste heat.

Energy Storage and Transmission

Energy is easy to store in the form of fossil fuels, and its transportation by various means -- train, barge, pipeline, tanker, truck -- is generally technologically straightforward, if not always cheap or environmentally benign. Electricity is generally more expensive to transmit than moving the amount of fuel required to make the electricity, and electricity is much more difficult to store. [227]

A distinction is made in the electricity industry between transmission and distribution: The former refers to moving electricity from generating centers to consumption centers, involving relatively long distances and high voltages (138 kilovolts or more). Distribution refers to moving electricity to individual users through networks of shorter, lower-voltage lines. Most transmission is done with overhead lines. Increasingly, distribution systems are being installed underground. One reason more transmission lines are not placed underground is that soil and rock are less able than air to carry

away the concentrated heat load imposed by transmission lines carrying large amounts of power. Technologies for underground transmission that could circumvent this problem are under intensive investigation: cables insulated with compressed gas; cryogenic cables running at the temperature of liquid nitrogen (80° kelvin), where electric resistance is 10 times lower than at normal temperatures; and superconducting cables running at the temperature of liquid helium (4° kelvin), where electrical resistance in certain materials is zero. All are expensive and probably can become economical only for the transmission of very large amounts of power. [228]

The environmental impacts of overhead transmission are the use of significant amounts of land, the unsightliness of towers and wires in scenic areas, and the effects of the strong electric fields that high-voltage lines produce in their vicinity. Some 28,000 square kilometers were dedicated to transmission lines in the United States as of the early 1970s, and some projections for the year 2000 envision twice that. [229] The health effects of exposure to the electric fields that exist under high-voltage lines are not well established, and more research is needed. [230] It is somewhat unsettling to discover that those fields are strong enough to light an unconnected fluorescent bulb at a distance of 50 meters from a 765-kilovolt line.

A number of improvements in energy systems would be made possible by the development of better means of energy storage. Direct use of sunlight for heating and cooling, for example, requires less supplemental fuel as more heat storage is available. The most economical methods for storing energy so far are insulated tanks of water or bins of rocks. Substances whose melting points are in the right temperature range for the application (60° to 100° C for heating, 200° C or more for thermal power plants or high-temperature industrial applications) could store significant amounts of energy as latent heat of melting. But various practical difficulties with this approach have so far resisted solution, despite research over several decades. [231] Characteristics of various means of heat storage are presented in Table 8-24.

TABLE 8-24 Thermal Energy Storage

Source: H. C. Hottel and J. B. Howard, *New energy technology: Some facts and assessments*, p. 96.

Electricity is extremely difficult to store as electricity. Small amounts are stored for use in scientific experiments in devices called capacitor banks, which accumulate electric charges on oppositely charged plates separated by insulators. But those devices store only small amounts of energy and are exceedingly expensive. Substantial amounts of electrical energy can be stored in the magnetic fields of large superconducting magnets (perhaps 10 to 50 MJ/m^3). Such magnets were still an experimental technology in the mid-1970s, but the possibility of storing commercial electricity that way was under investigation. [232]

Most "electricity storage" actually stores some other kind of energy that is readily produced from electricity and readily converted back to it. Batteries, for example, store electricity as chemical energy (see the description of fuel cells, above). Batteries tend to be heavy, bulky, and expensive, however, compared to equipment for storing and converting like amounts of energy with, say, gasoline. The familiar lead-acid automobile battery stores about 120 kilojoules of

electrical energy (33 watt hours) per kilogram, nickel-zinc batteries about twice as much, and high-temperature sodium-sulfur batteries 10 times as much (about 1200 kJ/kg). [233] The overall efficiency of charging and discharging (that is, electricity out divided by electricity in) in such batteries is 65 to 80 percent. So far, batteries have been much too expensive for use in storing the large amounts of electricity needed to supply peak loads in electric-utility systems, although they are

[228]See Hammond, Metz, and Maugh, *Energy*, chapter 16.
[229]Ibid.

used sometimes to store electricity produced by small windmills.

The principal method of electricity storage by utilities in the United States is pumped storage, wherein the energy is actually stored as the potential energy of water pumped uphill. Pumped-storage systems consist of two reservoirs, one high and one low, connected by pipes containing dual-purpose pump-turbines. During periods of low demand, such as late at night, electricity from the primary source (fossil fuels, fission, perhaps solar energy in the future) is used to pump water from the lower reservoir to the higher one. At times of high demand, the water is allowed to fall back to the lower reservoir, thus spinning the turbines and generating electricity. The overall efficiency of the exchange is near 70 percent. [234] Some environmental disruption is generally involved in the construction of the upper reservoir (the lower one is usually a natural body of water). There are few enough satisfactory sites that pumped storage is unlikely ever to amount to more than a small percentage of total generating capacity in the United States. Thus, it can meet only a little of the need for peaking and backup power.

Flywheels provide another means of storing energy, as mechanical energy of rotation of massive, rapidly spinning discs. The energy storable in flywheels is limited by the strength of materials -- as speed of rotation (and stored energy) increases, at some point the stresses in the wheel become too great and the material fractures and flies apart. Flywheels made of conventional steels are limited to the range of energy storage per kilogram characterizing lead-acid and nickel-zinc batteries. New high-strength materials and novel flywheel designs that exploit the special properties of those materials may be able to increase the performance roughly tenfold. [235] That would make flywheels potentially attractive for energy storage in electric-utility systems and perhaps also, if safety can be assured, as the means by which energy is stored in electric automobiles.

Hydrogen is a portable chemical fuel that can be manufactured by dissociating water using any of several processes, given a primary energy source. It can also be manufactured from fossil

fuels. Hydrogen is relatively clean burning, producing only water as a combustion product and oxides of nitrogen as a side product if it is burned in air. It is generally cheaper to transport hydrogen in pipelines than to transmit an equivalent amount of electricity. Hydrogen offers a means of storing and transporting energy obtained from intermittent sources such as sunlight, and it could offer a way for electricity from nuclear fission and nuclear fusion to serve as the energy source for aircraft and other applications requiring portability, long after the fossil fuels are gone. An important drawback of hydrogen produced by using electricity is the low overall efficiency of the process -- typically less than 60 percent. Thermochemical processes for the production of hydrogen are under intensive investigation; they consist of a series of chemical reactions at various temperatures, in which water is decomposed and all the other reactants are recycled. The primary energy source could be sunlight or some more conventional source. [236]

The energy stored in liquid hydrogen is three times that in an equal amount of gasoline by weight but one-third that in an equal amount of gasoline by volume. The low volumetric energy content and relative difficulty of maintaining hydrogen as a liquid (which requires very low temperatures) have led to interest in storing hydrogen as solid metal hydrides for use in automobiles. Such hydrides have twice the volumetric energy content of liquid hydrogen, or about two-thirds that of gasoline. They would appear also to be somewhat safer than using liquid or gaseous hydrogen in cars (although it is possible that gasoline is more dangerous than hydrogen in any case). Another approach is to combine hydrogen and carbon monoxide to produce the liquid fuel methanol ($2H_2 + CO \rightarrow CH_3OH$). Much research and development remains to be done before hydrogen and its derivatives see widespread use as fuel, but enthusiasts see such advantages that they already have coined the term the hydrogen economy to describe a hydrogen-centered energy system of the future. "Waste" Heat

Because it is not possible to convert heat entirely to work (see the discussion of the second law of thermodynamics in Box 2-3), all thermal power plants deliver heat as well as electricity. This is so whether the original energy source is the combustion of fossil fuel, fission, fusion, geothermal energy, or sunlight. Most commonly, the heat is considered a waste product and is delivered not to a customer, as the electricity is, but to the environment. The reasons for this lie in thermodynamics and economics: Thermodynamically, the energy discharged is of low quality (that is, it is not much warmer than the environment, and so its heat is not easy to put to use). Economically, it has been cheaper to burn more fuel to meet energy needs than to invest in equipment that could harness some of the low-quality energy being discharged from power plants.

This has not been true everywhere, however, and it will not necessarily be true in the future. Particularly in Europe, where fuel has been more expensive than in the United States, the technology of using heat discharged from electric power plants to heat buildings and supply energy for low-temperature industrial processes has been applied extensively. Sometimes this involves lowering somewhat the fraction of fuel energy that is converted to electricity, in order to increase the temperature and hence the usefulness of the discharged heat. In Sweden, the fraction of the fuel's energy converted to electricity in power plants averages 29 percent (compared to 32 percent in the United States), but the Swedes utilize another 24 percent of the fuel's energy as heat; they waste only 47 percent. In the United States, 68 percent is wasted. [238] Recognition in the United States, too, that economic and environmental constraints mean energy must be used more carefully, should lead to the siting of more industrial plants that use low-temperature heat next to power plants that can supply that heat very cheaply.

One must pay to get rid of most of the heat that is not used. That is, failure to remove heat from the condenser of a steam cycle and deposit it somewhere else would disrupt the system as effectively as a clogged drain disrupts a sink. The methods for removing the heat and discharging it somewhere in the environment all cost money and energy in varying degrees.

The simplest approach is once-through cooling -- taking cool water from a river, lake, bay, or ocean, passing it once through a condenser where it picks up the waste heat, and discharging it to the original source some 8° to 10° C (15° to 18° F) warmer than when it began. A fossilfueled electric power plant running at 1000 electrical megawatts with an efficiency of 40 percent warms about 32 cubic meters of water per second (500,000 gallons per minute) by 8° C. A nuclear plant delivering the same amount of electricity at 32 percent efficiency (the figure for an LWR) causes the same temperature rise in 53 cubic meters of water per second. (That corresponds to the entire flow of a moderate-size stream.) The thermal discharge to water from the nuclear plant is higher not only because the efficiency of operation is lower, but also because the fossil-fueled plant discharges about 15 percent of its waste heat directly to the atmosphere via the stack.

Ecological effects of once-through cooling include: direct effects on aquatic organisms due to warmer water or rapid changes in temperature when the plant goes on and off; reduction in the water's capacity to assimilate wastes, because its oxygen content is lower; increased evaporation from the water surface, reducing the availability of water downstream and increasing its salinity; destruction of organisms, particularly juveniles, which pass through the intakes and condensers; and water pollution by chemical compounds added to condenser water to suppress slime and scale. There is a large literature concerning these effects; how harmful they are in a given situation is often controversial. [239] In any case, once-through cooling is rarely considered acceptable for new power plants except at ocean sites, which are increasingly scarce because of competition for that land. Even in oceanside facilities, it is often deemed necessary to construct expensive outfalls that spread the warmed water over large areas or into deeper water offshore.

One alternative to once-through cooling that is possible in a few locations is to construct cooling ponds. They

---

[238] L. Schipper and A. Lichtenberg, *Efficient energy use and well-being: The Swedish example*.

[239]F. Parker and P. Krenkel, *Physical and engineering aspects of thermal pollution*; see also Chapter 10 here.

require 4 to 8 square kilometers (1000 to 2000 acres) of land per 1000 electrical megawatts of generating capacity, and a source of water to replace that which evaporates. The ponds might be usable for other purposes, such as aquaculture or algae farming. [240]

Coming into much wider use are *wet-cooling towers*, in which heated cooling water from the power plant condenser falls through an upward-moving stream of air to be cooled mainly by evaporation. The air may be forced through the tower by fans (in mechanical-draft towers) or by forces arising from the shape of the tower and the humidity inside (natural-draft towers). The first requires energy to operate; the second is large and expensive to build -- as much as 180 meters in diameter at the base and 150 meters high. Both kinds of wet tower consume significant amounts of water by evaporation -- 10 million cubic meters (8300 acre feet) per year for a 1000-megawatt fossil-fueled plant averaging 75 percent of peak capacity, 17 million cubic meters per year for an LWR of the same size and capacity factor. The total water consumption is about 60 percent higher than those figures, because it is necessary to discharge some water laden with dissolved salts that are not removed in the evaporation process. This discharge is called blowdown. A modest amount of water is also lost as drift (droplets blown out of the tower as liquid without evaporating). Both drift and blowdown water are laden with chemicals that have been added to the circulating water to control corrosion, scale, and slime -- they include sulfuric acid, chromates, copper compounds, and chlorine. [241]

Dry-cooling towers avoid the problems of water consumption and water pollution of wet towers by circulating the water through an elaborate array of closed passages so none is lost; the heat is transferred to air flowing over and around the passages much as in the radiator of an automobile. Dry towers, however, are expensive both to construct and to operate. Existing designs increase fuel consumption for a given net electricity output by about 4 percent. [242] They have been used only in small power plants.

Comparing Costs and Impacts of Energy Technologies

A major reason for the particularly rapid growth of energy use per capita in the past two decades was that energy was cheaper than what it replaced -- human labor and time, for example. More than this, it was so cheap in the United States in relation to the other expenditures of the middle and upper classes that there was little incentive for those people not to waste it with abandon. Two kinds of previously hidden costs have now become apparent. First, the cost of depleting the richest, most accessible fossil fuels must now be paid in the form of rapidly rising expenses for locating, extracting, and processing the leaner and more remote deposits that remain, and for developing and deploying sophisticated technologies to harness less limited substitutes. Second, as the combination of population growth and rising energy use per person has driven the sheer size of energy operations upward, the environmental and social costs of energy -- once ignorable -- have become pervasive and painful. Rising demand for other commodities (water, coastal land, investment capital), whose availability may be diminished by growing energy systems, has intensified the relatively new sensation of the high cost of energy.

Economic costs. The economic costs of energy technology can be broken down into capital costs (construction and interest during construction) and operating costs (fuel, water, wages, maintenance, insurance, and so forth, in operation). High capital costs cause special difficulties because the money must be spent, and interest paid on amounts borrowed, well before the facilities start to operate. This situation is exacerbated by high rates of growth, because the ratio of facilities under construction to facilities in operation is high during such periods. Summarized in Table 8-25 are the capital costs associated in the mid-1970s with energy facilities of various kinds. [243] Those amounts are roughly what one would have to pay (in 1974 dollars) to build or buy such facilities in the mid-1970s per kilowatt of energy flow

[240]W. Oswald, *Ecological management of thermal discharges*.
[241]An introduction to cooling technology is R. Woodson, *Cooling towers*; a more complete and more technical description is in Pigford, et al., *Fuel cycles*, chapter 6.
[242]Woodson, *Cooling towers*; Pigford, Keaton, and Cukor, *Fuel cycles*.
[243]Partly adapted from Anderson, et al. *An assessment*.

handled. The numbers illustrate the differences in cost between shallow, rich deposits and deep, lean ones (Persian Gulf compared to U.S onshore oil), and the still higher costs associated with synthetic fuels (coal liquefaction) and less exhaustible sources (solar, nuclear). The numbers also suggest that merely replacing the present thermal electricity generating plants in the United States (439 million electrical kilowatts in 1975) as they wear out will cost 150 billion to 200 billion 1974 dollars. One study performed for the federal government indicated that the investment in the U.S. energy industry between 1974 and 1985 would have to be 585 billion 1974 dollars in order to maintain an average annual growth of energy supply of 3.6 percent while reducing reliance on imports. [244] The Energy Policy Project of the Ford Foundation estimated that a capital investment of 2150 billion 1974 dollars would be required to maintain a total energy growth of 3.4 percent per year in the United States between 1975 and 2000. [245]

In each of the investment figures cited, electricitygeneration facilities account for about 43 percent. The especially heavy capital burden associated with electricity is due not only to the technical complexity of generating plants, but also to the historical necessity of building facilities with about twice as much electricitygenerating capacity as the average demand requires. The reasons for this situation and some of its ramifications are explored in Box 8-7.

The costs of construction, interest, taxes, labor, and other inputs (and, of course, profits) at each stage of energy processing determine the price of the energy form as it emerges from that stage. Recent prices of various energy forms in 1975 dollars are listed in Table 8-26. Note the large increases in cost that are associated with extensive processing.

Because nuclear plants are the most expensive to build of the presently available technologies for electricity generation, and because their fuel is relatively cheap, it becomes especially important economically that those plants be run near their full capacity as many hours per

TABLE 8-25 Capital Costs for Energy Technologies (1974 dollars)

Fuel and heat	Dollars per thermal kilowatt of flow (24-hour average)
Oil well, Persian Gulf	4

Box 8-7 Producing Electricity on Demand

Because no economical means for storing large quantities of electricity is available, and because electricity travels through wires at essentially the speed of light, a power company must generate the electricity it sells at virtually the instant its customers demand it. If 1,000,000 New Yorkers happen to turn on their 100-watt television sets to watch the evening news at the same moment, the load on Consolidated Edison's generating system instantaneously increases by 100 megawatts -- almost 40 percent of the capacity of the Indian Point nuclear generating plant. As this example suggests, of course, the amount of electricity demanded by customers, individually and in the aggregate, varies from minute to minute, from hour to hour, and indeed from season to season. The highest demands are called *peak loads*: the daily peak is associated with lights, television, electric ranges, and so forth being turned on in the evening; the yearly peaks are in the coldest part of winter (heating) and the hottest part of summer (air conditioning -- the larger demand of the two). The minimum demand on the system is called the *baseload*.

The newest, most efficient generating plants in a power company's inventory are baseloaded - they are kept running close to their full capacity as much of the time as their need for routine maintenance and freedom from breakdowns permit. Additional plants are brought on line to meet daily peaks, and others may stand by for most of the year waiting for those coldest and hottest days (or for the baseloaded plants to break down). The *load factor* -- for a single plant or for a whole system of plants -- is the amount of electric energy actually generated in a specified period

divided by the amount that could have been generated in that period if all plants had worked at full capacity the whole time. The load factor of the U.S. utility system in 1974 was about 45 percent. All that expensive generating capacity standing unused, of course, must still be paid for, and there is no one but consumers to pay (or taxpayers, if floundering utilities have to be rescued from bankruptcy by government).

A traditional approach has been to offer large manufacturing companies substantial discounts for buying large amounts of electricity late at night (in off-peak hours), thus permitting generating capacity that would otherwise not be used at that time to earn some revenue. An approach that has been suggested as being more likely to encourage conservation as well as raising the load factor would be peak pricing -charging a surcharge for electricity consumed during peak periods, to encourage people to move discretionary uses of electricity (for example, the operation of clothes washers and dryers) away from the peak times. This would require special meters -- doubtless worth it.

year as possible. That is, since a plant, once built, must be paid for whether it is running or not, and since the cost of nuclear fuel to run it is small compared to the plant's construction cost, the way to achieve a low cost per kilowatt hour of electricity is to produce as much electricity per plant per year as possible -- that is, to achieve a high capacity factor. (For this reason, power companies try to use their nuclear plants to meet the baseload and use other kinds of generating capacity to match the rises and falls associated with the peaks.) If the large nuclear power plants that first came into commercial operation in the late 1960s and early 1970s should prove incapable of maintaining high capacity factors over long operating lifetimes -- say, 20 to 25 years each -then the cost of electricity from fission would turn out to be much higher than has been advertised. The long-term reliability of large nuclear power plants is still unknown (the first one larger than 500 electrical megawatts began commercial operation only in 1968), but the operating record as of the mid-1970s is disturbing. The average capacity factor of nuclear plants has been 50 to 60 percent, rather than the predicted 70 to 80 percent. [246]

Resource requirements. Part of the economic cost of energy technology is the value of physical resources, other than fuels, that are used in the construction or operation of energy facilities. Land, water, and nonfuel mineral resources are three such resources on which present and future energy technologies can make heavy demands. It is not obvious that the apparent economic

value of those resources -- the price energy companies must pay to use them -- is an adequate measure of the real cost to society of making the resources unavailable for other uses now or in the future. It is therefore important to look at the actual quantities of resources involved, and not just at the present economic cost of those resources. Land and water requirements for a variety of energy technologies are indicated in Tables 8-27 and 8-28.

Requirements of various energy technologies for materials other than fuel and water need closer attention. Although the materials demands of such future technologies as controlled nuclear fusion are highly uncertain, because no one yet knows just what those systems will look like, it is apparent that demands on alloying elements and special-purpose materials such as vanadium, chromium, nickel, and beryllium could be significant if very large generating capacities are envisioned. [247] Heavy materials demands may be an important liability of the widespread use of some kinds of solar-energy technology, although solar systems are not likely to require as exotic materials as fusion will.

The construction and operation of energy facilities themselves requires some energy. In other words, it takes energy to get energy. It is a characteristic of rich energy resources, such as thick

coal beds right at the surface of the ground, that only a small amount of energy must be invested in exploration and harvesting in order to reap a large energy reward. If the resource is deeper or leaner, or if it must be processed extensively before use, the necessary investment in energy increases along with the economic one. It is possible in principle to envision an energy resource so lean or so intractable that more energy

[247]Kulcinski, *Fusion power*.

must be spent to obtain and process the fuel than it contains. Only if the fuel had some very special properties could that be considered a viable enterprise. (Food is an example of a fuel with such properties -- namely, it is suitable for running the bodily machinery of human beings. The U.S. system of food production and processing invests 6 to 60 kilocalories of other fuels for every kilocalorie of food energy consumed, as outlined in Box 8-6.)

The study of the energy investments needed to get energy has acquired the name *net energy* analysis. In such analysis one should distinguish among three general kinds of investments and/or losses: (1) the part of the resource that is dispersed or left in the ground in nonretrievable form in the course of extraction and processing operations; (2) the part of the resource that is actually used as energy to support extraction and processing operations; (3) the inputs of other energy forms (fuel, electricity) needed to support those operations.

Accurate figures for energy investment during construction are difficult to obtain. But those energy inputs cannot be neglected in net energy analysis, and they are especially important where an energy system is growing rapidly. In that situation, significant inputs of energy are being made to a large number of facilities under construction that will not yield energy outputs until they are completed. One analysis has indicated that light-watercooled nuclear reactors as a system become net consumers of energy if the system grows with a doubling time shorter than 4.5 years, even though each such reactor is a substantial net producer of energy over its operating lifetime. [248] This result, if confirmed, is a major setback for the view that dependence on fossil fuels can be reduced rapidly by means of the very rapid growth of nuclear power.

Assaults on people and ecosystems. Beyond the use of scarce resources, the environmental impact of energy technology and energy use can best be discussed by distinguishing between two aspects of the situation: what energy technology does *to* or puts *into* the environment, and what the consequences of those actions or inputs are (that is, how the environment responds to what is done to it or put into it). The inputs can be classified as effluents, accidents, and other environmental transformations. By *effluents* we mean routine discharges to the environment -- air, water, and land -- that are associated with the normal operation of energy systems (as distinguished from accidents). We define accidents broadly to include not only malfunctions caused by defective equipment or human error, but also disruptions caused by natural events (storms, earthquakes, tsunamis) and by malicious human intervention (sabotage, terrorism, acts of war). A summary of some of the main types of accidents, effluents, and environmental transformations associated with various energy technologies appears in Table 8-29.

The consequences of these inputs fall into four categories: (1) human death and disease as direct results; (2) direct damage to economic goods and services (for example, crops, domestic animals, property, tourism); (3) disruption of natural biological and geophysical processes, with consequent risk or damage to the "free" goods and services those processes provide; (4) aesthetic impact (litter, cluttered landscape, impaired visibility). Note that a single input may produce consequences of all four kinds. Oxides of nitrogen produced by combustion, for example, cause or aggravate respiratory disease, damage crops, alter the acidity of rainfall, and contribute to photochemical smog that impairs visibility. The effects on health, property and ecological systems that result from pollution and other disruptions -- not only from energy technology but from other activities producing similar inputs to the environment -- are the subject of detailed treatments in Chapter 10 and Chapter 11.

Impact on social systems. Adverse impacts of energy technology on human well-being can manifest themselves not only in the form of direct economic costs and damages to the physical environment but also as disruptions of the fabric of social systems. These can result, for example, from the kinds and physical scales of technologies that are chosen, from the geographical patterns of location of energy facilities, and from the degree of centralization and interconnectedness in energy systems. [248a] Impacts of particular concern include:

[248] P. F. Chapman, *The ins and outs of nuclear power*. See also ERDA 76-1, Appendix B, Net energy analysis of nuclear power production.

[248a] An extended discussion of the social consequences of alternative energy futures for the United States is given by A. Lovins, *Energy strategy: The road not taken*. See also R. Budnitz and J. Holdren, "Social and environmental costs of energy systems"; and E. Cook, *Man, energy, society*.

TABLE 8-29
Some Negative Impacts of Energy Production and Use

ACCIDENTS
- Roof collapse or gas explosion in mine
- Tanker fire or explosion (oil or liquefied natural gas)
- Dam failure
- Refinery fire
- Core meltdown and breach of containment of nuclear reactor
- Leakage of radioactive waste from storage facility
- Fire in nuclear fabrication or reprocessing
- Electrical fire
- Gas explosion in building
- Automobile crash

EFFLUENTS
- Unburned or incompletely burned fuel: hydrocarbons, carbon monoxide, plutonium

"Combustion" products and side products: carbon dioxide, water vapor, nitrogen oxides, sulfur oxides, lead compounds (from gasoline additives), fission products, tritium (fission and fusion)

Activation products (from neutrons in fusion and fission)

Trace contaminants: ash particles, mercury and other heavy metals (in coal and petroleum), radon (in uranium ore, coal, and geothermal steam), hydrogen sulfide (in geothermal steam), salts and brines (in geothermal steam or hot water, wastes from harvesting fossil and nuclear fuels)

Stray electromagnetic fields and ionizing radiation: fields (from microwave and overhead transmission systems), neutrons and X-rays (from fission and fusion reactors)

Noise

Heat

ENVIRONMENTAL TRANSFORMATIONS

Subsidence of ground (extraction of fossil fuels, geothermal steam)

Loss of soil and vegetation, alteration of topography (unreclaimed surface mining)

Alteration of river flows and evaporation patterns by hydro projects

Suburbanization from use of automobiles

Landscape clutter with transmission lines, oil derricks, other facilities

aggravation of inequity; redistribution of population; facilitation of military developments; and increased vulnerabilities (of the energy sector or society as a whole, to disruptions of natural or human origins). Some examples related to specific aspects of energy technology appear in Table 8-30. More extensive discussions of some of these matters will be found in Chapters 14 and 15.

Of perhaps equal importance are the adverse effects of society's responses to impacts or threats of impacts. These responses may take the form of uneasiness and mistrust at the level of the individual, and centralization of authority and misuse of power (leading in turn to loss of public participation in decision making and even loss of civil liberties) at the level of governments. Conceivably the most serious liability of such energy sources as fission and fusion is that, in the forms now in use or envisioned, they lend themselves to economic application only in units so large as to foster excessive centralization.

ENERGY USE AND CONSERVATION

Increasing the availability of energy by means of expanding reliance on old technologies and developing and deploying new ones is a costly and risky enterprise, economically as well as environmentally. Minimizing environmental and social risk should be elevated to the top of the list of criteria governing the choice of which technologies are to be relied upon most heavily. But it seems likely that the energy sources best able to meet that criterion will be both expensive economically and slow to be fully developed and deployed. For the United States and other industrial nations, there is no mix of technologies available or in prospect that can make ten to thirty years of further energy growth at 4, 3, or even 2 percent per year look appealing.

It is essential therefore, to examine the possibility of avoiding such growth by rational conservation of energy. By this we mean not doing without energy, or "going

TABLE 8-30
Some Social Impacts of Energy Technology

AGGRAVATION OF INEQUITY	
Fossil fuels	Create worst air pollution in central cities from which poor cannot escape
Nuclear fission and fusion	Steers rich-country research and development into channels with little direct early benefit for poor countries
End-use	Energy-intensive mechanization and automation may eliminate unskilled jobs
REDISTRIBUTION OF POPULATION AND ECONOMIC ACTIVITY	
Hydropower	Displacement of valley residents
Offshore oil, imported oil, and gas	Coastal urbanization around support facilities
Western coal	Haphazard development on the High Plains
Solar	Development in the Southwest desert
FACILITATION OF MILITARY DEVELOPMENTS	
Fission	International proliferation of nuclear weapons
Imported oil	Oil revenues fund armaments for exporting nations
Laser fusion	Links to military lasers and design of fusion bombs
OTHER ALTERED VULNERABILITIES	
Hydropower	Dam failure from earthquake or sabotage
Fission	Vulnerability to terrorist nuclear bombs or radiological weapons
Imported oil	Political blackmail by exporters
All-electric economy	Dependence on central authority; regional blackout from central-system accident or sabotage

TABLE 8-31
Approaches to Energy Conservation in the Short and Middle Terms

	Short term (5 years)	**Middle term (5-15 years)**
LEAK-PLUGGING	More insulation in buildings	More efficient cars
	More efficient air conditioners	More efficient building design
	Use of heat pumps for heating	More efficient power plants
MODE-MIXING	Switch freight to rail	Increase durability of goods (more repair, less
	Dress more appropriately for weather	

	Short term (5 years)	Middle term (5-15 years)
		manufacture)
	Switch containers to glass returnables	Reliable, convenient urban transit
		Switch intercity passengers to fast rail carriers
OUTPUT-JUGGLING	More sailboats, fewer motorboats	More communication, less business travel
	More backpacks, fewer trail bikes	More education, art, music, less motorized recreation
	More books, fewer movies	
		More health services, less heavy manufacturing
BELT-TIGHTENING	Car pools, lower speed limit, less pleasure driving	Live closer to work
	Houses cooler in winter, warmer in summer	Smaller dwellings

back to caves and candles" but, rather, doing better with the energy that is available -- increasing the amount of human well-being extracted from each bit of energy use. It is helpful in this context to distinguish among four classes of energy conservation measures:

1. "leak-plugging" or the "technical fix," whereby ways are found to perform exactly the same services for less energy, by improving technology or operating procedures or both -- essentially no difference is noticed by the consumer;
2. "mode-mixing," whereby the same general functions and services of energy are performed, but with significant differences in approach -- the consumer perceives some difference, but does not feel worse off;
3. "output juggling," whereby the mix of goods and services in the economy is changed to emphasize those areas that deliver the highest contributions to income and employment per unit of energy use -- consumers perceive significant differences, but most do not feel worse off;
4. "belt-tightening," whereby changes in behavior or expectations are required that many consumers regard as disruptive and detracting from well-being.

Examples of measures in the four categories are given in Table 8-31 for short-term (next five years) and middle-term (five to fifteen years) periods, in which significant impact of the various conservation measures could begin to be felt. Neither with respect to time nor with respect to the categories themselves are the boundaries always sharply defined. Major effort could accelerate the impact of some measures or neglect could delay the impact of any of them. One person might consider, say, bicycling to work a case of mode-mixing that actually made him/her better off, while another would consider bicycling a clear case of belt-tightening. Obviously, conservation based on the first three categories will be easiest to implement; they are the first things a rational society will do when it perceives the need for conservation in time. Of course, modest forms of belttightening may also be undertaken willingly by a rational society interested in gaining

economic and environmental benefits tomorrow in exchange for restraint today. The most severe forms of belt-tightening, enforced by rationing, long gasoline lines, brownouts, and so on, are the result of discounting the need for rational conservation and failing to act in time.

Several careful studies have shown that the energysaving potential of rational conservation in the United States is enormous. [249] Their conclusions have been based on sector-by-sector breakdowns of energy use in the United States and examinations of the opportunities for conservation in each sector. Such a breakdown for 1973 is shown in Table 8-32. One insight that has emerged is that the same mix of goods and services enjoyed by the U.S. population in the early 1970s *could* have been provided at a level of energy use around 60 percent of that which actually prevailed. (Makhijani and Lichtenberg arrived at 62 percent, considering only measures in the leak-plugging and mode-mixing categories; using more recent information about attainable efficiencies, Ross and Williams calculated a figure of 57 percent with leak-plugging measures alone.)

A somewhat more instructive (but also more difficult) approach is to take into account population growth, economic growth, and difficulties in implementing conservation measures in order to calculate the realistically attainable effect of conservation in slowing energy growth at various times in the future. An admittedly rough cut at this approach by the Office of Emergency Preparedness in the Executive Office of the President of the United States concluded in 1972 that measures of modest economic and social impact (mostly leakplugging plus a little mode-mixing) could cut *in half* the growth in use of energy expected under business-asusual growth forecasts for the period between 1971 and 1985.

A more thorough study of overall conservation potential was made by the Energy Policy Project of the Ford Foundation, which analyzed and described three scenarios: (1) Historical growth -- a continuation of the 1950-1970 trend; (2) Technical Fix-- accounting for

attainable rates of implementation of measures in the leak-plugging and mode-mixing categories but no output-juggling or belt-tightening; and (3) Zero Energy Growth -- in which output-juggling and lifestyle changes that some would consider belt-tightening were added to the Technical-Fix measures. (Energy use in this "Zero Growth" scenario actually only levels off in the year 2000, at a value about a third larger than the 1975 figure.) The Ford results and those of several other forecasts with and without conservation are summarized in Table 8-33.

The remarkably consistent conclusion of the independent evaluations outlined in Table 8-33 is that increases in efficiency alone could be saving 13 trillion to 25 trillion megajoules per year by 1985 and 66 trillion megajoules per year by the year 2000, compared to forecasted energy use in the absence of conservation measures. (The largest figure mentioned is nearly equal to *total* U.S. energy use in 1970; a trillion megajoules is 0.95 quadrillion Btu.) Promoting some output juggling and lifestyle changes in addition to the increases in efficiency could raise the savings to as much as 90 trillion megajoules in the year 2000.

A major two-year energy study being conducted for ERDA by the National Academy of Sciences indicated in its interim report in January 1977 that the range of scenarios being considered for the United States in the year 2010 spanned a range of total energy use from 74 trillion to 220 trillion megajoules. [249a] The lower figure is about the same as U.S. energy use in 1975, and represents a drastic downward revision in the low end of the range of energy futures given credibility by major organizations. Obviously, very large efforts at increasing the efficiency of energy use would be required to bring about this low-growth future, but the flavor of the Academy's report suggested this might be achieved without great economic disruption. [249b] Before considering more closely the economic implications of such major programs of energy conservation, it is useful to look more closely at some of the methods by which the savings could be achieved.

Energy in Buildings

According to Table 8-32, almost 20 percent of all energy use in the United States goes for heating and air conditioning dwellings and commercial buildings. Such buildings are, for the most part, poorly insulated, overventilated (more than enough air changes per hour, for

[249a] National Academy of Sciences, *Interim Report of the National Research Council Committee on Nuclear and Alternative Energy Systems*.

[249b] See also P. M. Boffey, "Academy study finds low energy growth won't be painful", *Science*, vol. 195, p. 380 (January 28).

each of which a buildingful of outside air must be heated or cooled to the desired inside temperature), and not designed to take advantage of the outside environment when it is suitable (for example, admitting sunlight through south-facing windows in winter). [250] This is in addition to the strange penchant of Americans -- much rarer where energy has been more expensive -- for heating the same buildings in winter (to 24° C, or 75° F) that they overcool in summer (to 20° C, or 68° F). Even the very large buildings operated by major firms, from which one might expect thriftier practices, are often operated in needlessly wasteful fashion -- for example, without reducing furnace thermostat settings drastically when the buildings are unoccupied. [251]

Such shortcomings in energy management in buildings are compounded by two others: the widespread use, especially in dwellings, of heating and cooling units that are much less efficient than is possible and desirable, and excessive lighting in commercial buildings, which is an inefficient way to heat in winter and adds a heavy burden on the air-conditioning system in the summer. Heating with electrically driven heat pumps (which move heat from the outside to the inside), on the market in the 1970s, delivers 2 or 3 times as much heat energy per unit of fuel consumed as the more frequently encountered resistive electrical heating (which merely converts electricity into heat); and that factor could rather easily be increased to at least 4. [252] There was a difference of a factor of 2.5 in efficiency between the most efficient room air conditioner on the market in the early 1970s and the least efficient one -- that is, one required 2.5 times less electricity than the other to perform the same amount of cooling. [253] And the illumination levels in most commercial buildings almost certainly exceed what is needed for good vision and comfort by at least a factor of 2. [254]

A 1975 study by the American Institute of Architects concluded that achievable energy conservation measures

Table 8-33
Projections of U.S. Annual Energy Use With and Without Conservation (trillion MJ)

Projections	Use in 1985	Use in 2000
ERDA (1975) "no new initiatives"	113	174

conservation; Council on Environmental Quality, *Environmental quality*, 1974; Institute of Energy Analysis, *Economic and environmental implications of a U.S. nuclear moratorium*.

that would remedy the foregoing defects and others in buildings in the United States could save 25 trillion megajoules per year by 1990. That is the equivalent of 12 million barrels of oil per day--twice the amount of imports to the United States in 1975--and somewhat more energy than nuclear power could deliver in 1990 even if the crash program of expansion recommended by some were undertaken. [255]

Industry

Industry accounted for about 40 percent of U.S. energy use in the 1970s (Table 8-32). The energy squeeze of 1973 and 1974 led to almost immediate energy savings of 15 to 30 percent (without loss of output) by many large firms, simply by plugging obvious energy leaks in their processes. [256]

More substantial changes can produce significantly larger savings. One of the most promising avenues is

---

[250] See, for example, Steadman, *Energy*; R. Stein, *A matter of design*.

[251] Contrary to a widespread misconception, basic physics guarantees that energy will be saved if the temperature is lowered overnight, notwithstanding the fact that the furnace must run vigorously for a while to warm the building again when it is turned on in the morning. See American Physical Society, *Efficient use*.

heavier reliance on *cogeneration* of electricity and process steam or process heat. The term means generating electicity within large industrial facilities and applying the part of the fuel's energy not converted into electricity to process needs on the spot. The overall efficiency can be much higher than when electricity is purchased from a utility and fuel for direct heat and steam generation is purchased separately. [257]

A substantial part of industrial energy use is for the production and refining of basic raw materials: iron and steel, aluminum, plastics, glass, paper, cement. Significant fractions of each year's production of all of those materials, except the last, disappear each year into municipal waste-disposal systems. In many cases, substantial energy savings can be realized by recycling such materials, not to mention the desirable reduction in pressure on the dwindling supplies of virgin raw materials. [258] Some examples of this are suggested in Table 8-34. (The reader handy with arithmetic might notice that the energy saved by recycling a metric ton of paper happens not to be much different from the energy one could recover by burning the waste paper as fuel instead; one cannot do both, and counting the savings both ways must be avoided in making projections.) There is no energy savings in recycling glass -- that is, consuming old glass and remelting it to make new -- but there is a large savings in switching to returnable bottles. [259] In general, in fact, making a product more durable yields a much bigger energy gain than recycling it. [260] Recyclability is not a substitute for durability but should complement it.

To the extent that part of the consumption of raw materials such as steel and aluminum must continue to come from virgin materials, energy can be saved by changes in the processes that are used for producing finished metal from ore. The basic-oxygen process for steel production uses almost 4 times less energy per ton of product than the open-hearth process, but in 1970 that process still was used in producing only half of the United States output. [261] A new process for producing aluminum uses 43 percent less energy than the standard electrolysis method. The aluminum industry in the early 1970s was using 2.8 percent of all electricity from utilities in the United States. [262]

Transportation

Of the quarter of United States energy use that occurs in the transportation sector, more than half is used in automobiles. Actually, this computation counts only fuel burned in moving freight and people. If one were to assign to the transportation sector those energy expenditures in the industrial and commercial sectors that are part of transportation activities -- manufacturing cars and planes, building railroads and highways, refining lubricating oil, and so on -- then

transportation as a whole would account for 35 to 40 percent of all U.S. energy use, and the automobile at least 21 percent. [263]

TABLE 8-35
Fuel Used in Various Modes of Transportation in the United States, 1970

Mode of transportation	Percentage of total transportation fuel use
Urban passenger (auto, bus, subway)	35
Intercity passenger (auto, plane, bus, train)	26
Urban freight (truck)	14
Intercity freight (truck, plane, train, waterway, pipeline)	15
Military aviation	3.6
General aviation (private aircraft)	0.6
Other (other military, passenger and pleasure boats, etc.)	6

Source: E. Hirst, *Energy consumption for transportation in the United States*.

A breakdown of U.S. fuel use in transportation by function is given in Table 8-35. Of the part used for urban passenger transport, automobiles account for 97 percent, and of the energy used for intercity passenger transport they use 77 percent; of the energy used for intercity freight, trucks use about 48 percent. [264] These statistics, however, do not accurately reflect the number of passenger miles and ton miles carried by the different modes, because the efficiences in passenger miles per gallon and ton miles per gallon of fuel differ so drastically from one kind of transportation to another. (We bow to convention and familiarity in this section and use the English units of measure; the reader can convert at 132 megajoules per gallon.) Of course, the transportation efficiency depends not only on the technical characteristics of the vehicle

(technical efficiency) but also on how full it is compared to its capacity (load factor). Efficiencies of various modes of freight and passenger transportation are detailed in Table 8-36.

TABLE 8-36
Transportation Efficiencies, 1970 Technology

Passengers	Technical efficiency (seat mi/gal)	Average load factor (passenger/seat)	Transportation efficiency (passenger mi/gal)*
Two-deck suburban train	400	0.50	200

Source: R. Rice, *System energy and future transportation*.

[264]E. Hirst, *Energy consumption for transportation in the U.S.*

Clearly, four basic strategies are available for reducing energy use in transportation: (1) increase the technical efficiency of a given kind of vehicle (for example, reduce speed, increase engine efficiency, improve streamlining); (2) increase the load factor (car pools, less duplication in airline schedules); (3) switch traffic to more efficient modes (cars to buses, trucks to trains); (4)

reduce the amount of motorized transportation (plan errands better, replace trips with telecommunication, bicycle or walk for short trips.)

The most obvious target for increased technical efficiency is the automobile, both because it is inefficient now and because it is so heavily used. There are abundant opportunities for improvement. For example, small electric cars would be much more efficient in urban traffic than conventional autos, notwithstanding the inefficiency of electricity generation, because they do not idle and because they can recover energy spent accelerating by using the electric motor in reverse as a generator while braking. (This is called regenerative braking.) Charging could be done at night when other electricity demands are low, so no increase in electricitygenerating capacity would be required. [265]

Improving automobiles powered by combustion engines is also possible. Lighter cars, low-loss tires, more efficient transmissions, and better streamlining could reduce automotive consumption of fuel by at least 15 to 35 percent without changing the basic engine at all. [266] Among those the biggest energy-saver is reducing vehicle weight. With modest improvements, the sparkignition, Otto-cycle (intermittent combustion) gasoline engine that powers most cars in America today can meet stricter emission standards and get significantly better mileage than the vehicles of the early 1970s, according to a study completed in 1975 by the Jet Propulsion Laboratory (JPL) of the California Institute of Technology in Pasadena. [267] The improvement would be about 22 percent without use of the stratified-charge concept pioneered by Honda, and about 33 percent with the stratified charge. [268] [In a stratified-charge engine, burning begins in a small region inside the cylinder where the fuel-to-air ratio is high and then spreads into the rest of the cylinder where the ratio is low; the result is good combustion of a mixture that on the average is leaner (contains a lower ratio of fuel to air) than a conventional engine can burn. This produces better mileage and lower emissions of pollutants.]

Further improvements in economy could be obtained by more drastic engine changes. A diesel engine could provide almost a 40-percent improvement in mileage over 1974 Otto-cycle engines, a gas turbine engine a 62 percent improvement, and a Stirling-cycle continuouscombustion engine an improvement of 80 percent, according to the JPL results. (These calculations of improvement do not include the gains to be made by reducing vehicle weight and other changes.) Gas-turbine engines (also called Brayton-cycle engines) have been powering experimental automobiles for many years. The Stirling-cycle engine is in many respects similar to steam engines (Rankine-cycle), but its "working fluid" is a noncondensable pressurized gas, such as hydrogen or helium, instead of water. It appears to be superior to the steam engine for automotive applications. Both the gas-turbine and the Stirling-cycle engines are more expensive than conventional Otto-cycle engines and for fundamental reasons will probably remain so, but a concerted development effort and mass production probably could reduce the cost penalty to around $200.

It does not seem unreasonable, then, to expect, and indeed to require by law, that the technical efficiency of automobiles be steadily and significantly increased over the next ten years. A 40-percent decrease in automotive fuel consumption from the 1974 level, which is achievable by 1980 without major engine changes and without decreasing miles driven, would save 2 million barrels of oil per day. [269] Large additional savings in the same period could be achieved by more

car-pooling, by reducing reliance on the automobile for very short trips, and by improving bus service to attract commuters away

[265]For a discussion of electric cars, see National Academy of Sciences, *An evaluation of alternative power sources for low-emission automobiles*.
[266]See, for example, J. Pierce, "The fuel consumption of automobiles; and American Physical Society", *Efficient use*.
[267]Jet Propulsion Laboratory, *Should we have a new engine: An automobile power systems evaluation*.
[268]These percentages were obtained in the JPL study for engines of equivalent performance. Naturally, sacrificing some performance could lead to even bigger gains in mileage.
[269]Pierce, *The fuel consumption*.

from their cars. In the middle term, introduction of the more radical engine changes and of better urban transit systems could continue the drop in fuel consumed per passenger mile.

Large savings in transportation energy are also possible by switching intercity passengers from cars and planes into fast, comfortable trains on routes up to 1000 kilometers or so. Switching long-distance freight transport from trucks onto trains should be encouraged, too. A detailed study by transportation specialist Richard Rice of what could be done by the year 2000 indicated that the United States might have 117 percent more passenger traffic and 47 percent more freight traffic in that year than in 1970 (measured in passenger miles and ton miles) while using 13 percent *less* transportation fuel. [270]

Economic and Social Impact of Conservation

The view that energy conservation should be the cornerstone of a rational U.S. energy policy has been attacked by many in the energy industry, who appear to believe that conservation will have dire economic consequences. Loss of jobs, economic stagnation, and thwarting the legitimate aspirations of the poor are generally mentioned as the specific consequences of saving energy. There is much evidence to suggest, however, that that view is incorrect. Energy conservation does not merely make sense environmentally; it also makes sense economically.

First of all, slowing the growth of energy consumption by means of rational conservation measures can save a great deal of money. For, although technological improvements to increase energy efficiency often require some additional capital investment over conventional practice, that investment is usually less than the investment that would be needed to produce from new sources (offshore oil, nuclear fission, geothermal development) an amount of energy equal to that saved. In this sense, conservation is the cheapest new energy source. The Ford Foundation Energy Policy Project's Technical Fix scenario reduces energy-related capital investment (the sum of the investment for supply and for conservation) by 285 billion 1970 dollars between 1975 and 2000, compared to the Historical Growth scenario. [271] The investment capital saved by conservation, of course, would in principle be available to support this country's many other

pressing needs -- better health care, nutrition, educational facilities, environmental cleanup, and so on.

Direct savings to consumers in the form of money not spent on energy is another side of the same coin. Many consumer investments in energy conservation, such as buying extra insulation, pay off very quickly. The value of the energy saved exceeds the expenditure in a short time, or, in the case of financed purchases, lower fuel bills more than compensate for increased loan payments immediately. [272] Money saved in this way can be spent in ways that contribute directly to the consumer's sense of well-being (which expenditures on energy wasted because of poor insulation and needlessly inefficient appliances and automobiles do not).

Furthermore, less energy can actually mean more employment. The energy-producing industries make up the most capital-intensive major sector of the U.S. economy and one of the least labor-intensive. [273] This means that each dollar of investment capital taken out of energy production and invested elsewhere, and each dollar saved by an individual because of reduced energy use and spent elsewhere in the economy, is likely to benefit employment.

In summary, the link between energy use and economic prosperity is not firm, but flexible. The notion that there is a one-to-one correspondence between energy consumption and economic prosperity is probably the most dangerous delusion in the energy-policy arena. It is true that very poor countries use only a little energy per person, and that rich countries use much more, but within a given prosperity bracket there is enormous variation in energy used per dollar of GNP. In 1974, three western European countries -- Sweden, Denmark and Switzerland -- had per-capita GNPs *higher* than that of the United States, despite their using only around half the energy per person (see Table 8-2.) How do those countries produce so much more GNP per unit of energy

[270] R. Rice, *Toward more transportation with less energy*.
[271] Energy Policy Project, *A time to choose*.
[272] Schipper, *Raising the productivity*.
[273] See ibid., and references therein.

used than the U.S.? The answer is complex, of course, and has partly to do with the fact that those countries have a somewhat larger fraction of their economic activities in services (such as health care and education), which are less energy-intensive per dollar and per job than manufacturing, than does the United States. Those peoples are also more careful with their energy than we are. [274] It is clear from such comparisons between countries, as well as from comparisons of different sectors within the U.S. economy, that the United States could change the pattern of its economic growth in ways that would greatly reduce the growth in its energy consumption without a corresponding cost in prosperity. [275]

PERSPECTIVES ON THE ENERGY PROBLEM

Why worry about energy? What has gone wrong or is likely to? The many people who are deeply troubled by the energy situation in the United States can be divided, to a great extent, into two groups, according to their perceptions of the general nature of the situation: those who believe this country is in danger of having too little energy, too late, and those who believe that the threat is too much energy, too soon.

The specific problems envisioned by the too-littletoo-late school have been widely articulated: running out of cheap domestic energy resources, dependence on unstable foreign sources, high prices, economic stagnation, and the perpetuation of poverty. The too-muchtoo-soon camp is most troubled by the prospect of excessive growth in energy use, stimulating premature transitions to untested technologies accompanied by undesirable or even unbearable costs to human health, ecosystems, and human values.

Not surprisingly, the two camps have rather different views of the role of new energy technology, as well as of the nontechnological dimensions of the energy problem. The goal of new technology in the eyes of the too-littletoo-late school is to restore the era of abundant, cheap energy. According to the too-much-too-soon group, the first priority in shaping and choosing new energy technologies should be to minimize the social and environmental impacts of obtaining energy and of using it. The principal nontechnological concern of the too-little-toolate people is that environmentalists and others may block progress toward the desired goal of abundant, cheap energy. The nontechnological dimensions of the energy problem perceived by the too-much-too-soon group include coming to grips with limits and redistributing the finite economic pie that limits must eventually imply.

The strategies of the two groups for dealing with the energy situation, then, are almost diametrically opposed. The too-little-too-late group favors crash programs to develop and deploy all resources and technologies, with priority to whatever promises to be cheapest. The too-much-too-soon group wants to slow down, buy time by maximizing the efficiency of energy use, and use that time to select a mix of energy technologies that is as benign environmentally and socially as money and ingenuity can make it.

The two perspectives sketched out here are in some sense caricatures of a broader and more complex spectrum of opinion, of course, and the situation is complicated further when the focus of concern is broadened to include the diversity of countries beyond the United States. Nevertheless, the dangers facing the industrial nations are rather neatly summed up by the Scylla of too-little-too-late and the Charybdis of too-much-toosoon. Readers may draw their own conclusions from the material here and in Chapters 10-12, as to which danger is the more real. Energy policy, being a matter of steering a course that gives the widest margin of safety against the greatest hazard, is a highly controversial subject that we defer until Chapters 14 and 15.

Dinneen, G. U., and G. L. Cook. 1974. "Oil shale and the energy crisis". *Technology Review*, vol. 76, no. 3 (Jan.), pp. 26-33. Useful survey article on the technology and prospects of exploiting oil shale.
Doyle, W. S. 1976. *Strip mining of coal: Environmental solutions*. Noyes Data Corporation, Park Ridge, N.J. Comprehensive, technical summary of reclamation methods and costs.
Duffie, J. A., and W. A. Beckman. 1974. *Solar energy thermal processes*. Wiley, New York. An engineering text.
-----. 1976. "Solar heating and cooling". *Science*, vol. 191, pp. 143-149 (January 16). Useful progress report on solar technology for heating and cooling buildings.
Dunham, J. T.; Carl Rampacek; and T. A. Henrie. 1974. "High-sulfur coal for generating

electricity". *Science*, vol. 184, pp. 346-351 (April 19). Surveys methods of sulfur control available in the early 1970s.
Eckholm, Erik P. 1975. *The other energy crisis: Firewood*. Worldwatch Institute Washington, D.C. Informative treatment of pressure on forest resources to supply energy needs in poor countries.
Eisenbud, Merril. 1973. *Environmental radioactivity*, 2d ed. Academic Press, New York. Useful collection of quantitative information and references on behavior of radioactive isotopes in the environment.
Elliott, D.; and L. Weaver, eds. 1972. *Education and research in the nuclear fuel cycle*. University of Oklahoma Press, Norman. Contains good coverage of the technologies of uranium enrichment and fuel reprocessing, as they stood in the late 1960s.
Emmett, J.; J. Nuckolls; and L. Wood. 1974. "Fusion power by laser implosion". *Scientific American*, June, pp. 24-37. The best available general article on laser fusion.
Energy Research and Development Administration (ERDA). *See*U.S. Energy Research and Development Administration.
Engineering Research Institute. 1957. *A report on the possible effects on the surrounding population of an assumed release of fission products into the atmosphere from a 300 megawatt nuclear reactor located at Laguna Beach, Michigan*. University of Michigan, Ann Arbor. An obscure study conducted for the USAEC in connection with the construction of the Fermi experimental liquid metal fast breeder reactor. Indicated that a severe accident under adverse weather conditions could kill 188,000 people in nearby Detroit.
Environmental Protection Agency (EPA). *See*U.S. Environmental Protection Agency.
Ergen, W. K., et al. 1967. *Emergency core cooling: Report of advisory task force committee on power reactor emergency cooling*. USAEC, Washington, D.C. An important official study of a critical element of the safety of light-water reactors, much cited in later work.
Farmer, F. R., ed. 1977. *Nuclear reactor safety*. Academic Press, New York. Useful coverage at a technical level of safety issues surrounding the LMFBR, as well as other reactor types.
Feiveson, H. A., and T. B. Taylor. 1976. "Security implications of alternative fission futures". *Bulletin of the Atomic Scientists*, vol. 32, no. 10 (Dec.), pp. 14ff. Suggests that a thorium/uranium-233 fuel cycle could have significant advantages over uranium-235/plutonium with respect to safeguards against diversion for weapons.
Finney, B. C.; R. E. Blanco; R. C. Dahlmann; F. G. Kitts; and J. P. Witherspoon . 1975. *Nuclear fuel reprocessing*, National Technical Information Service, Springfield, Va., ORNL-IM-4901. Good, up-to-date survey of technology and expected environmental impacts of nuclear fuel reprocessing.
Fletcher, K; and M. Baldwin. 1973. *A scientific and policy review of the prototype oil shale leasing program final environmental impact statement of the U.S. Department of the Interior*. Environmental Impact Assessment Project, Washington, D.C. Good treatment of water requirements of oil shale development and of the problem of disposing of spent shale.
Flowers, Sir Brian (Chairman). 1976. *Nuclear power and the environment*. Sixth report of the Royal Commission on Environmental Pollution. Her Majesty's Stationery Office, London. Very thorough and scholarly review of the pros and cons of nuclear power. Recommends that "a major commitment to fission power and a plutonium economy should be postponed as long as possible."

Forbes, I.; D. Ford; H. Kendall; and J. MacKenzie. 1971. "Nuclear reactor safety: An evaluation of the new evidence". *Nuclear News*, September, pp. 32-40. The paper by four members of the Massachusettsbased Union of Concerned Scientists that initiated a prolonged controversy about the adequacy of emergency core-cooling systems for light-water reactors.
Ford, D. F.; H. W. Kendall; and J. J. MacKenzie. 1972. "A critique of the AEC's interim criteria for emergency core-cooling systems (ECCS)". *Nuclear News*, January, p. 28. Another important piece of the ECCS controversy (see Forbes, Ford, and MacKenzie).
-----; T. Hollocher, H. Kendall, J. MacKenzie, L. Scheinman, and A. Schurgin . 1975. *The nuclear fuel cycle*. M.I.T. Press, Cambridge, Mass. Excellent reviews of hazards in uranium mining and milling, fuel reprocessing, and waste management, together with a short summary of the light-water-reactor safety controversy. Highly recommended.
Fox, R. W. (Chairman). 1976. *Ranger uranium environmental inquiry*. Australian Government Publishing Service, Canberra. Detailed review of nuclear technology and associated issues, undertaken in connection with Australia's deliberations about exporting her uranium.
Franklin, W.; D. Bendersky; W. Park; and R. Hunt. 1975. "Potential energy conservation from recycling metals in urban solid wastes". In *The energy conservation papers*, R. Williams, ed.
Fuller, R. 1975. *We almost lost Detroit*. Reader's Digest Press, Garden City, N.Y. Notwithstanding the sensational title, a generally sober and accurate popular account of the 1965 accident at the Fermi breeder reactor near Detroit, as well as other reactor accidents around the world.
Garvey, G. 1972. *Energy, ecology, economy*. Norton, New York. A perceptive statement by a Princeton University political scientist, emphasizing the difficulty and importance of bringing ecological insights into cost-benefit analysis of energy technology.
General Electric Co. 1975. *Nuclear power: The best alternative*. GEZ6301.4A. San Jose, Calif. A piece of industry propaganda, illustrating not only the standard arguments for all-out nuclear development but also what seems to be an astonishing degree of contempt for the intelligence of the intended audience.
Gesell, T.; J. Adams; and L. Church. 1975. "Letters: Geothermal power plants-environmental impact". *Science*, vol. 189, p. 328 (August 1). Raises the issue of radon gas released in geothermal operations.
Gillette, R. 1972. "Nuclear safety. (Pt. 3), Critics charge conflicts of interest". *Science*, vol. 177, no. 4053, p. 970 (September 15). One in a series of articles by this reliable and objective reporter on the light-water reactor safety controversy.
-----. 1973. "Nuclear safeguards: Holes in the fence". *Science*, vol. 182, pp. 1112-1114 (December 14). Reports the laxity of safeguards in effect against theft of bomb-grade nuclear materials in the United States in the early 1970s, as determined by an investigation by the General Accounting Office.
------. 1974. "GAO calls security lax at nuclear plants". *Science*, vol. 186, pp. 906-907 (December 6). Reports a General Accounting Office finding that sabotaging a nuclear power reactor would not be as difficult as is commonly supposed.
-----. 1975 "Geological Survey lowers its sights". *Science*, vol. 189, p. 200 (July 18). Reports a drop by a factor of 3 in USGS estimates of undiscovered recoverable U.S. oil and gas, a major concession to M. K. Hubbert and other critics of the higher earlier estimates.

-----. 1975. Nozzle" enrichment for sale. *Science*, vol. 188, p. 912 (May 30). Description of the Becker process for enriching uranium and the impact the marketing of this process by the Federal Republic of Germany (West Germany) and others may have on the world situation.
-----. 1975. "Nuclear proliferation: India, Germany may accelerate the process". *Science*, vol. 188, pp. 911-914 (May 30). Spread of nuclear weapons through experimental and commercial reactors and supporting facilities made available through international "cooperation."
-----. 1975. "Oil and gas resources: Academy calls USGS math misleading". *Science*, vol. 187, pp. 723-727 (February 28). The dispute between optimists (at the U.S. Geological Survey) and pessimists (advising the National Academy of Sciences) over the amount of domestic gas and oil remaining to be found in the United States.
Glaser, P. 1974. "Power from the sun". *Unesco Courier*, vol. 27, pp. 16-21. Popular discussion of solar electricity production using satellites.
-----. 1977. "Solar power from satellites". *Physics Today*, vol. 30, no. 2 (February), pp. 30-38. Argues that satellite power stations could be built for $1500 per kilowatt.
Glasstone, S., and A. Sesonske. 1963. *Nuclear reactor engineering*. Van Nostrand, Princeton, N.J. Standard reference work for the physics and technology of fission reactors.
Gofman, J. W.; and A. R. Tamplin. 1971. *Poisoned power*. Rodale Press, Emmaus, Pa. Two early critics of nuclear power state their case. Emphasis is on routine emissions.
Goldsmith, M. 1971. *Geothermal resources in California: Potentials and problems*. California Institute of Technology Environmental Quality Laboratory, Pasadena, Report 5. Sober look at geothermal's prospects by an observer with no axe to grind.
Goldstein, I. S. 1975. "Potential for converting wood into plastics". *Science*, vol. 189, pp. 847-852 (September 12). Fulfillment of all plastic needs from wood does not seem impossible, technically or economically.
Golenpaul, A., ed. 1975. *Information please almanac*. 29th ed. Dan Golenpaul Associates, New York.
Golueke, C., and W. Oswald. 1963. "Power from solar energy via algae-produced methane". *Solar Energy*, vol. 7, no. 3, pp. 86-92. An early description of one possible approach to bioconversion of solar energy.
Gough, W., and B. Eastlund. 1971. "The prospects of fusion power". *Scientific American*, February, pp. 50-64. Excellent survey of progress toward harnessing fusion. Still a useful introduction in 1976.
Greenburg, William. 1973. "Chewing it up at 200 tons a bite: Strip mining". *Technology Review*, vol. 75, no. 4, pp. 46-55. Well-illustrated documentation of damage in Appalachian strip-mining.
Gregory, D. 1973. "The hydrogen economy". *Scientific American*, January, pp. 13-21. Possibility of replacing hydrocarbons as portable fuel.
Grooms, D. W. 1976. *Nuclear materials safeguards: A title bibliography. Vol. 1, 1964-1974*. National Technical Information Service, Springfield, Va. A very useful guide to literature that is otherwise hard to find.
Gruen, Victor. 1975. *Atomenergie und "Des Kaisers neue Kleider." Die Zukunft* (Austria vol. 12, end of June, pp. 15-19. A noted environmental planner and author uses the fable of the emperor's new clothes as a vehicle to express his critique of nuclear power.

Gyftopolous, E.; L. Lazaridis; and T. Widmer. 1974. *Potential fuel effectiveness in industry*. Ballinger, Cambridge, Mass. Prepared by the Energy Policy Project of the Ford Foundation, this report documents the potential for large energy savings in U.S. industry.
Haefele, W. 1974. "Energy choices that Europe faces". *Science*, vol. 184, pp. 360-367 (April 19). Useful survey of Europe's options by the head of the energy project at the International Institute for Applied Systems Analysis in Austria.
----- and A. Manne. 1974. *Strategies for a transition from fossil to nuclear fuels*. International Institute for Applied Systems Analysis, Laxenburg, Austria, Report RR-74-7.
Haefele, W., and C. Starr. 1974. "A perspective on fission and fusion breeders". *Journal of the British Nuclear Energy Society*, vol. 13, no. 2 (April), pp. 131-139. Two strong advocates of fission argue that fusion's potential advantages are small. (See the rebuttals in the April 1975 issue of the same journal by Holdren and von Hippel.)
Haefele, W.; J. Holdren; G. Kessler; and G. Kulcinski; with contributions from A. Belostotsky, R. Grigoriants, M. Styrikovich, and N. Vasiliev . 1977. *Fusion and fast breeder reactors*. International Institute for Applied Systems Analysis, Laxenburg, Austria. Booklength report of a major cooperative study, with collaborators from the U.S., the Federal Republic of Germany, and the U.S.S.R., comparing technical, resource, and environmental aspects of fusion reactors and LMFBRS.
Hagan, R. M., and E. B. Roberts. 1973. "Ecological impacts of water storage and diversion projects". In *Environmental quality and water development*, C. R. Goldman; J. McEvoy, III; and P. J. Richardson, eds. W. H. Freeman and Company, San Francisco, pp. 196-215. Very thorough and well-documented treatment.
Hall, D. B. 1971. "Adaptability of fissile materials to nuclear explosives". In *Proceedings of symposium on implementing nuclear safeguards* (Kansas State University, October 25-27, 1971). Praeger, New York. Definitive statement by an expert on the usability of oxide and contaminated forms of fissile materials for nuclear explosives.
Halsted, T. A. 1975. "The spread of nuclear weapons -- is the dam about to burst?" *Bulletin of the Atomic Scientists*, vol. 31, no. 5, pp. 8-11. A discussion of the status of the Nonproliferation Treaty just before the review conference of 1975.
Hambleton, W. W. 1972. "The unsolved problem of nuclear wastes". *Technology Review*, vol. 74, no. 5 (March/April), pp. 15-19. The individual most responsible for stopping the USAEC's ill-advised commitment to waste storage in a Lyons, Kansas, salt mine explains the difficulties.
Hammond, A. L. 1973. "Dry geothermal wells: Promising experimental results". *Science*, vol. 182, pp. 43-44 (October 5). Progress report on the hot-dry-rock approach.
-----. 1975. "Artificial tornadoes: A novel wind energy concept". *Science*, vol. 190, pp. 257-258 (October 17). A clever exploitation of aerodynamics to extract wind energy from an area larger than the generator itself.
-----. 1976. "Nuclear proliferation: Warnings from the arms control community". *Science* vol. 193, pp. 126-130 (July 9). Inadequacy of existing safeguards against the spread of weapons via commercial nuclear power.
-----, W. D. Metz, and T. H. Maugh, II. 1973. *Energy and the future*. American Association for the Advancement of Science, Washington, D.C. Surveys advances in the technologies of fission, fusion, MHD, fossil-fuel conversion, and energy transmission and storage.
Hammond, O. H., and Baron R. E.. 1976. "Synthetic fuels: Prices, prospects, and prior art". *American Scientist*, vol. 64, pp. 407-417 (July/August). Excellent survey of technology for

oil shale, tar sands, and liquefaction and gasification of coal.
Hannon, B. 1972. "Systems energy and recycling: A study of the beverage industry". *Environment*, vol. 14, no. 2, pp. 11-21. Indicates the substantial amount of energy used for beverage containers and how that amount could be reduced by recycling.
-----. 1974. "Options for energy conservation". *Technology Review*, vol. 76, no. 4, pp. 24-31. Useful survey of evident possibilities for increased energy efficiency, together with some insights into its effects on employment and GNP.
Harte, J., and R. H. Socolow. 1971. *Patient Earth*. Holt, Rinehart and Winston, New York. Case studies in management of resources and environment, together with instructive introductions to the basics of energy, water, radiation, population growth. Highly recommended.
Harwood, S.; K. May; M. Resnikoff; B. Schlessinger; and P. Tames. 1976. "The cost of turning it off". *Environment*, vol. 18, no. 10 (December), pp. 17-26. The problems of decommissioning nuclear reactors after they wear out.
Hasiba, H. H.; R. P. Trump; and A. David. 1973. *In-situ process options for the recovery of energy and synthetic fuels from coal, oil shale, and tar sands*. American Institute of Mining, Metallurgical and Petroleum Engineers, Inc., New York, AIME paper SPE 4710.
Healy, T. J. 1974. *Energy, electric power, and man*. Boyd and Fraser, San Francisco. A good undergraduate text with emphasis on generation, applications, and regulation of electricity.
Hein, R. 1974. "Superconductivity: Large scale applications". *Science*, vol. 185, p. 221-222 (July 19). Potential of superconduction technology in energy production, storage, transmission, and end use.
Herendeen, R. 1974. "Energy and affluence". *Mechanical Engineer*, October. Shows how direct and indirect energy use vary with income class.
----- and A. Sebald. 1975. "Energy, employment, and dollar impact of certain consumer options". In *The energy conservation papers*, Robert H. Williams, ed. Use of energy analysis to show the way toward less energy-intensive life-styles.
Heronemus, W. E. 1975. "Wind power: A near-term partial solution to the energy crisis". In *Perspectives on energy*, L. C. Ruedisili and M. W. Firebaugh , eds. Systematic look at large-scale use of wind power in electric utility systems.
Hirsch, R. and W. Rice. 1974. "Nuclear fusion power and the environment". *Environmental Conservation*, vol. 1, Winter, pp. 251-262. Progress toward fusion and a brief discussion of the environmental implications of success.
Hirst, E. 1972. *Energy consumption for transportation in the U.S.* National Technical Information Service, Springfield, Va., ORNL-NSF-EP15. [A shorter version appeared as Transportation energy use and conservation potential, *Bulletin of the Atomic Scientists*, vol. 29, no. 9, p. 36-42.] A thorough study assembling much useful data about how energy is used in moving people and freight in autos, trucks, aircraft, buses, and so on.
-----. 1974. "Food-related energy requirements". *Science*, vol. 184, pp. 134-138 (April 12). Shows that food production, processing, delivery, marketing, storage, and preparation account for about 12 percent of total U.S. energy use.

-----. 1976. "Transportation energy conservation policies". *Science*, vol. 192, pp. 15-20 (April 2). Advocates higher gasoline taxes and tight fuel-economy standards for new automobiles.

-----. 1976. "Residential energy use alternatives: 1976 to 2000". *Science*, vol. 194, pp. 1247-1252 (December 17). Potential for large energy savings through increased efficiency.
----- and R. Herendeen. 1973. *Total energy demand for automobiles*. Society of Automotive Engineers, New York. (Reprinted in U.S. Senate Committee on Interior and Insular Affairs, *Energy Conservation:* Hearings on S.2176, 93d Cong., 1st sess., August 1973.) Finds that energy used in manufacturing, in servicing, and in otherwise supporting automobiles is half as great as the energy autos use directly as fuel.
----- and J. Moyers. 1973. "Efficiency of energy use in the United States". *Science*, vol. 179, p. 1299-1304 (March 30). Surveys possibilities of energy conservation in buildings, transportation, and industry, identifying large potential savings.
Hocevar, C. J. 1975. *Nuclear reactor licensing -- a critique of the computer safety prediction methods*. Union of Concerned Scientists, Cambridge, Mass. Detailed technical critique by an expert on computer analysis of reactor safety who resigned from the USAEC's principal contractor for safety analysis.
Holdren, J. P. 1971. "Adequacy of lithium supplies as a fusion energy source". In *Controlled thermonuclear research*. U.S. Congress, Joint Committee on Atomic Energy. Government Printing Office, Washington, D.C. Shows that availability of lithium is unlikely to limit the use of deuterium-tritium fusion.
-----. 1974. "Hazards of the nuclear fuel cycle". *Bulletin of the Atomic Scientists*, vol. 30, no. 8 (October), pp. 14-23. Surveys risks of routine emissions, accidents, sabotage, and theft and diversion of nuclear materials for weapons at reactors and other fuel-cycle facilities.
-----. 1975. "Energy and prosperity: Some elements of a global perspective". *Bulletin of the Atomic Scientists*, vol. 30, no. 1 (January), pp. 26-28. Presents a scenario combining lowered population growth and a shift of the bulk of energy growth from rich countries to poor ones.
-----. 1975. "The relevance of environmental concerns in contemplating development of fission-fusion hybrids. A personal view". In *DCTR fusion-fission energy systems meeting*, U.S. Energy Research and Development Administration, pp. 209-216. Argues that hybrids may sacrifice the potential environmental advantages that make fusion desirable.
-----. 1975. "Uranium availability and the breeder decision". *Energy systems and policy*, vol. 1, no. 3. Uses USAEC and USGS data to show that nonbreeder reactors could economically meet forseeable nuclear generating requirements through the year 2020 using low-grade uranium. This suggests high priority on the breeder reactor is unjustified.
------. 1976. "*Auswirkungen der Energieprobleme auf die Unternehmung*". *Journal für Betriebswirtschaft* (Austria), vol. 1/ 76. pp. 29-33. Argues that reductions in the growth rate of energy use need not adversely affect industrial economics.
-----. 1976. "Zero-infinity dilemmas in nuclear power". In Committee on Insular and Interior Affairs, U.S. House of Representatives, *Reactor safety study (Rasmussen report)*, Serial No. 94-61, Government Printing Office, Washington, D.C., pp. 357-364. Shortcomings of methodology and presentation in the Rasmussen Report, together with other ingredients of the decision-makers' dilemma surrounding nuclear power.
-----. 1977. "Costs of energy as potential limits to growth". In *The sustainable society: Social and political implications*, D. Pirages, ed., Praeger, New York. Rising economic, environmental and social costs of energy supply -- systematic assessment and implications.
------; T. K. Fowler; and R. F. Post. 1976. "Fusion power and the environment". In *Energy and the environment: Cost-benefit analysis*, R. A. Karam and K. Z. Morgan, eds.,

Pergamon, New York. Elucidates the magnitude of the potential environmental advantages of fusion over fission, while emphasizing the effort that would be necessary to translate the potential into reality.
----- and P. Herrera. 1971. *Energy*. Sierra Club Books, New York. A pre-embargo introduction to the energy dilemma, emphasizing the environmental liabilities of supply technologies and the underexploited potential of energy conservation.
Hollocher, T. C. 1973. "Storage and disposal of high level wastes". In D. F. Ford , et al., The nuclear fuel cycle. One of the best introductions to the nuclear-waste problem.
----- and J. J. MacKenzie. 1975. "Radiation hazards from the misuse of uranium mill tailings". In *The nuclear fuel cycle*, Ford, D. F., et al. The best survey of the tailings problem in Grand Junction and elsewhere on the Colorado plateau.
Hottel, H. C., and J. B. Howard. 1971. *New energy technology: Some facts and assessments*. M.I.T. Press, Cambridge. Heavily technical coverage of coal gasification and liquefaction, with briefer treatment of oil shale, sulfur control, nuclear fission, and solar energy. Dated in important respects.
Hubbert, M. K. 1974. *U.S. energy resources: A review as of 1972*. Senate Committee on Interior and Insular Affairs, Washington, D.C., 93-40 (92-75). Useful update of Hubbert's earlier work on resource estimation.
Huettner, D. A. 1976. "Net energy analysis: An economic assessment". *Science*, vol. 192, pp. 101-104 (April 9). Focuses on the limitations of net energy analysis as a major basis for policy decisions.
Inglis, D. R. 1973. *Nuclear energy: Its physics and its social challenge*. Addison-Wesley, Reading, Mass. Even-handed introduction to the physics, applications, and problems of nuclear energy by a distinguished veteran of the field's early years.
Institute for Energy Analysis. 1976. *Economic and environmental implications of a U.S. nuclear moratorium*. Oak Ridge Associated Universities, Oak Ridge, Tennessee. Suggests that doing without nuclear power is possible, but expresses reservations about the high use of coal that would result.
International Atomic Energy Agency (IAEA). 1970. *Environmental aspects of nuclear power stations*. IAEA, Vienna. Conference proceedings containing a variety of useful papers on radiation, thermal pollution, and other topics.
International Institute for Applied Systems Analysis (IIASA). 1975. *Proceedings: Workshop on energy resources*. IIASA, Laxenburg, Austria. Up-to-date review of global energy resources, emphasizing fossil and nuclear fuels.
James, L. W., and R. L. Moon. 1975. "GaAs concentrator solar cell". *Applied Physics Letters*, vol. 26, p. 467-470 (April 15). A breakthrough in solar-cell technology, permitting 1000-fold concentration of the incident sunlight (with mirrors) without the loss of efficiency that characterizes other cells under those circumstances.
JCAE. *See*U.S. Congress, Joint Committee on Atomic Energy.

Jet Propulsion Laboratory (JPL). 1975. *Program review: Comparative assessment of orbital and terrestrial central power stations*. Jet Propulsion Laboratory, Pasadena. An extensive NASA-sponsored study emphasizing the economics of solar generation of electricity as measured against conventional systems.
-----. 1975. *Should we have a new engine? An automobile power systems evaluation*. 2 vols. JPL, Pasadena. Very thorough study of engine options -- turbines, steam engines, diesels,

and others -- comparing performance, economics, and emissions.
Kansas State University. 1972. *Proceedings of symposium on implementing nuclear safeguards*. Praeger, New York. Authoritative papers on the risks of nuclear theft and diversion.
Karam, R. A., and K. Z. Morgan, eds. 1976. *Energy and the environment: Cost benefit analysis*. Pergamon, New York. Proceedings of a symposium, emphasizing the fission-coal comparison.
Kasper, W. 1974. "Power from trash". *Environment*, vol. 16, no. 2 (March), pp. 34-38. Potential for using municipal waste for electricity production.
Kelley, J. H., and E. A. Laumann, eds. 1975. *Hydrogen tomorrow: Demands and technology requirements*. Jet Propulsion Laboratory, Pasadena. A substantive technical assessment with an extensive bibliography.
Kendall, H. W. 1975. *Nuclear power risks: A review of the report of the APS study group on light water reactor safety*. Union of Concerned Scientists, Cambridge, Mass. A prominent physicist and nuclear critic cuts through the waffling language of the American Physical Society report, to underline that document's disturbing conclusions about reactor safety.
----- and S. Moglewer. 1974. *Preliminary review of the AEC reactor safety study*. Sierra Club, San Francisco, and Union of Concerned Scientists, Cambridge, Mass. Identifies major shortcomings in the reactor-safety study and concludes accident probabilities and consequences are underestimated.
Komanoff, Charles. 1976. *Power plant performance*. Council on Economic Priorities, New York. A detailed examination of the reliability of coal-fired and nuclear power plants suggests nuclear's presumed cost advantage is illusory.
Krieger, David. 1975. "Terrorists and nuclear technology". *Bulletin of the Atomic Scientists*, vol. 31, no. 6 (June), pp. 28-34. A sobering evaluation of perhaps the greatest social/environmental hazard of nuclear power.
Kruger, P., and C. Otte, eds. 1973. *Geothermal energy: Resources, production, stimulation*. Stanford University Press, Calif. Good introduction to the field.
Kubo, A. S., and D. J. Rose. 1973. "Disposal of nuclear wastes". *Science*, vol. 182, p. 1205 (December 21). A brief but systematic treatment of the options for managing high-level nuclear wastes. Good introduction to the subject.
Kulcinski, G. 1974. "Fusion power: An assessment of its potential impact in the USA". *Energy Policy*, vol. 2, p. 104. Very comprehensive and useful treatment of the technological side of fusion, including impact on the resources that will be needed to build fusion reactors.
Lagler, K. 1971. "Ecological effects of hydroelectric dams". In *Power generation and environmental change*, D. Berkowitz and A. Squires, eds. One of the few available popular treatments of this subject. Mainly a listing, with little elaboration.
Lash, T., and J. Bryson. 1974. *Comments of the Natural Resources Defense Council, Inc. and the Sierra Club on the USAEC WASH-1539*. Natural Resources Defense Council, Palo Alto, Calif. Systematically demolishes a very unsatisfactory environmental-impact statement prepared by the USAEC on retrievable surface storage of radioactive wastes.
Lave, L. B., and L. P. Silverman. 1976. "Economic costs of energy-related environmental pollution". In *Annual review of energy*, J. M. Hollander and M. K. Simmons, eds. Lave continues to do the best work available on economic quantification of energy's environmental impacts.
Levin, R. 1972. "Conversion and enrichment in the nuclear fuel cycle". In *Education and*

research in the nuclear fuel cycle, D. Elliott and L. Weaver , eds. Explains in unusual detail the technology of uranium enrichment by gaseous diffusion.
Lewis, A. 1974. *The outlook for oil shale*. University of California, Lawrence Livermore Laboratory, Livermore, UCRL-75242. Economic costs and technological obstacles are surveyed.
Lewis, H. W., et al. 1975. "Report to the American Physical Society by the study group on light-water reactor safety". *Reviews of modern physics*, vol. 47, supplement I (summer). An exceedingly thorough and careful examination of the status of light-water reactor safety by an independent group of physicists. Unfortunately, some disturbing conclusions are buried in the rhetoric of a complacency not justified by the substantive content.
Lewis, R. 1972. *The nuclear power rebellion: Citizens versus the atomic industrial establishment*. Viking, New York. A history of the USAEC and the Joint Committee on Atomic Energy, emhasizing controversies and conflicts with independent scientists and citizen groups.
Lidsky, L. M. 1975. "Fission-fusion systems: Hybrid, symbiotic, and Augean". *Nuclear Fusion*, vol. 15, pp. 151-173. The most comprehensive survey paper on hybrids.
Lieberman, M. A. 1976. "United States uranium resources: An analysis of historical data". *Science*, vol. 192, pp. 431-436 (April 30). Argues on the basis of drilling and discovery rates that much less high-grade uranium remains to be discovered than official projections indicate.
Livingston, R. S., and B. McNeill. 1975. Beyond petroleum. vol. 1, *Biomass energy chains*. Stanford University, Energy Information Center, Stanford, Calif. A careful look at the use of bioconversion as a large-scale substitute for fossil fuels. Eucalyptus trees are found attractive for this purpose.
Lovins, A. 1976. "Energy strategy: the road not taken". *Foreign Affairs*, October, pp. 55-96. Compelling case for low energy growth and reliance on "soft" technologies. Emphasizes evils of large scale and centralization.
-----, and John Price. 1975. *Non-nuclear futures: The case for an ethical energy strategy*. Ballinger, Cambridge, Mass. An eloquent and thoughtful exposition of some drawbacks of nuclear power.
Lund, R. T. 1977. "Making products live longer". *Technology Review*, vol. 79, no. 3 (January), pp. 49-55. Potential savings in energy and materials are significant, but there are some obstacles.
Lundin, F.; J. Lloyd; J. Smith; E. Archer; and D. Holaday. 1969. "Mortality of uranium miners in relation to radiation exposure, hardrock mining and cigarette smoking 1950-1967". *Health Physics*, vol. 16, pp. 571-578.
Makhijani, A. 1976. "Solar energy and rural development for the Third World". *Bulletin of the Atomic Scientists*, vol. 32, no. 6 (June), pp. 14-24. A scientist now working in Indian villages describes possibilities for tailoring solar technologies to local needs.

-----; and A. Lichtenberg. 1971. *An assessment of energy and materials utilization in the U.S.A.* University of California, Electronic Research Laboratory, Berkeley, ERL-M310, revised. [Also published in slightly abridged form under the title, "Energy and well-being", *Environment*, vol. 14, no. 5 (September 1972).] A pioneering disaggregation of energy end uses in the United States, showing how much energy goes for major raw materials and for specific goods and services.

Marchetti, C. 1973. "Hydrogen and energy". In *Proceedings of IIASA planning conference on energy systems*. International Institute for Applied Systems Analysis, Laxenburg, Austria, Report PC-3. Useful survey of possible applications of hydrogen by an innovative advocate of the hydrogen economy.
-----. 1977. "Carbon dioxide and the problem of geoengineering". *Climatic Change*, vol. 1, no. 1.
Martin, J. E.; E. D. Harward; and D. T. Oakley. 1971. "Radiation doses from fossil-fuel and nuclear power plants". In *Power generation and environmental change*, D. Berkowitz and A. Squires, eds. M.I.T. Press, Cambridge, Mass. Study showing the radiation dose from a modern coal plant is 5 times greater than the dose from a pressurized-water reactor but 10,000 times less than that from a boiling-water reactor.
Masters, G. M. 1974. *Introduction to environmental science and technology*. Wiley, New York. Readable introductory text surveying population, mineral resources, energy, food, and air pollution. Coverage is strongest on technologies for pollution control.
Maugh, T. H., II. 1976. "Natural gas: United States has it if the price is right". *Science*, vol. 191, pp. 549-550 (February 13). Unconventional deposits would become exploitable if the price went up.
McCaull, J. 1973. "Windmills". *Environment*, vol. 15, no. 1. (January/February) pp. 6-17. History and contemporary prospects, dated somewhat by developments in a rapidly moving field.
McCulloh, T. H. 1973. "Oil and gas". In *United States mineral resources*, D. A. Brobst and W. P. Pratt, eds. Government Printing Office, Washington, D.C., Geological Survey paper 820. Solid treatment of geology and availability of oil and gas, written before the U.S. Geological Survey revised its estimates of U.S. resources downward.
McIntyre, H. C. 1975. "Natural uranium heavy-water reactors". *Scientific American*, October, pp. 17-27. Good description of heavy-water reactor technology.
McPhee, J. 1974. *The curve of binding energy*. Farrar, Straus, and Giroux, New York. A brilliant and frightening introduction to the link between nuclear power and nuclear bombs, written around a biographical sketch of one-time preeminent bomb designer Theodore Taylor.
Meinel, A. B., and M. P. Meinel. 1972. "Physics looks at solar energy". *Physics Today*, February, pp. 44-50. Introductory article emphasizing electric power generation.
-----. 1976. *Applied solar energy*. Addison-Wesley, Reading Mass. A detailed and thorough engineering text, covering availability of the resource, optics, and heat transfer with the comprehensiveness appropriate for those intending to become specialists in solarsystem design.
Merriam, Marshal. 1972. "Windmills for less developed countries". *Technos*, April/June, pp. 2-23. Excellent discussion of applications of windmills where they are most needed.
-----. 1977. "Wind energy for human needs". *Technology Review*, vol. 79, no. 3 (January), pp. 28-39.
Merrigan, J. A. 1975. *Sunlight to electricity*. M.I.T. Press, Cambridge, Mass. Good short text on photovoltaics.
Metz, W. D. 1976. "Fusion research: What is the program buying the country?" *Science*, vol. 192, pp. 1320-1323 (June 25). A perceptive progress report and critique of the U.S. fusion-research program.
-----. 1976. "Laser enrichment: Time clarifies the difficulty". *Science*, vol. 19, pp. 1162-

1163, 1193 (March 19). The laser approach appears more difficult and expensive than overoptimistic early estimates indicated.
-----. 1976. "Energy research: Accelerator builders eager to aid fusion work". *Science*, vol. 194, pp. 307-309 (October 15). Possible use of heavy-ion beams in place of lasers or electron beams to initiate fusion microexplosions. Also mentions link between classified inertial-confinement fusion work and fusion weapons design.
Metzger, P. 1972. *The atomic establishment*. Simon and Schuster, New York. Well written, critical history of the USAEC and the Joint Committee on Atomic Energy.
Miller, A. 1973. "A coal miner looks at the energy crisis". *The Center Magazine*, November/December, pp. 35-45. The head of the United Mine Workers expresses some perceptive views about strip-mining, reclamation, and other topics.
Morgan, K. Z. 1976. "Effects of radiation on man: Now and in the future". In *Energy and the environment: Cost benefit analysis*. R. A. Karam and K. Z. Morgan, eds. Pergamon, New York. One of the preeminent radiation health physicists in the world discusses reasons for continuing concern about radiation exposure in medicine and the nuclear industry.
Morrow, W. 1973. "Solar energy: Its time is near". *Technology Review*, vol. 76, no. 2, pp. 31-42. Excellent survey article covering thermal and electric applications of solar energy.
Morse, F. H., and M. K. Simmons. 1976. "Solar energy". In *Annual review of energy*, J. M. Hollander and M. K. Simmons, eds. Good status report on the various approaches. Excellent bibliography.
Mostert, Noel. 1974. *Supership*. Knopf, New York. Highly readable account of the hazards of supertankers by a talented journalist and environmentalist, who spent a long voyage researching the topic.
Moumoni, Abdou. 1973. "Energy needs and prospects in the Sahelian and Sudanese zones in Africa: Prospects of solar power". *Ambio*, vol. 2, no. 6, pp. 203-213. Useful example of analysis aimed at tailoring energy technologies to local resources and needs.
Naill, R. F.; D. L. Meadows; and J. Stanley-Miller. 1975. "The transition to coal". *Technology Review*, vol. 78, no. 1 (Oct./Nov.), pp. 18-29. Application of systems-dynamics computer modeling to explore U.S. energy options.
National Academy of Sciences (NAS). 1969. *Resources and man*. W. H. Freeman and Company, San Francisco. A sober and articulate analysis of the resource side of the human predicament -- food, energy, materials -- with a refreshing lack of waffling.
-----. 1972. *The effects on populations of low levels of ionizing radiation*. NAS, Washington, D.C. Still the most competent and comprehensive major study of effects on humans of prolonged exposure to low-level radiation.
-----. 1973. *An evaluation of alternative power sources for low-emission automobiles*. NAS, Washington, D.C. Part of the bookshelf of any specialist on the topic of alternative engines.

-----. 1974. *Rehabilitation potential of western coal lands*. Ballinger, Cambridge, Mass. This report to the Energy Policy Project of the Ford Foundation indicates that strip-mined lands in regions receiving an average of less than 10 inches of rainfall probably cannot be reclaimed at all.
-----. 1975. *Mineral resources and the environment*. NAS, Washington, D.C. A major NAS study focusing most heavily on mineral fuels -- oil, gas, coal, and uranium. Several important appendix volumes and a summary volume are available.
-----. 1975. *Air quality and stationary source emission control* Committee on Public Works,

U.S. Senate/Government Printing Office, Washington, D.C. Superb review of state-of-the-art of pollution control for power plants.
-----. 1976, *Energy for rural development: Renewable resources and alternative technologies for developing countries*. NAS, Washington, D.C. Very useful survey of technologies, suppliers, and research organizations, covering wind, hydropower, biomass, solar heat, solar-electric systems, geothermal energy, and energy storage.
-----. 1977. *Interim Report of the National Research Council Committee on Nuclear and Alternative Energy Systems*. NAS, Washington, D.C. Useful discussion of the characteristics of the U.S. energy problem, plus the suggestion that energy use as low as 74 trillion megajoules (70 quadrillion Btu) is conceivable for the U.S. in 2010.
National Council on Radiation Protection and Measurement. 1975. *Krypton-85 in the atmosphere: Accumulation, biological significance, and control technology*. NCRP Publications, Washington, D.C. July.
Nephew, E. A. 1973. "The challenge and promise of coal". *Technology Review*, vol. 76, no. 2 (Dec.), pp. 21-29. The best short survey article on the technology and environmental impacts of coal mining.
----- and R. L. Spore. 1974. "Coal mining and the environment". In *Energy conservation and the environment*. Oak Ridge National Laboratory, Tenn., ORNL-NSF-EP-77. Research summary emphasizing results of a major study of economic costs of reclaiming surface mined land in Appalachia.
Nero, Anthony V., Jr. 1976. *A guidebook to nuclear reactors*. University of California, Lawrence Berkeley Laboratory, report LBL-5206. Very useful compilation of reactor characteristics and specifications, accessible to the nonspecialist.
Newton, G. C., Jr. 1976. "Energy and the refrigerator". *Technology Review*, vol. 78, no. 3 (Jan.), pp. 56-63. Detailed look at refrigerator technology and the means available for increasing the efficiency of that appliance.
Nisbet, I. 1974. "Hydroelectric power: A nonrenewable resource?" *Technology Review*, vol. 76, no. 7 (June), p. 5. Addresses the worldwide problem of the silting up of reservoirs.
Norman, R. 1974. "Water salination: A source of energy". *Science*, vol. 186, pp. 350-352 (October 25). Considers recovery of that part of the energy in the hydrologic cycle that is spent by the sun in evaporating fresh water from the ocean. Concludes the energy would be expensive and the environmental impact in estuarine regions high.
Norton, J. J. 1973. "Lithium, cesium, and rubidium". In D. A. Brobst and W. P. Pratt, eds. *United States mineral resources*. Government Printing Office, Washington, D.C. One of only a few documents giving data on lithium resources (needed for deuterium-tritium fusion reactors).
NSF-NASA Solar Energy Panel. 1972. *An assessment of solar energy as a national energy resource*. National Technical Information Service, Springfield, Va. The first high-powered "official" study to conclude that solar energy could meet a significant fraction of the U.S. energy needs in the period 2000 to 2020.
Nuclear News. 1975. World list of nuclear power plants. Vol. 18, no. 10 (Aug.), p. 63. Locations, types, sizes, and start-up dates of plants in operation and under construction.
-----. 1974. "Nuclear process heat topical meeting". *Nuclear News*, vol. 17, no. 15 (Dec.), pp. 81-83. Surveys prospects for nonelectric industrial applications of the heat generated in nuclear reactors and finds them unencouraging for the near future.
-----. 1975. *Ten reactors currently do not have enough fuel storage*. Vol. 18, no. 6 (mid-

April), p. 64A.
Nuclear Regulatory Commission. See U.S. Nuclear Regulatory Commission.
Odum, H. T. 1971. *Environment, power, and society*. Wiley, New York. Ambitious attempt to view ecology and society in the same energy-centered framework. Ranges from obscure and overdrawn to brilliant.
Office of Emergency Preparedness (OEP), "Executive Office of the President of the United States". 1972. *The potential for energy conservation*. Government Printing Office, Washington, D.C. Solid, persuasive study by many talented contributors, showing how increased end-use efficiency could cut the energy growth anticipated between 1972 and 1985 in half. The OEP was disbanded by President Richard M. Nixon not long after this study was published.
Okrent, D., et al. 1974. *Estimates of risk associated with dam failure*. University of California, Los Angeles, report UCLA-ENG-7423. Suggests that sudden failure of dams upstream of major cities could cause thousands to hundreds of thousands of deaths per incident.
ORNL-NSF Environmental Program. 1974. *Energy conservation and the environment*. Oak Ridge National Laboratory, Tenn., ORNL-NSF-EP-77.
Oswald, W. 1973. "Ecological management of thermal discharges". *Journal of Environmental Quality*, vol. 2 (April/June), pp. 203-207. Use of the heat in power-plant discharges for agriculture.
Othmer, D., and O. Roels. 1973. "Power, fresh water, and food from cold, deep sea water". *Science*, vol. 182, pp. 121-125 (October 12). Potential harnessing of ocean thermal gradients.
Parker, F., and P. Krenkel. 1970. *Physical and engineering aspects of thermal pollution*. CRC Press, Cleveland. Detailed technical treatment for specialists.
Patterson, Walter C. 1976. *Nuclear power*. Penguin, Harmondsworth, UK. The best "environmentalist" introduction to nuclear power.
Perry, A. M., and A. M. Weinberg. 1972. "Thermal breeder reactors". *Annual review of nuclear science*, vol. 22, p. 317ff. Breeding and near-breeding in various thermal reactor designs.
Perry, H. 1970. "Environmental aspects of coal mining". In *Power generation and environmental change*, D. Berkowitz and A. Squires, eds. Introductory survey by a prominent specialist in fossil fuels.
-----. 1974. "Coal conversion technology". *Chemical Engineering*, vol. 81, no. 15 (July 22), pp. 88-102. Technical problems and potential of gasification and liquefaction of coal.
-----. 1974. "The gasification of coal". *Scientific American*, March, pp. 19-25. Readable introduction to gasification for power generation and industrial and domestic uses, with Scientific American's usual good diagrams.

Pierce, J. 1975. "The fuel consumption of automobiles". *Scientific American*, January, pp. 34-44. Excellent treatment of where the energy goes in an automobile-rolling friction, flexing tires, air drag, and so on-together with the prospects for improvements.
Pigford, T. 1974. "Environmental aspects of nuclear energy production". *Annual Review of Nuclear Science*, vol. 24, pp. 515-559. Quantitative look at the emissions from nuclear fuel cycles by a nuclear engineer who is highly respected both by critics and proponents of using nuclear power.

-----; M. J. Keaton; B. Mann; P. M. Cukor; and G. Sessler. 1974. *Fuel cycles for electrical power generation*, Pt. 1. Teknekron, Inc., Berkeley, Calif., Report EED 103. One of the major comparative studies of environmental impacts of electricity generation alternatives. Superb fuel-cycle diagrams.
Pimentel, D.; W. Dritschilo; J. Krummel; and J. Kutzman. 1975. "Energy and land constraints in food protein production". *Science*, vol. 190, pp. 754-761 (November 21). Argues that interlocking problems of land, water, energy, and environmental disruption severely limit the amount of protein that can be produced, making population control essential.
Pimentel, D.; L. Hurd; A. Bellotti; M. Forster; I. Oka; O. Sholes; and R. Whitman . 1973. "Food production and the energy crisis". *Science*, vol. 182, p. 443-449 (November 2). Traces energy use in U.S. production of corn in detail, and shows energy implications of adopting this style of agriculture in developing countries.
Poole, A. 1975. "The potential for energy recovery from organic wastes". In *The energy conservation papers*, R. H. Williams, ed., Ballinger, Cambridge, Mass. Authoritative and up to date.
Portola Institute. 1974. *Energy primer*. Portola Institute, Menlo Park, Calif. A splendid large-format guide to the literature of solar energy and energy conservation.
Post, R. F.; J. R. Morris; and F. J. Hooven. 1974. "Letters". *Scientific American*, March, pp. 8-10. Continuation of the flywheel discussions. (See below.)
Post, R. F.; and S. Post. 1973. "Flywheels". *Scientific American*, December, pp. 17-23. An intriguing look at how recent advances in highstrength materials may make an old idea for energy storage newly practical in transportation and electric-utility applications.
Post, R. F., and F. L. Ribe. 1974. "Fusion reactors as future energy sources". *Science*, vol. 186, p. 397-407 (Nov. 1). An optimistic progress report by prominent fusion researchers at the Livermore and Los Alamos laboratories.
Primack, J.; F. Finlayson; N. Rasmussen; R. Weatherwax; H. Kouts; F. von Hippel ; and H. Bethe. 1975. "Nuclear reactor safety". *Bulletin of the Atomic Scientists*, vol. 31, no. 7 (September), pp. 15-41. Views of critics and supporters of the Rasmussen report on reactor safety.
Pugwash Conference on Science and World Affairs. 1973. "Report of the working group on energy of the 23d conference". *Pugwash Newsletter*, Fall. [Reprinted in Congressional Record, Senate, vol. 119, pp. S18727-S8730 (October) and in Perspectives on energy. L. C. Ruedisili and M. W. Firebaugh, eds.] The Pugwash conferences are held annually by an international group of distinguished and influential scientists. A major topic of the 1973 meeting was nuclear energy. The summary report states "grave concern" over unresolved questions of reactor safety, radioactive waste management, and use of nuclear materials for bombs by countries or terrorists.
Ramseier, R. 1974. "Oil on ice". *Environment*, vol. 16, no. 4 (May), pp. 6-14. Possibility of oil spills in the Arctic and their effects on climate.
Rattein, S., and D. Eaton. 1976. "Oil shale: The prospects and problems of an emerging energy industry". In *Annual review of energy*, J. M. Hollander and M. K. Simmons, eds. Excellent coverage of environmental effects and economic obstacles.
Read, W.; A. Choda; and P. Cooper. 1974. "Solar timber kiln". *Solar Energy*, vol. 15, no. 4, pp. 309-316. One of many possible industrial applications of solar energy.
Resnikoff, M. 1975. "Expensive enrichment". *Environment*, vol. 17, no. 5 (July/Aug.), pp.

28-35. Notwithstanding the title (cryptically substituted for the author's descriptive one by the magazine's editors), this article deals with reprocessing of nuclear fuels -- the technical difficulties, the economic costs, the environmental impacts.
Resources for the Future. 1968. *U.S. energy policies: An agenda for research*. Johns Hopkins Press, Baltimore. Although dated in some respects by the events of the 1970s, this book offers a useful compilation of information about state and federal policies related to coal, oil, gas, uranium, and electricity, as they evolved from the 1930s through the 1960s.
Revelle, R. 1976. "Energy use in rural India". *Science*, vol. 192, pp. 969-975 (June 4). Villagers provide themselves far more energy from biological sources than they buy, but they use it ineffectively.
Reynolds, W. C. 1974. *Energy: From nature to man*. McGraw-Hill, New York. A well-written and absorbing introduction to energy technology aimed at college undergraduates outside engineering.
Rice, R. 1972. "System energy and future transportation". *Technology Review*, vol. 74, no. I (January), pp. 31-37. Energy intensity of alternative modes of moving people and freight. One of the basic references in the field.
-----. 1974. "Toward more transportation with less energy". *Technology Review*, vol. 76, no. 4 (Nov.), pp. 44-53. Outlines a scenario for the year 2000 in which the United States obtains far more passenger miles and ton miles than in the 1960s with less energy.
Rieber, M. 1973. "Low sulfur coal: A revision of reserve and supply estimates". *Genter for Advanced Computations, Document* 88. University of Illinois, Champaign-Urbana. Revises downward the accepted estimates of U.S. reserves of low-sulfur coal by correcting for the low energy content per pound of many Western coals.
Rochlin, G. I. 1977. "Nuclear waste disposal: Two social criteria". *Science*, vol. 195, pp. 23-31 (January 7). A penetrating look at questions of irreversibility and other aspects of the technical/ethical dilemma of radioactive wastes.
Rose, D. J. 1974. "Nuclear eclectic power". *Science*, vol. 184, pp. 351-359 (April 19). The case for a major role for nuclear fission by an articulate proponent.
----- and M. Clark. 1961. *Plasmas and controlled fusion*. M. I.T. Press, Cambridge, Mass. Classic text on harnessing fusion by means of magnetic confinement.
----- and M. Feiertag. 1976. "The prospect for fusion". *Technology review*, vol. 79, no. 2 (December), pp. 20-43. A critical review.
Ross, M., and R. Williams. 1977. "The potential for fuel conservation". *Technology Review*, vol. 79, no. 4 (February), pp. 48-57. A useful summary of recent patterns of energy use in the United States and of the potential for greater efficiency.
Rotty, R. M.; A. M. Perry; and D. B. Reiser. 1975. *Net energy from nuclear power*. Institute for Energy Analysis, Oak Ridge, Tenn., IEA report 75-3. Probably the most comprehensive study to date of this question; concludes even light-water reactors using Chattanooga shales turn an energy profit.

Rubin, M. 1974. "Plugging the energy sieve". *Bulletin of the Atomic Scientists*, vol. 30, no. 10 (December), pp. 7-17. Survey of potential for more-efficient end use of energy.
Ruedisili, L. C., and M. W. Firebaugh, eds. 1975. *Perspectives on energy*. Oxford University Press, New York. Collection of articles emphasizing sources of energy supply. A mixed bag, useful for its variety of viewpoints and a considerable number of good pieces resurrected from obscure publications.

Scherer, H. N., and B. J. Ware. 1975. "The impact of high voltage lines". *Bulletin of the Atomic Scientists*, vol. 31, no. 7 (Sept.), pp. 51-52.
Schipper, L. 1975. *Energy conservation: Its nature, hidden benefits and hidden barriers*. Energy and Resources Group, University of California, Berkeley, ERG 75-2. Excellent introduction to the potential of more efficient energy use.
----- and A. Lichtenberg. 1975. "Efficient energy use and well-being: The Swedish example". *Science*, vol. 194, pp. 1001-1013. Careful analysis of energy use in the U.S. and Swedish economics, showing exactly where greater efficiencies enable Swedes to extract more well-being per unit of energy than do Americans.
Schoen, R.; A. S. Hirshberg; J. M. Weingart; and J. Stein. 1975. *New energy technology for buildings*. Ballinger, Cambridge, Mass. Prepared for the Energy Policy Project of the Ford Foundation, this report emphasizes solar technology for buildings and the economic and institutional barriers to its implementation.
Schumacher, E. F. 1973. "Western Europe's energy crisis: Problem of life-styles". *Ambio*, vol. 2, no. 6, pp. 228-232. The guru of intermediate technology applies his thinking to Europe's energy dilemma.
-----. 1976. "Patterns of human settlement". *Ambio*, vol. 5, no. 3, pp. 91-97. Connection between settlement patterns and energy use.
Science and Public Policy Program, University of Oklahoma. 1975. *Energy alternatives: A comparative analysis*. Government Printing Office, Washington, D.C. Comprehensive although somewhat unwieldy comparison of energy-supply alternatives, with extensive bibliographies.
Scientific American. 1971. *Energy and power*. Freeman and Company, San Francisco. Collection of articles from the September 1971 Scientific American. The best are those by Hubbert, Cook, Summers, Luten, and Tribus and McIrvine.
Seaborg, G. T. 1970. *Nuclear milestones*. W. H. Freeman and Company, San Francisco. A personal history of the nuclear age; by its nature uneven in coverage, but still informative.
Sellers, W. D. 1965. *Physical climatology*. University of Chicago Press. Good basic text.
Shapley, Deborah. 1971. "Plutonium: Reactor proliferation threatens a black market". *Science*, vol. 172, pp. 143-146 (April 9). Short discussion of the growing threat of theft of fissile material for bombs as reactors spread.
Shurcliff, W. A. 1976. "Active-type solar heating systems for houses: A technology in ferment". *Bulletin of the Atomic Scientists*, vol. 32, no. 2 (Feb.), pp. 30-40. Up-to-date survey.
Singer, S. F. 1975. "Oil resource estimates". *Science*, vol. 188, p. 401 (May 2). A critique of the estimation procedures employed by M. K. Hubbert and the Committee on Mineral Resources and the Environment of the National Academy of Sciences.
Smith, C. 1972. "Shipment and reprocessing of irradiated power reactor fuels". In *Education and research in the nuclear fuel cycle*, D. Elliott and L. Weaver, eds. Good technical description of the reprocessing technology in place in the 1960s.
Smith, K.; J. Weyant; and J. P. Holdren. 1975. *Evaluation of conventional power systems*. University of California, Berkeley, Report ERG75-7. Detailed survey of economic and environmental costs of electricity generation with coal, oil, gas, and nuclear fission.
Socolow, R. H. 1977. "The coming age of conservation". *Annual Review of Energy*, vol. 2. An international perspective on prospects for conservation.
Sørenson, B. 1975, "Energy and resources". *Science*, vol. 180, p. 255-260 (July 25). A

scenario for supplying Denmark's energy needs with wind and sunlight.
Speth, J. G.; A. R. Tamplin; and T. B. Cochran. 1974 ". Plutonium recycle: The fateful step". *Bulletin of the Atomic Scientists*, vol. 30, no. 9, pp. 15-22. The case against permitting the recycle of plutonium as fuel for light-water reactors.
Spinrad, B. 1971. "The role of nuclear power in meeting world energy needs". In *Environmental aspects of nuclear power stations*, International Atomic Energy Agency, Vienna. Forecasts high global growth of electricity use and a dominant role for nuclear energy in providing the electricity.
Squires, A. M. 1974. "Clean fuels from coal gasification". *Science*, vol. 184, pp. 340-346 (April 19). Good review article by a prominent coal enthusiast.
-----. 1972. "Clean power from dirty fuels". *Scientific American*, October, pp. 26-35. Emphasizes use of coal in gas turbine/steam turbine combined-cycle power stations.
Stauffer, T. 1974. "Oil money and world money: Conflict or confluence?" *Science*, vol. 184, p. 321-325 (April 19). This assessment of the economic impact of the 1973/1974 oil embargo finds it smaller than many accounts.
Stein, R. 1972. "A matter of design". *Environment*, vol. 14, no. 8 (October), pp. 16-29. Identifies significant opportunities for energy conservation in the construction and operation of commercial buildings.
Steinhart, J. 1975. "The impact of technical advice on the choice for nuclear power". In *Perspectives on energy*, L. C. Ruedisili and M. W. Firebaugh , eds. A critical and penetrating analysis that deserves much wider readership.
----- and Steinhart, C. 1974. "Energy use in the U.S. food system". *Science*, vol. 184, pp. 307-316 (April 19). History of increasing use of energy in the growing and processing of food.
Stewart, R. J. 1976. "Oil spills and offshore petroleum". *Technology Review*, vol. 78, no. 4 (February), pp. 46-59. Data and analysis of experience and prospects with respect to oil spills.
Summers, C. 1971. "The conversion of energy". *Scientific American*, September, pp. 148-160. (Reprinted in Energy and power, Scientific American, ed., W. H. Freeman and Company, San Francisco, 1971.) Capsule introduction to technological aspects of energy conversion.
Szego, G.; and C. Kemp. 1973. "Energy forests and fuel plantations". *Chemtech*, May, pp. 275-284. Proposal to use fast-growing pine or eucalyptus trees as fuel for power-plant boilers.
Tamplin, A., and T. Cochran. 1974. *Radiation standards for hot particles*. National Resources Defense Council, Washington, D.C. Proposes lowering the standard for the permissible lung burden of plutonium particles by roughly 100,000 times, based on the hypothesis that doses delivered locally by small "hot" particles are more dangerous than uniformly-distributed doses of equal energy.
Taylor, T. B. 1973. "Diversion by non-governmental organizations". In *International safeguards and nuclear industry*, M. Willrich, ed. Johns Hopkins Press, Baltimore. A look at nuclear theft by subnational groups, by a preeminent authority on nuclear weapons.

Taylor, T. B. 1975. "Nuclear Safeguards". *Annual Review of Nuclear Science*, vol. 25, pp. 407-421. The best short treatment of the technical basis for concern that small groups could produce nuclear bombs with stolen nuclear materials.

Theobald, P. K.; S. P. Schweinfurth; and D. C. Duncan. 1972. *Energy resources of the United States*. Government Printing Office, Washington, D.C., Geological Survey circular 650. Summary of the U.S. Geological Survey position before its estimates of U.S. gas and oil were revised sharply downward in 1975.
Thorndike, E. H. 1976. *Energy and environment: A primer for scientists and engineers*. Addison-Wesley, Reading, Mass. Good intermediate-level text.
Total Environmental Action. 1975. *Solar energy home design in four climates*. Total Environmental Action, Harrisville, N.H. A guide for the serious builder.
Tybout, R. and Löf, G. 1970. "Solar house heating". *Natural Resources Journal*, vol. 10, no. 2 (April), pp. 268-326. A classic paper in the contemporary literature of solar energy, showing that solar heat could compete with electric resistive heating in sunny parts of the United States.
United Nations. *Annual. Statistical yearbook*. U.N. Publications, New York. This is the basic reference for our international energy-use statistics.
-----. 1967. *Utilization of oil shale*. U.N. Publications, New York. Summarizes early experience in oil-shale utilization in the USSR and elsewhere.
U.S. Atomic Energy Commission (USAEC) "Annual". *The nuclear industry*. Government Printing Office, Washington, D.C., WASH 1174-73. The 1973 volume, in particular, is useful for its treatment of the status of the uranium industry and for updates on other unglamorous aspects of the fuel cycle.
-----. 1957. *Theoretical possibilities and consequences of major accidents in large nuclear power plants*. Government Printing Office, Washington, D.C., WASH-740. Much-quoted early study of the consequences of a hypothetical accident at a small power reactor. Gives a worst case of 3400 early fatalities, an event the study deems to have low but unspecified probability.
-----. 1964/ 1965. *WASH-740 update file*. USAEC, Public Documents Room, Washington, D.C. An update of the 1957 reactor-safety study was begun in 1964 but aborted after preliminary results had indicated higher casualty estimates than the earlier study.
-----. 1970. *Potential nuclear power growth patterns*. Government Printing Office, Washington, D.C., WASH-1098. Dated forecasts, but useful for the detailed descriptions of the characteristics of various reactor designs and fuel mixes, and for estimates of low-grade uranium resources.
-----. 1972. *Contaminated soil removal facility: Richland, Washington*. National Technical Information Service, Springfield, Va., WASH1520. Describes some of the problems that have developed in the handling of radioactive wastes from military programs.
-----. 1972. *Elk River dismantling: Environmental statement*. National Technical Information Service, Springfield, Va., WASH-1516. One of the few available documents that deals with decommissioning nuclear reactors at the end of their operating lifetimes.
-----. 1973. *Nuclear fuel resources and requirements*. Government Printing Office, Washington, D.C., WASH-1243.
-----. 1973. *The safety of nuclear power reactors and related facilities*. National Technical Information Service, Springfield, Va., WASH1250. An uneven but in some respects very useful compendium of information about light-water reactors, radiation, waste-handling, regulations, and related topics.
-----. 1974. *Environmental impact statement on the liquid metal fast breeder reactor program*. Government Printing Office, Washington, D.C., WASH-1535. Prepared after a

successful environmentalist lawsuit demanded a programmatic (as opposed to reactor-byreactor) impact statement, this controversial document slights plutonium problems and unresolved questions about breeder safety, but contains considerable valuable information about nonnuclear alternatives.
-----. 1974. *Environmental survey of the nuclear fuel cycle*. National Technical Information Service, Springfield, Va., WASH-1248. An official look at emissions, water use, land use, and so on, emphasizing steps in the fuel cycle other than the reactor itself.
-----. 1974. *Generic environmental impact statement: Mixed-oxide fuel*. National Technical Information Service, Springfield, Va., WASH1327, draft. Controversial, and certainly incomplete, discussion of the consequences of plutonium recycle for light-water reactors.
-----. 1974. *High-level radioactive waste management alternatives*. National Technical Information Service, Springfield, Va., WASH1297. A generally even-handed and data-rich assessment of the known options for managing nuclear wastes.
-----. 1974. *Management of commercial high-level and transuranium contaminated radioactive waste*. USAEC Washington, D.C., WASH-1539 draft. Scandalously incomplete and incompetent environmental impact statement, deplored publicly by environmentalists and privately by nuclear industry trade associations.
-----. 1974. *Nuclear power growth 1974-2000*. Government Printing Office, Washington, D.C., WASH-1139(74). Forecast of an expanding role for nuclear power through the year 2000, although at a slower rate than euphoric earlier forecasts.
-----. 1974. *Reactor safety study*, 12 vols. Government Printing Office, Washington, D.C., WASH-1400 draft. Draft of the so-called Rasmussen report on the safety of light-water reactors. Badly organized, carelessly printed, needlessly tedious, and systematically overoptimistic. Some of the errors were remedied in the final draft (see U.S. Nuclear Regulatory Commission, *Reactor safety study*), but new errors were introduced.
-----. 1974. *Solar energy: A bibliography*. National Technical Information Service, Springfield, Va. Very useful and comprehensive guide to the literature.
-----. 1974. "A special safeguards study (the Rosenbaum report)". *Congressional Record*, April 30, 974, pp. S 6621-6630. High-level study revealing shocking gaps in U.S. safeguards against theft of nuclear materials.
U.S. Congress, House of Representatives, Committee on Science and Technology. 1975. *ERDA Authorization Hearings: Part 1, 1976 and transition period conservation*. Government Printing Office, Washington, D.C. Notable for its inclusion in full of the American Physical Society study, Efficient use of energy, pt. 1.
U.S. Congress, Joint Committee on Atomic Energy (JCAE). 1969 and 1970. *Hearings on environmental effects of producing electric power*, pts. 1 and 2. Government Printing Office, Washington, D.C. Extensive coverage of environmental effects of coal and nuclear fission.

CHAPTER 9
Materials

The idea that we are moving into a world of absolutely secure and effortless abundance is nonsense.

-- Kenneth Boulding, 1970

Materials discussed in this chapter include nonfuel mineral resources, forest products, natural and artificial fibers, and some other chemicals; excluded (except for occasional purposes of comparison) are fuels, foods, and drugs.

The world situation with respect to materials has many similarities to the energy situation. The near-term difficulties arise not so much from "running out" in an absolute sense as from the rising environmental costs of mobilizing and using ever larger quantities, from the economic and social dislocations that result from substituting one class of resources for another, and from the political ramifications of the nonuniform geographical distribution of resources and the capacity to exploit them.

In the longer term, the question of scarcity looms larger. It is sometimes asserted that, since our planet is quite literally made of materials, and since, with negligible exceptions, these do not leave the planet but remain here even after use, civilization can never run out of them. Although this assertion is true in a narrow sense, it misses the real issues. For "nonrenewable" resources, such as chromium and mercury, exhaustion occurs in the practical sense when the remaining unexploited material and the dispersed used material are so dilute that concentrating them simply

costs too much in dollars, energy, or environmental disruption. "Too much" in this context means that the benefits of having the concentrated material do not match the costs of getting it. [1] For "renewable" resources, such as wood or cotton, the question is what levels of population and consumption per person can be supported by the sustainable yield. A

[1] An excellent exposition of this point is given by Earl Cook, *Limits to exploitation of nonrenewable resources*.

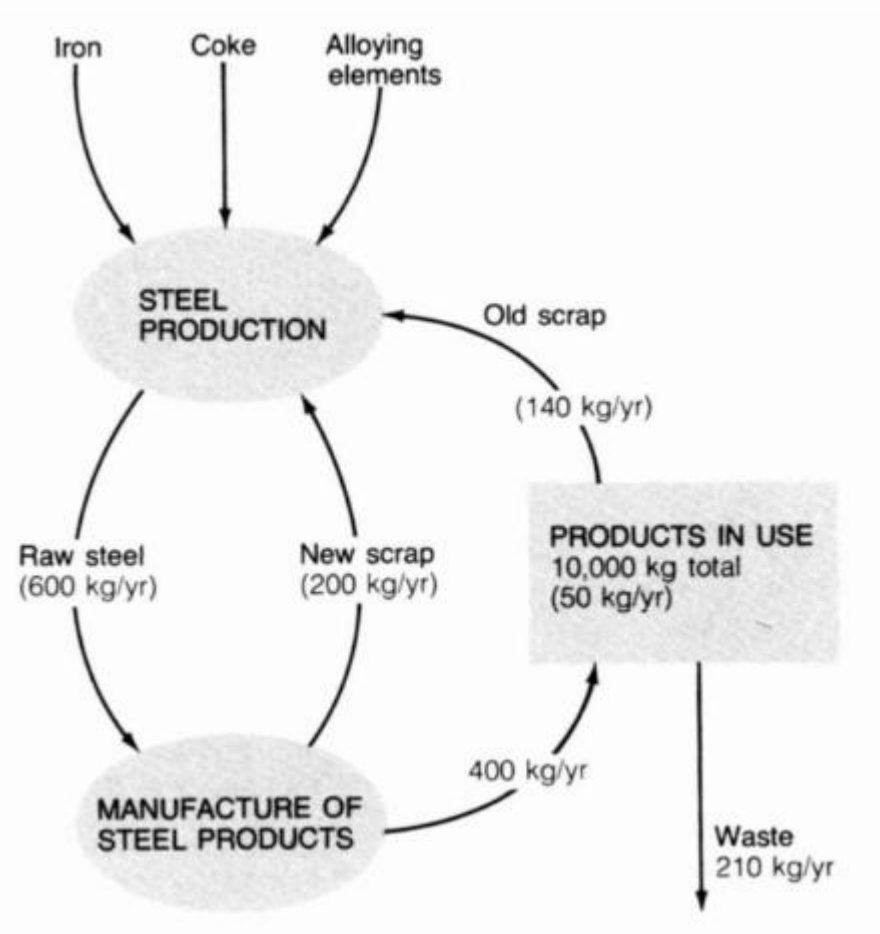

FIGURE 9-1
Stock and flow of steel in the United States, per capita. There is an annual increase in the stock corresponding to about 0.5 percent. The average residence time of steel in the economy is about 29 years. (After Garrels et al, 1975.)

TABLE 9-1 Amount and Value of Materials Flows in the United States in 1972, per Inhabitant

Material	Flow (kilograms per person per year)	Value (dollars per person per year)
Sand and gravel	4100	5.47

Material	Flow (kilograms per person per year)	Value (dollars per person per year)
Stone	3900	5.94
Petroleum	3500	85.10
Natural gas	2300	18.97
Coal	2300	17.07
Forest products	1250	20.00
Iron and steel	550	24.43
Cement	360	6.55
Clays	270	1.26
Salt	200	1.66
Natural fibers and oils	23	15.00
Aluminum	23	12.40
Copper	11	8.06
Lead	7	1.26
Zinc	7	2.07
Natural rubber	5	1.40
All other metals	16	7.69
All other nonmetals	550	1.57
	---	---
Totals	19,300	236.75

Note: Fuels are included for comparison. Values are 1972 prices in 1972 dollars.

Source: National Commission on Materials Policy, *Material needs and the environment today and tomorrow*.

"sustainable" yield must be consistent with other demands on land, water, sunlight, human labor and the other inputs to production; and the level of environmental disruption it entails must be neither intolerable nor growing.

It needs to be emphasized that achievable and sustainable levels of renewable materials production are different concepts. What might be achieved only with the assistance of nonrenewable inputs (say, concentrated phosphate inputs for high-yield crop production) is, in the long term, not sustainable.

MATERIALS USE: FLOWS AND STOCKS

Most data published on use of materials refer to annual production or flow -- for example, tons of iron per year or cubic meters of wood per year. Less frequently tabulated but very important is the stock of material in service -- for example, the total tonnage of steel tied up in the artifacts of

civilization (buildings, vehicles, railways, etc.). As with materials balances encountered in other applications, the flow equals the stock divided by the average lifetime of the material in use ("residence time"), if the stock is constant in size.

The relation between stock and flow for steel in the United States is indicated schematically in Figure 9-1. The stock of steel in products in use is about 17 times the annual production and about 25 times the actual annual increase in the stock. The difference between production and input to stock is "new scrap": trimmings, shavings, and so on, which are recycled as feed to the steelproduction process. "Old scrap" is material recycled for the production of new steel following use as manufactured products.

Patterns of Supply and Use in the United States

Table 9-1 shows the amounts of materials mobilized per person (flows) in the United States in 1972, together with the value of these materials in 1972 dollars. Fuels are included for comparision, and amount to 42 percent

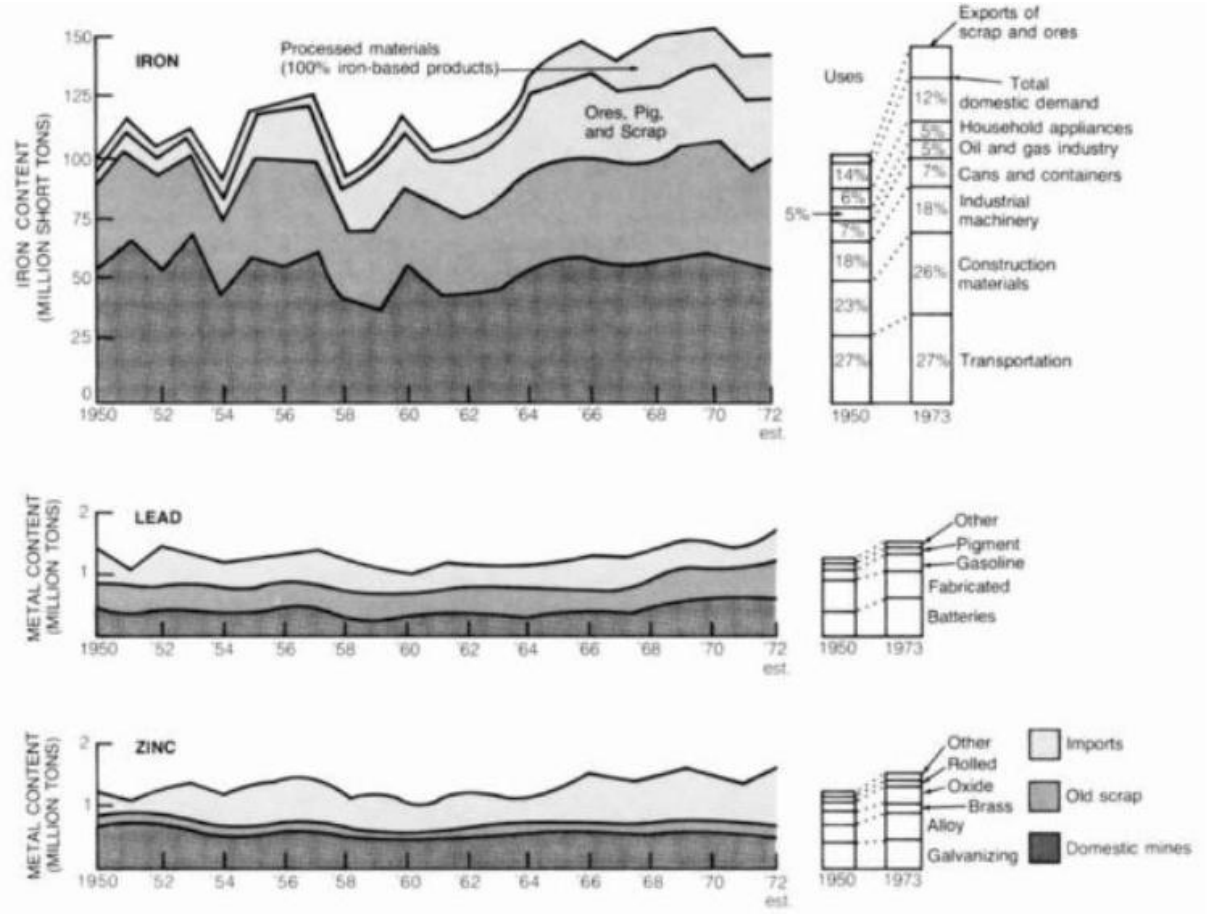

FIGURE 9-2
Supplies and uses of iron, lead, and zinc in the United States, 1950-1972. (Data from National Commission on Materials Policy, 1973.)

of the mass and 51 percent of the value of the totals shown. (Note that the prices are pre-oil-embargo: the figure given in Table 9-1 for petroleum corresponds to $3.33 per barrel, roughly a fourth of the price three years later. The increase between 1972 and 1975 in the "value" of the oil alone exceeds the total value in 1972 for all the materials shown).

About a fourth of the value of the materials mobilized in the U.S. in 1972 was accounted for by metals. [2] The history of the sources and uses of the five most important ones -- iron and steel (counted as one), aluminum, copper, lead, and zinc -- from 1950 to 1972 is depicted graphically in Figures 9-2 and 9-3. Except for aluminum, the upward trend in annual use has been gradual. The impression that much of the industrial growth taking place in this period has been based on the use of newer, lighter materials in place of the traditional metals is reinforced by the data for plastics shown in Figure 9-4. Note that the mass of plastics being produced in the early 1970s already exceeded that of aluminum, copper, lead, and zinc combined. The continuing dominant role of iron and steel among industrial materials should not be underestimated, however. The growth between 1950 and 1972 in the tonnage of iron flowing into the U.S. economy (from 100 to 140 million tons per year) exceeds by a factor of more than two the total tonnage of flow of aluminum and plastic combined in 1972.

Use of the traditional construction materials, sand, gravel, and crushed stone, more than tripled in the United States between 1950 and 1972, as shown in Figure 9-5. These represent ten times the bulk of all the metals used, and hence are among the best indicators of the size of society's large-scale environmental transformations. Supplies of fertilizers, an index of the size of perturbations in natural nutrient cycles, are shown for the U.S. between 1950 and 1972 in Figure 9-6.

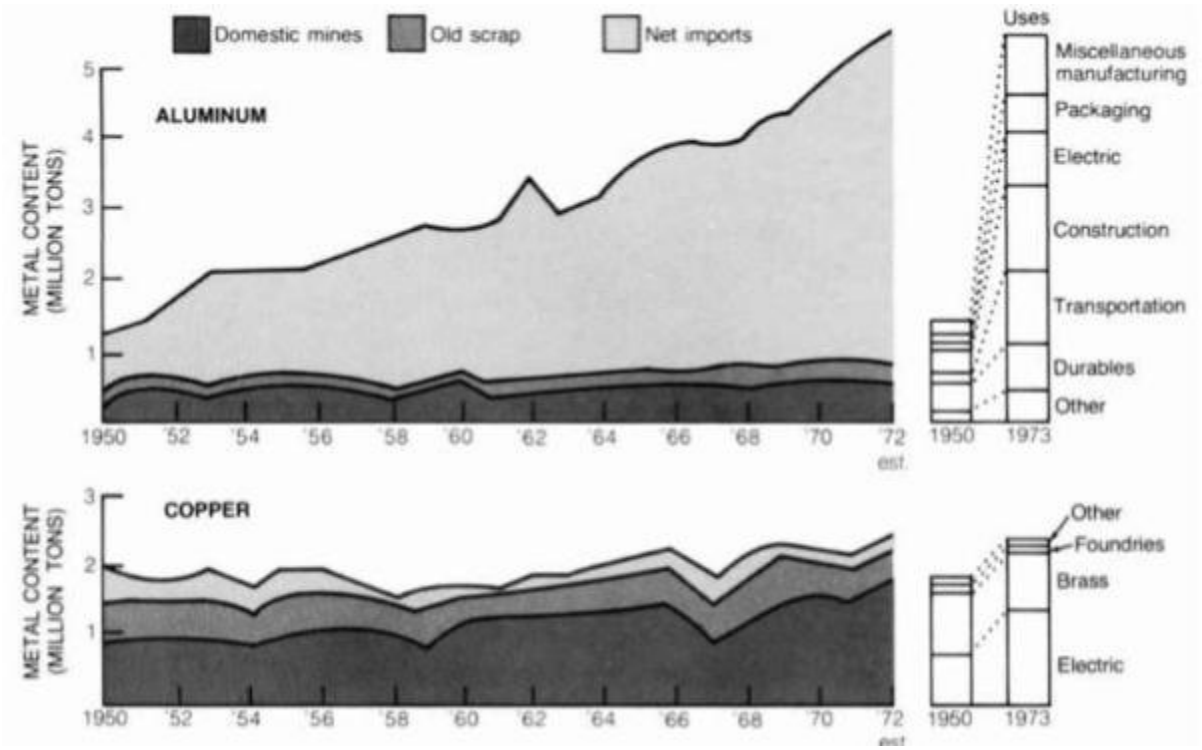

FIGURE 9-3

Supplies and uses of aluminum and copper in the United States, 1950-1972. Aluminum substitutes for copper in many electric applications, and for steel in construction, transportation, and packaging. (Data from National Commission on Materials Policy, 1973.)

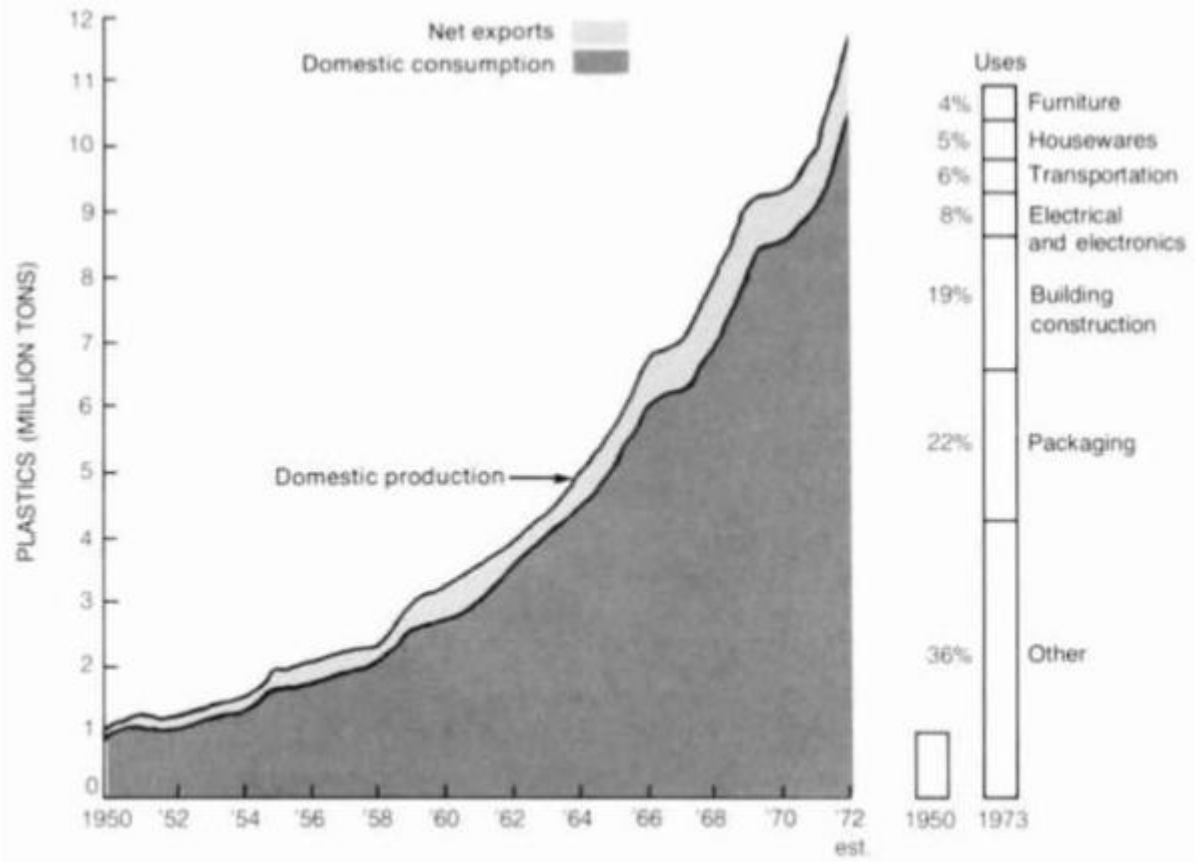

FIGURE 9-4

Supplies and uses of plastics in the United States, 1952-1972. Most plastics are derived from natural gas or petroleum. (Data from National Commission on Materials Policy, 1973.)

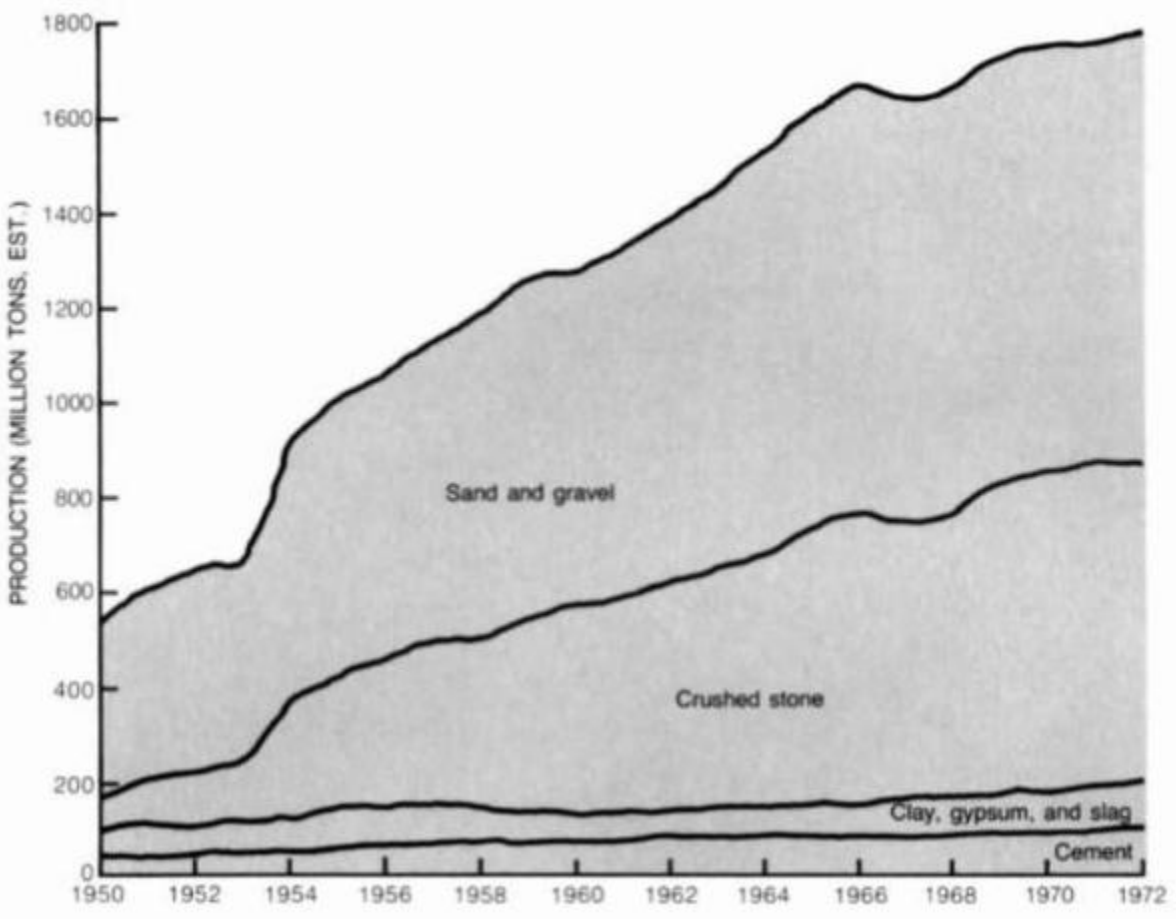

FIGURE 9-5
Supplies of nonmetallic construction materials in the United States, 19501972. (Data from National Commission on Materials Policy, 1973.)

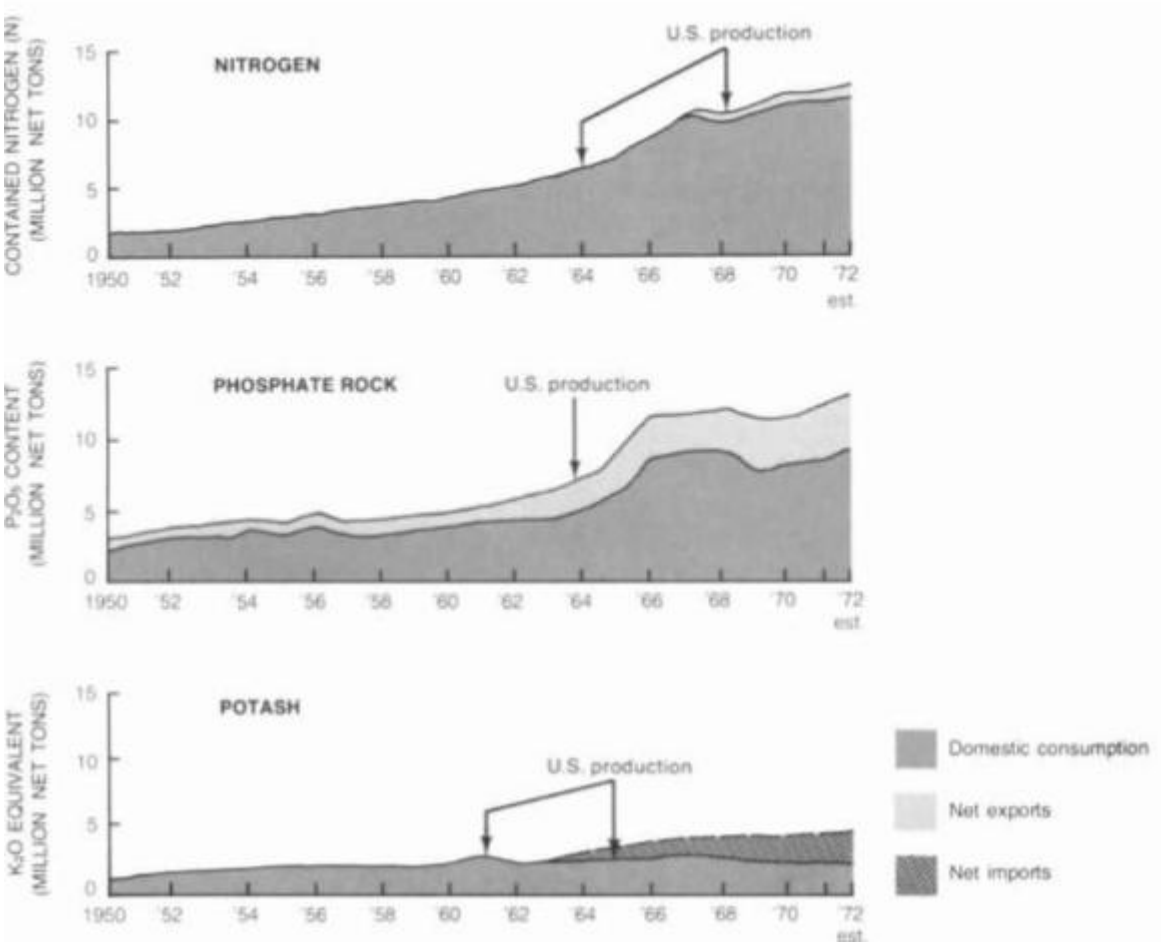

FIGURE 9-6
Supplies of fertilizers in the United States, 1950-1972. (Data from National Commission on Materials Policy, 1973.)

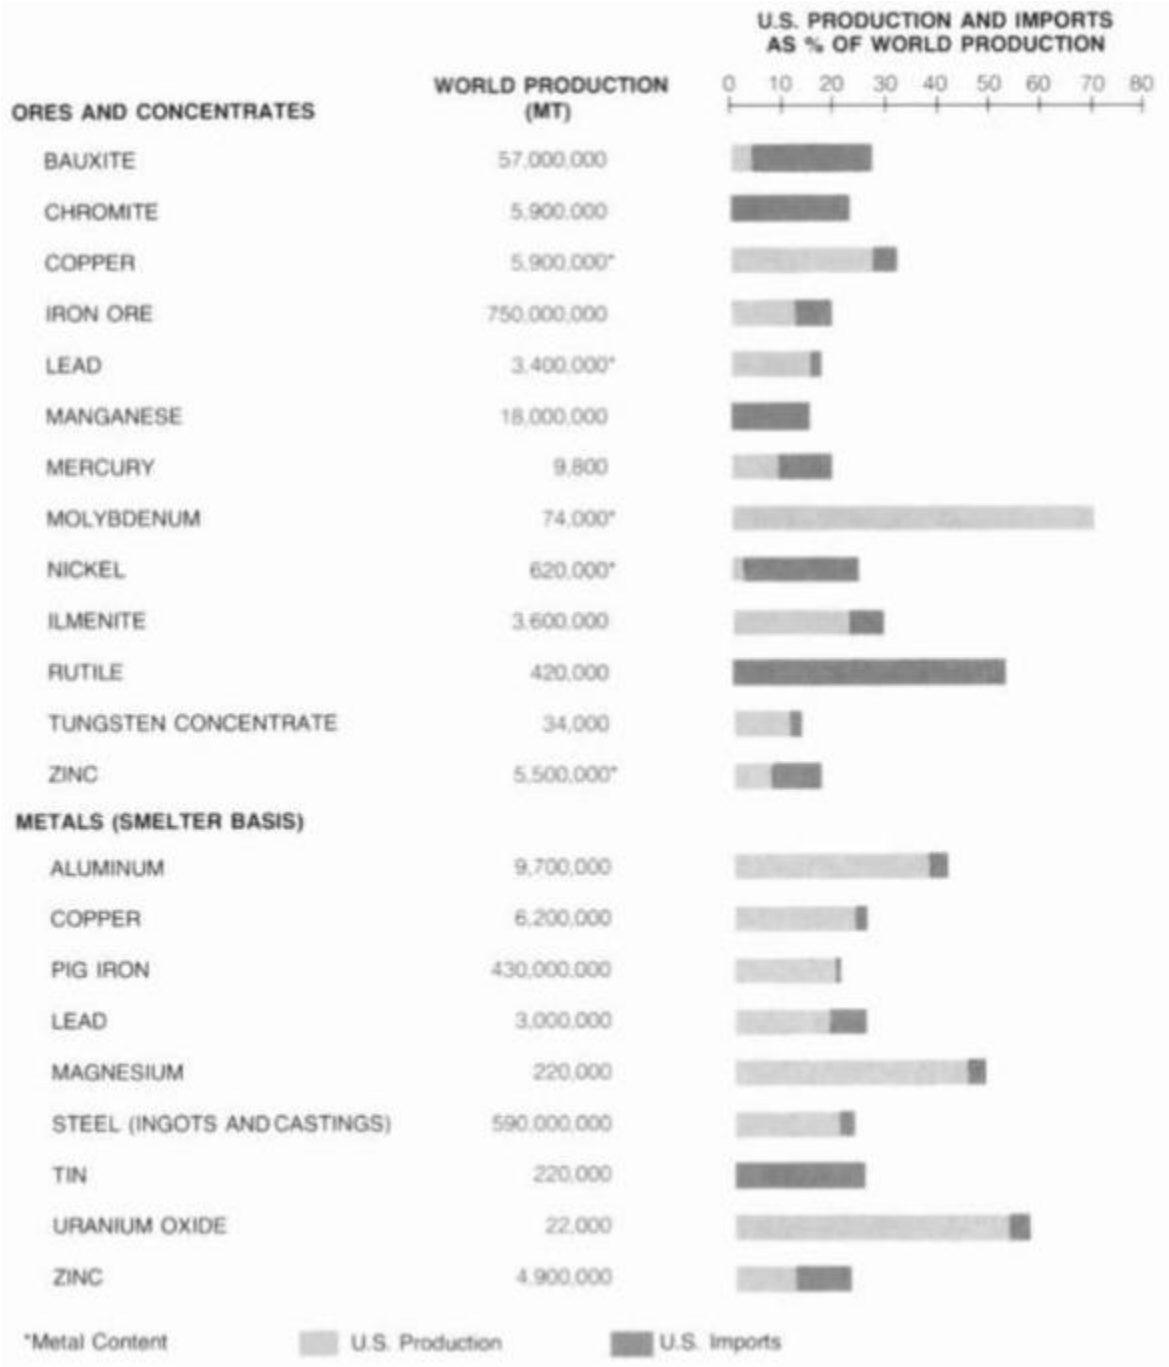

FIGURE 9-7
U.S. production and imports as a fraction of world production for selected materials, 1970. (Data from National Commission on Materials Policy, 1973.)

Materials Supply Worldwide

The share of worldwide use of materials accounted for by the United States, based on an index of 31 of the most important metals, nonmetals, and mineral fuels, fell from nearly 50 percent to around 32 percent between 1950 and 1972. [3] This decline in U.S. dominance was due not to the

poor countries gaining in affluence and increasing their use of materials, but rather to medium-rich regions -eastern and western Europe, the Soviet Union, Japan -growing richer.

The sizes of U.S. material production and imports as fractions of world production are indicated for some important minerals in Figure 9-7. If figures for consumption in Europe, the Soviet Union, and Japan are added to the U.S. figures for these materials, the total in most cases would reach 85 or 90 percent. The extent of U.S. dependence on imports for its supply of a larger variety of materials is shown in Figure 9-8, together with the countries from which the bulk of the imports come.

What do these data mean? Concern about the size of the U.S. share of world consumption and about the fraction of this share that is imported takes several forms.

[3] Ibid., pp. 2-15.

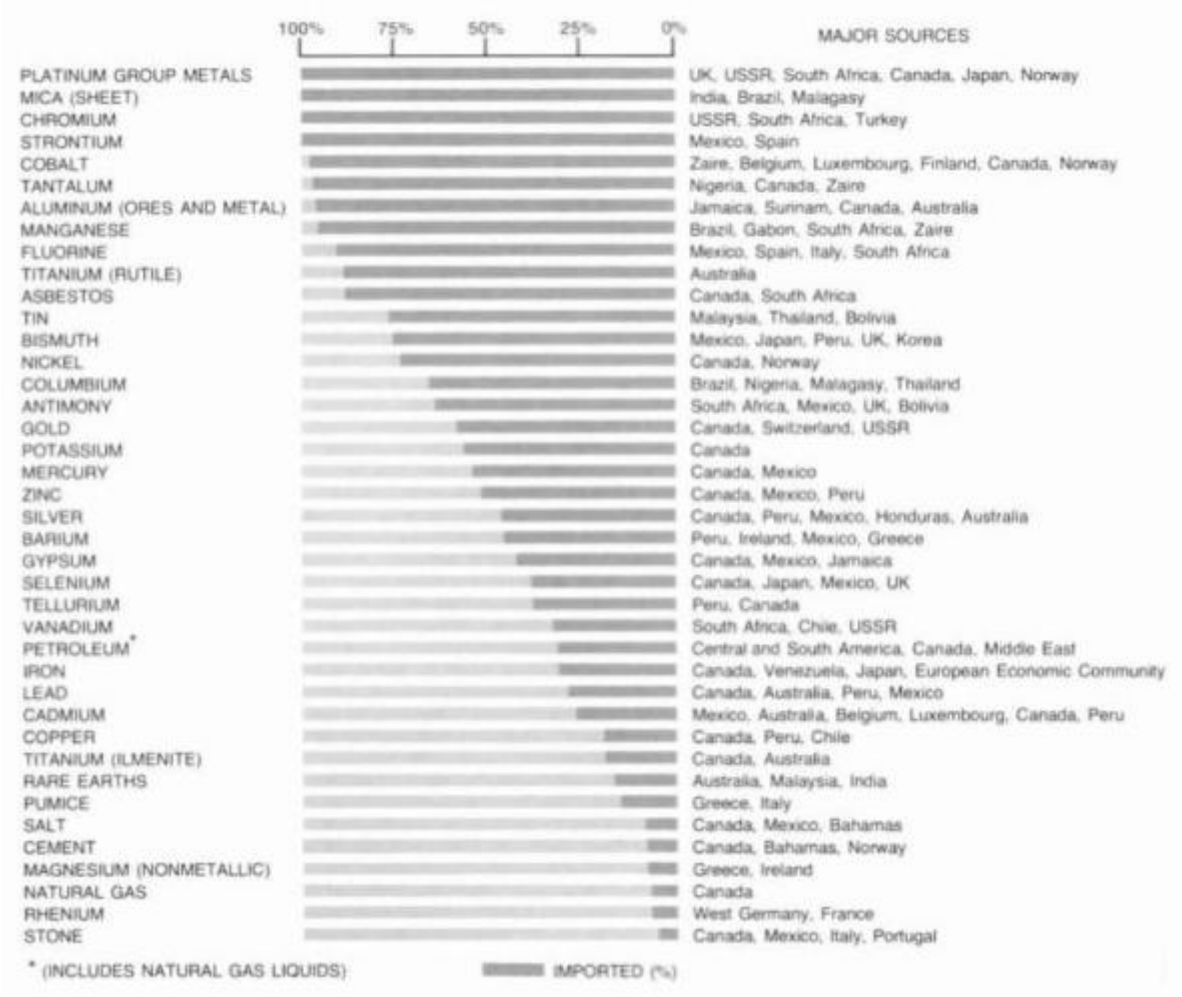

FIGURE 9-8
Percentage of U.S. mineral requirements imported in 1972. (Data from National Commission on Materials Policy, 1973.)

Is it equitable for so small a fraction of the world's population to consume so much? Are the aspirations of the poor countries compromised by the outflow of their richest mineral resources, or would they be compromised even more by a reduction of the flow of money (or the goods they buy with it) in the opposite direction? Can the United States (or other developed countries) afford the dollar outflow associated with rising dependence on imports? At what degree of dependence on imports does a nation's vulnerability to politically motivated embargos become too high a price to pay?

Most economists would argue that there is no problem of equity as long as the United States pays for what it uses; other countries sell what they have and use the proceeds to buy what they need (such as food from the U.S.). Such interdependence need be neither unfair nor threatening. Indeed, interdependence may be stabilizing. A counterargument is that until recently the world market prices of raw materials produced in the poor countries were held unduly low by means of the economic and political power of the DC consumers. The economies of the rich countries flourished on the cheap raw materials provided by the poor countries, who had little to show for the transaction. Regardless of one's

TABLE 9-2 Requirements for 4 Billion Newcomers at U.S. per capita Stock of Metals

Metal	1970 U.S. stock per capita (kilograms)*	Requirement for 4 billion people (million MT)	1972 world production (million MT)**
Steel	10,000	40,000	625
Copper	150	600	5.9
Lead	150	600	3.4
Aluminum	125	500	9.7
Zinc	100	400	4.9

* Harrison Brown, *Human materials*.

** U.S. National Commission on Materials Policy, *Material needs*.

viewpoint on the history of this situation, it is clear that LDC holders of mineral resources of various kinds are watching with intense interest the results of the OPEC experiment in drastically raising the price of oil. [4]

A longer view of the resource situation in international terms must take account of the fact that the real costs of resource extraction will increase as the deposits of highest quality become depleted. If the high-grade deposits possessed by countries now poor are sold to rich countries in exchange for short-term cash flow, these poor countries may find in a few decades that materialsintensive industrial development in a world of sharply increased materials costs is

simply beyond their economic reach, regardless of how cleverly they have invested the funds won from the sale of the last low-cost materials on Earth.

The strictly physical aspects of the dynamics of the rich-poor gap in use of energy and materials have been examined by Harrison Brown, whose intriguing diagram illustrating the development of that gap is reproduced in Figure 15-1. [5] Brown has emphasized elsewhere that the gap between rich and poor countries in stocks of materials is a more realistic measure of the differences in prosperity than are the flows on which most comparisons rest. [6] That is, for example, the 10,000 kilograms of steel per person in use in the United States is a better index of prosperity than the 600 kilograms per person per year that is added to the stock and replaces losses. Brown calculates that raising the 1970 world population to the 1970 per-capita stock of major metals characteristic of the ten richest nations would require more than 60 years' output of the world's mines (at 1970 production levels), ignoring continuing demands in the rich countries and all losses everywhere.

Let us look at the problem another way. How much material would it take to provide the next 4 billion inhabitants of the world with the per-capita stock of steel, copper, lead, aluminum, and zinc that the U.S. had around 1970? The numbers are given and compared with recent world production of these metals in Table 9-2. These are enormous quantities -- perhaps four times the cumulative amounts that have ever been mined. [7] There is no doubt that this much material exists; however, the economic, energetic, and environmental costs of extracting it are likely to be formidable.

There is little reason to suppose, moreover, that the bulk of the world's mineral production in the coming decades will be used to build up the per-capita stock in the parts of the world that are now poorest and where most of the population growth is expected. Rather, it will probably continue to go for replacement of losses and enlargement of stocks in countries already rich.

PROSPECTS FOR NEW MINERAL SUPPLIES

What is the potential for future exploitation of the "nonrenewable" materials in Earth's crust? Evaluation of this issue requires knowledge of the geological features that govern the existence and distribution of various minerals, together with information about the technology, economics, energetics, and environmental impact of extracting minerals and converting them to useful forms.

---

[4] For further discussion on these points, see, for example, E. R. Fried, *International trade in raw material: myths and realities*; H. H. Landsberg, "Materials: some recent trends and issues", *Science*, Vol. 191, pp. 637-641 (February 20, 1976); E. N. Cameron, *The contribution of the United States to national and world mineral supplies*.

[5] Harrison Brown, *The fissioning of human society*.

[6] Harrison Brown, *Human materials production as a process in the biosphere*.

[7] This figure follows from the assumption that the U.S. has about one-third of the existing world stocks (in proportion to its share of GNP), and that the stocks represent about two-thirds of the cumulative amount ever mined (the latter figure based on an estimate for steel in

H. Brown, *Human materials*).

Geologic Factors

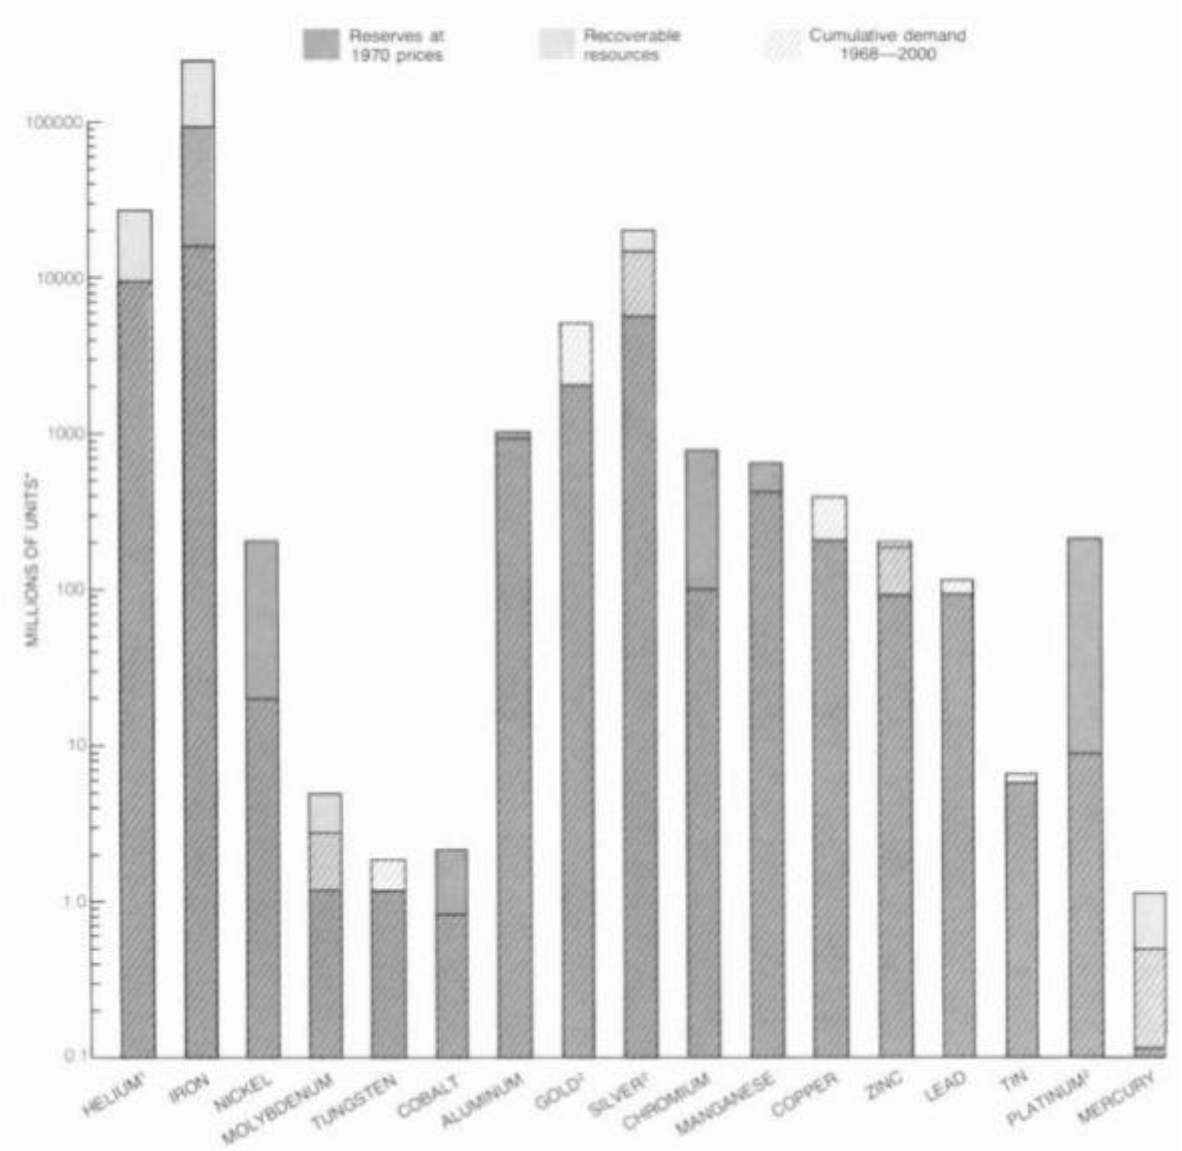
The resources of the Earth's crust are very unevenly distributed -- a result of the uneven distribution of the processes that led to their deposition and concentration. Consequently, some areas of Earth (and thus some nations) are richly endowed with mineral wealth, while others are depauperate. The distribution of coal, for instance, presumably represents the pattern of distribution of certain types of swamp plant communities that existed several million years ago. Some minerals have been formed by weathering and sedimentation; others have been concentrated at local fractures or other discontinuities in Earth's crust; still others have been formed and concentrated by the violent processes occurring at the intersections of tectonic plates. [8]

The concentration of some minerals varies more or less continuously from very high-grade ores to concentrations below the average abundance of the element in the crust. Certain types of copper ores exhibit this pattern of deposition, as do the ores of other important metals, such as iron and aluminum. Many others, including ores of lead, zinc, tin, nickel, tungsten, mercury, manganese, cobalt, precious metals, and molybdenum, do not. They show sharp discontinuities in concentration.

The frequently discontinuous distribution of ores, as well as other factors, make untenable the views of certain economists who think that only economic considerations determine the availability of mineral resources. They have the idea that, as demand increases, mining will simply move to poorer and poorer ores, which are assumed to be progressively more and more abundant. These economists have misinterpreted a principle called the "arithmetic-geometric ratio" (A/G ratio) -- a principle developed by mineral economist Sam Lasky for application to certain types of ore deposits within certain limits. It is valid only for those ores (such as porphyrycopper deposits) and only within those limits. The idea is that, as the grade of ore decreases arithmetically, its abundance will increase geometrically until the average abundance in Earth's crust is reached. Often it is assumed that the additional cost of mining the low-grade ores can easily be absorbed, since the dollar value of mineral resources is at present only a small part of the gross national product. But, as noted above, the geological facts of mineral distribution do not support this proposition as a general view. Although some ores approximate a distribution where the A/G ratio may be applied, most do not. [9]

Resource Estimation

Just as with the nonrenewable energy resources treated in the preceding chapter, in discussions of nonfuel minerals, one must distinguish between reserves (material whose location is established and which is known to be extractable with present technology near present prices) and resources (material whose location is known or suspected, but whose quality is such that it requires new technology and/or substantially higher prices for exploitation to be feasible).



Several techniques are widely used to estimate the adequacy of mineral resources for the future. The simplest (but least informative) is to calculate how long present reserves will last at present consumption rates. The number of years obtained by dividing reserves by the present consumption rate is sometimes called the "static reserve index." Often reserves stand at only 20 to 50 years' supply, simply because there is little incentive to spend money to establish additional reserves when that much material is already at hand. For many materials, at least, more supplies will be discovered in the future when the effort is made. On the other hand, the static reserve index does not account for future increases in consumption. In this respect, the static reserve index is an overgenerous indicator of adequacy, partly compensating, or perhaps overcompensating, for the underestimate that results from using only present reserves.

More sophisticated analyses may use detailed information about past patterns of exploration and about the size of unexplored areas that offer geological promise of holding the ores in question to estimate the "ultimately recoverable" quantities. These ultimately recoverable amounts can then be compared with regional and global cumulative consumption figures obtained from economic

---

[8]See, for example, P. A. Rona, *Plate tectonics and mineral resources*; P. W. Guild , *Discovery of natural resources*, and Chapter 2 of this book.

[9]See Thomas S. Lovering, "Mineral resources from the land"; and Preston Cloud, "Mineral resources today and tomorrow".

*Metric tons unless otherwise noted [1]Cubic meters [2]Troy ounces FIGURE 9-9 Global supplies of selected minerals compared with cumulative demand. The scale is logarithmic. (After Cloud, 1975.)

models based on various assumptions about patterns of development. These calculations may not be much more reliable as predictions than the static reserve index, so sensitive are they to the economic assumptions and to assumptions about what ores may be exploitable with unknown future technologies. They should be regarded, therefore, not as predictions but rather as possible outcomes if certain specified assumptions turn out to be correct. [10]

In this spirit, we present in Figure 9-9 some estimates derived by Cloud [11] largely from figures compiled by the U.S. Bureau of Mines. [12] There the forecasted cumulative global demand from 1968 to 2000 for various minerals is compared to the reserves at 1970 prices and, in some cases, to the recoverable resources at specified higher prices. Forecasted demand exceeds the estimated

supply for copper, zinc, lead, tin, gold, and tungsten. The higher demands that would result from establishing a richcountry level of materials stock for the present and projected population of the world, as discussed above, would make the picture even more pessimistic.

The United States situation for reserves and resources of the principal mineral commodities is summarized in Table 9-3.

AUGMENTING RESOURCES: RECYCLING, SUBSTITUTION, LOW-GRADE ORES

Besides the discovery of new supplies of mineral wealth, there are three approaches available to forestall or alleviate shortages of specific materials. One is to increase the fraction of economic needs met by recycling material that was previously incorporated into products and used, or by capturing and reusing process ingredients not embodied in final products (for instance, certain chemicals). The second is substitution, which itself takes many forms: substitution of abundant or renewable materials for scarce and/or nonrenewable ores in specific products; substitution of resource-conserving product designs for resource-intensive ones; substitution of resource-conserving functions and activities for resourceintensive ones. The third approach is to exploit "ores" in which the concentration of the desired material is very low; in the vision of the future enjoyed by some technologists, these "ores" include sea water and common rock.

Recycling

In principle, recycling is capable of greatly reducing the ratio of virgin material to total material in the inputs to industrial civilization. There are physical limits to how far this ratio can be reduced, however, which arise in two ways: (a) some irretrievable dispersal of material in use is inevitable; and (b) if the stock of material in use is not constant but growing, all of the growth must be supplied from virgin material (unless a one-time windfall is available in the form of a stockpile of scrap accumulated before recycling was being practiced to the maximum feasible extent).

There are also engineering-economic limitations on the degree of recycling; these arise from the difficulties of producing a product of sufficient purity for certain applications at a price competitive with virgin materials. Naturally, as the price of virgin materials rises, more elaborate technologies for recycling become economically attractive. Even where price alone might seem to make recycling appropriate, however, institutional obstacles sometimes intervene. These may take the form of freight rates, tax policies, regulations, existing capital equipment, or practices embedded in tradition. All of these have the effect of encouraging the use of virgin materials at the expense of recycling. [13]

Table 94 shows the fractions of consumption of various materials obtained from recycling old scrap in the United States around 1970. The amounts that are theoretically recyclable -- that is, the fractions of consumption that could be met by theoretically available scrap -- are generally much higher; for example, 70 to 80

percent for copper and aluminum and 27 percent for magnesium. Notwithstanding this potential, between 1950 and 1970 the fraction of consumption actually provided by recycling was decreasing in the United States for most materials. [14]

Urban solid wastes in the United States in 1971 comprised 230 million tons of paper, plastics, rubber, metals, organic material, and other debris. Threequarters of this amount was collected, but only a small fraction was recycled. Most was disposed of by incineration and landfill (see also Chapter 10). The Environmental Protection Agency estimated the amounts that *could* have been recovered as 34 million tons of paper, 13 million tons of glass, and 15 million tons of ferrous metals. [15]

Substitution

Substitution of one type of material for another is a venerable tradition in human history (think of the Stone Age, followed by the Bronze Age, and then the Iron Age) and is done for many reasons. The rapid growth of the use of aluminum and plastics in the past three decades has been at least in part the result of substituting these materials in applications that otherwise would have been served by wood or steel. These substitutions were made, not so much because of scarcity or high prices of iron and wood, but rather because of the superior properties of plastic and aluminum (e.g., strength-to-weight ratio, durability, ease of fabrication) in the desired applications. The substitution of synthetic fibers for cotton and wool has apparently been due to a combination of price and the more desirable properties of the substitutes from some points of view. On the other hand, the replacement of materials derived from contemporary plants (distillation products of wood, alcohol from molasses and grain) by petroleum as the basis for much of the organic chemical synthesis industry was very largely a matter of price. [16]

A return to photosynthetic material as the basis for production of plastics and other synthetics would not be

enormously expensive; in some cases plant products might be competitive with oil at the latter's 1976 price of about $12 per barrel. Use of wood or other crops grown for this raw-material function might also prove to be more benign environmentally than reliance on low-grade fossil resources such as oil shale. In the short to middle term, however, it seems more likely that industrial civilization will rely increasingly for its hydrocarbon feedstocks on coal, the supplies of which are much greater than those of gas and oil, and the cost of which will probably remain for some time below that of fresh photosynthetic material. [17]

For the long term, the extent to which the need for materials can be met by renewable (photosynthetic) substances will depend on the size of the global population and, of course, on the amount of material required per person. The size of U.S. wood-product consumption around 1970, at roughly 240 million metric tons, exceeded that of all synthetic polymers by 13-fold. This means that meeting the needs of the present U.S.

population for synthetics from wood-based materials, assuming a wood-to-synthesis conversion efficiency of 33 percent, [18] would require increasing U.S. wood-product production by 25 percent. (The actual processes, efficiencies, and energy requirements for doing this require much closer investigation.) On a global basis, the number would certainly be less encouraging than for the United States, and the unexploited part of Earth's photosynthetic potential may be needed more for food production than for raw material for plastics. [19] The versatility of photosynthetic material -- usable as food, fuel, chemical feedstock, construction material, paper -- is both an asset and a liability. It is a liability because there are so many competing uses for a finite photosynthetic potential. Again, this is one of the more obvious reasons that there is an inverse connection between population size and the material standard of living that can be sustained in the long term.

Possibilities for substitution among the major industrial metals have been the subject of much discussion. [20] Optimists argue that there are more abundant substitutes for almost everything that is scarce or potentially scarce, and this is at least partly true. Aluminum, iron, magnesium, and titanium are among the most abundant elements in Earth's crust (see Chapter 2), and these could replace many scarcer materials.

One problem is that the substitutes often are distinctly inferior in some important properties: tungsten's high melting point is unequalled by other metals; platinum's efficiency as a catalyst is unparalleled; gold's properties in electrical contacts cannot be duplicated by other materials; stainless steel cannot be made without chromium; and mercury has physical and chemical properties that (in important respects) are unique. It must also be recognized that some often-cited substitutes are themselves not very abundant. The main substitutes for mercury in advanced batteries, for example, are cadmium and silver. These are in fact also scarce. The main substitute for tungsten in most applications is molybdenum, which is also scarce.

Another defect in the optimistic view is the possibility that technologies not yet invented, but eventually needed, will make large demands on particularly scarce resources. It is possible, for example, that controlled nuclear fusion would make heavy demands on beryllium, niobium, chromium, and lead. [21] It is also possible that efficient solar cells would require large amounts of gallium.

Nevertheless, it is hard to disagree with the optimists to this limited extent: no metals that are scarce enough to be exhausted in the next hundred years or so seem to be so vital to civilization that their exhaustion demonstrably would mean large-scale catastrophe. Unfortunately, the complacency about materials supply that such a statement tends to generate is unwarranted, for two reasons beyond the obvious uncertainties. First, the rising costs and lowered technical efficiency associated with an increasing general scarcity of useful metals and with the substitution of inferior alternatives significantly steepens the path to material prosperity that today's less developed countries must climb. Substitution may only make the rich a little poorer, but it could make the poor much less likely to get richer. Second, as has been recognized by many for a long time, the tightest limits on civilization's expanding use of materials of all kinds are probably not raw supply or even economic costs but, rather, the environmental impact of extraction, processing, and use. [22]

In the long term, a possible exception to even the limited optimism about material supply expressed here is phosphorus, for this is one element that is neither very abundant in Earth's crust nor replaceable. Concern that the world could not support more than 2 billion people without the use of phosphate fertilizer, and that resources of phosphate rock could be exhausted before the end of the twenty-first century, were expressed in a major study

---

[18]The efficiency corresponds to that of existing wood-to-chemical cellulose processes. See Sarkanen, *Renewable resources*.

sponsored by the Institute of Ecology in 1972. [23] This alarming conclusion was criticized elsewhere as unduly pessimistic, because the static reserve indices of phosphate rock, based on the sum of identified and hypothetical reserves, range from several hundred to one thousand years, both for the United States and for the world. The Institute of Ecology's work assumed a continuation of the exponential growth rate in phosphorus use that has prevailed for the past few decades, however, and their results are correct only if this assumption holds. [24] It seems overwhelmingly likely that other factors will stop the expansion of world agriculture before minable phosphorus supplies run out. Nevertheless, if a stabilized phosphate consumption should be as much as five times that of the early 1970s, world supplies might be gone in two hundred years. As a long-term problem, then, this is a very serious matter. The question of how civilization might manage in a world without high-grade phosphorus resources does not seem to have been carefully addressed.

One obvious way to ameliorate supply problems for phosphorus and other potentially scarce materials is to learn to use them more efficiently -- that is, to get more of the desired output per unit of input. It is not at all clear how to do this for phosphorus. What is needed is a way to increase the fraction of the phosphorus applied to the soil that plants take up. For many other materials, raising the efficiency of use is not so difficult. The amount of metal used in automobiles can be reduced by making them smaller, for example, and the flow of metals through automobiles can be reduced by making them more durable. (Making a product more durable is almost always preferable to recycling in terms of energy inputs. [25]) More drastic changes for the better than simply making the same device smaller or more durable can also be envisioned. An example is the replacement of heavy, cumbersome, noisy, slow, mechanical calculating machines (they were about the size and weight of today's office electric typewriters and several times as expensive) with tiny, light, silent, fast, efficient, and relatively inexpensive hand-held calculators. This is a splendid demonstration that progress and economic growth can

be based on extracting a greatly increased amount of service from each unit of energy and material.

Even more fundamental substitutions are those where the function is changed, but the overall service performed is similar. An example of this sort (already mentioned in the foregoing chapter, but as relevant for saving materials as for saving energy) is the substitution of communication for transportation.

Low-Grade Ores and the Energetics of Materials

It is all but inevitable that the highest-quality ores -those closest to the surface, or having the highest concentration of metals compared to waste materials -are the first to be exploited. The progression toward lower-quality material can be slowed by ingenuity and frugality in design, substitution, and recycling, but, across the entire range of nonrenewable materials, it cannot be stopped. As the quality of ore diminishes, all else being equal, both the amount of waste material and the energy used to separate metal from waste must increase. The viability of the cornucopian vision -- the vision of a world where a population several times today's is supported in material abundance by materials obtained either from renewable sources or from the nearly inexhaustible principal constituents of sea water and Earth's crust -- depends strongly on whether the energy use and waste production associated with the nearly inexhaustible materials are manageable.

Some insight into the difficulties that this hypothetical future world would entail can be gleaned from Table 9-5, which compares the lowest grade of minable ores in 1975 with the grade characteristic of common rock. For aluminum, iron, and titanium, it is possible that "common rock" will be mined, although at sharply increasing multiples of present impact. For minerals above copper in the table, the mining of common rock seems unlikely ever to occur. The energetics of extracting copper from its ores as a function of grade are illustrated in Figure 9-10. One would expect qualitatively similar curves to prevail for other metals.

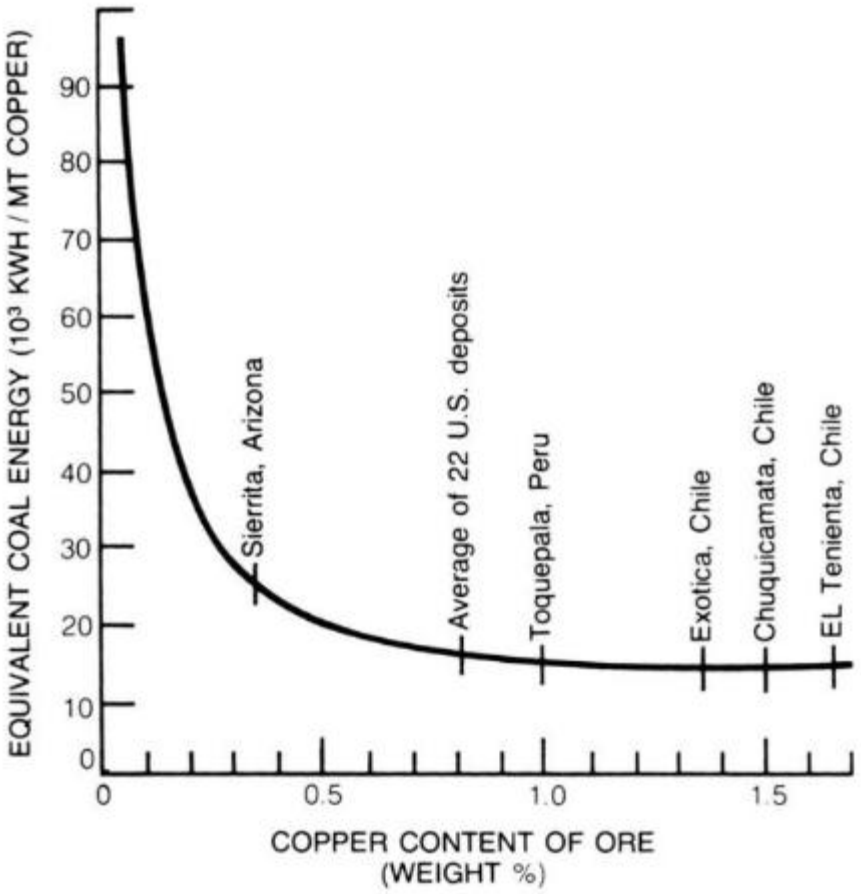

FIGURE 9-10 Energy requirements for different grades of sulfide copper ores. (From Cook, 1975. Copyright 1975 by the American Association for the Advancement of Science.)

Some further comparisons of the energy intensity of various materials are presented in Table 9-6. Evidently, substituting the light, abundant metals for the heavier, scarce ones will carry a heavy energy cost. Substituting titanium for stainless steel (which requires chromium) would be especially expensive in energy consumed, unless ways are found to reduce greatly the amount of material of this type now used in industrial society.

CONCLUSIONS

The materials situation has much in common with the energy situation in its structure and characteristics, and, in fact, the two are tightly linked by the energy requirements of obtaining materials and the materials requirements of obtaining energy.

Like energy resources, materials resources can be divided usefully into nonrenewable and renewable kinds -- stocks and flows. The dividing line is not quite as

sharp for materials as for energy, however, inasmuch as energy's capacity to do useful work can be used only once, whereas materials can be recycled. Dispersed "nonrenewable" material resources can in principle be made "renewable" by the application of sufficient energy to reconcentrate the dispersed matter, but in many cases the energy cost is so high as to make the renewablenonrenewable distinction quite clear in practical terms.Like the energy situation, the problem with materials is not running out in the absolute sense. In the short to middle term, humanity is running out of some particular forms of materials, such as tungsten and mercury, which society is accustomed to having and in this sense is dependent upon (analogous to oil and natural gas). But there are replacements with somewhat different characteristics (such as titanium and aluminum), which are vastly more abundant and with which it appears possible (at first glance, at least) to fashion a substantially similar, if not identical, material standard of living (analogous to oil shale, low-grade uranium in breeder reactors, and fusion fuels on the energy side).The difficulties, then, are somewhat more subtle than just plain "running out." They include:

1. Managing a smooth transition (technically, economically, socially) from a system based on scarce materials to a system based on more abundant ones -- in other words, the problem of "getting from here to there."
2. Avoiding the imposition of unbearable environmental and/or social burdens that may attend some of the technologies of abundance.
3. Preventing the prospects of people now poor from plummeting as the real economic costs of the material basis of prosperity rise.

Those who view with optimism, or even complacency, the prospects of dealing with these difficulties generally assume: that energy will be cheap in the future; that substitutes for the scarcest materials will always turn up on time; that management will be skillful; that the market mechanism will allocate the real costs of scarcities efficiently; and that environmental problems will be nuisances rather than deep threats to human welfare. We believe that the weight of the evidence on all these questions supports a much more pessimistic conclusion, and that deliberate large-scale changes in the pattern of "business-as-usual" with respect to materials production and use will be necessary.

Specifically, by far the most attractive option appears to be to learn how to derive more well-being out of each kilogram of material that flows through society -- by recycling, by paring down oversized artifacts, by increasing durability, by substituting among alternative processes that meet the same human goals in ways that reduce the use of materials. Choices among alternative materials to meet the same needs should be made with more emphasis on minimizing environmental disruption in extraction, processing, and use; and the energy intensity of materials should become a major criterion (the smaller the better). The potential of much heavier reliance on renewable sources of materials as a means of reducing both energy intensity and environmental impact should be investigated and compared with the use of low-grade nonrenewable resources.

Only if the rich countries alter their consumptive behavior in these directions (which they can afford to do, and which also would in all probability ease their unemployment problems), can the depletable, relatively inexpensive, high-grade resources that remain be preserved for what we

believe should be their highestpriority use -- the construction of an affordable bridge to a modest level of prosperity for people in less developed countries who are now desperately poor.

Tremendous amount of quantitative information about renewable and nonrenewable materials crammed into one document, together with a large number of far-reaching policy recommendations.

U. S. National Commission on Supplies and Shortages. 1976. *Government and the nation's resources*. Government Printing Office, Washington, D.C. While it makes a number of useful suggestions for improving government's capacity to anticipate and moderate shortages, this report is most notable for its dogmatic adherence to a cornucopian view of substitutability and smooth operation of the market -- a view almost completely unencumbered by recognition of the difficulties posed by rising economic and environmental costs and the limitations of substitution, as discussed in this chapter. As one example of the depth of analysis on these points, we note that a table of "substitutes" on pp. 21-22 lists tungsten as the only substitute for molybdenum in tool steel, and, elsewhere in the table, molybdenum as the only substitute for tungsten in the same application. The table also lists natural gas as a substitute for coal.

SECTION IV
Understanding Environmental Disruption

But our inability to assign definite values to these causes of the disturbance of natural arrangements is not a reason for ignoring the existence of such causes in any general view of the relations between man and nature, and we are never justified in assuming a force to be insignificant because its measure is unknown, or even because no physical effect can be traced to it as its origin.

-- George Perkins Marsh, 1864

There is only one solution. Man must recognize the necessity of cooperating with nature. He must temper his demands and use and conserve the natural living resources of this earth in a manner that alone can provide for the continuation of his civilization.

-- Fairfield Osborn, 1948

As the human population grows and the quantity of energy and materials used by each person increases, it is becoming apparent that the resource whose sufficiency is most in doubt is neither space, nor energy, nor metallic ores, but rather the capacity of natural processes to maintain a hospitable environment. These processes include dispersal and detoxification of wastes, cycling of nutrients, natural controls on crop pests and agents of human disease, management of water flows, and regulation of climate. How these functions are accomplished was described in Chapter 2 through Chapter 4. We now consider how they can be overloaded or undermined by the activities of human society, and outline what the consequences for human welfare are or may be.

The subject of environmental problems is large and diverse, and it is easier to deal with when viewed in some logical framework. We find it useful, as the basis for such a framework, to distinguish among three steps in environmental disruption: (1) what society does to the environment (the *insult*); (2) what the environment does as a consequence of what is done to it (the *response*); and (3) the resulting damage to human well-being (the *environmental cost*).

Insults include: the discharge of material effluents to air, water, and the land surface; the production of heat, noise, and electromagnetic radiation; removal of plants and animals; and physical transformations such as drilling, damming, dredging, filling, mining, pumping, paving, and erecting structures. Some of these impacts occur as accidents as well as intentionally, and some are produced by the interaction of human activities and natural events.

Environmental responses to the insults include: accumulation of materials in undesirable forms, concentrations, and locations; changes in the diversity, abun-

dance, and distribution of organisms; reduction of primary productivity; changes in host-parasite and predator-prey relationships; loss of water storage and control of water flow; loss of nutrient storage capability; geologic events such as erosion, subsidence, slides, and earthquakes; alteration of flows of solar and terrestrial radiation through the atmosphere; and changes in patterns of atmospheric and marine circulation and of humidity and rainfall. Often several such responses are simultaneous and interconnected.

The human costs of environmental disruption fall for the most part into the following categories: death, disease, and malformation from exposure to harmful substances and radiations (including but not limited to cancer, birth defects, and genetic effects); epidemic and parasitic disease; hunger, starvation, and impoverishment owing to loss of terrestrial and marine productivity; death, injury, and impoverishment from floods, slides, and other meteorological or geological events arising from society's impacts; other damages to property such as by air and water pollution; irretrievable loss of genetic information and potential services with the extinction of species; aesthetic degradation and denial of recreational resources; and economic costs of replacing or supplementing diminished natural services with technology. These costs may manifest themselves in a sudden and drastic increase, they may creep up gradually over a long span of time, or some of them may appear in the form of increased fluctuations (that is, variability) in such processes as food production and epidemic disease.

We have chosen somewhat arbitrarily to divide our coverage of environmental disruption into two categories, according to the nature of the pathway between insult and cost. We deal in Chapter 10 with what we have called direct assaults on human health -- namely, phenomena in which the pathway between insult and human costs does not depend on disruption of environmental or geophysical systems as an intermediate link. In Chapter 11, we discuss indirect assaults on human wellbeing, wherein the disruption of an environmental system is the essential link between the insult and the human cost. Obviously, the same impact can lead to costs via both pathways: water pollution as a health hazard to people who ingest the water represents a direct assault and therefore is treated in Chapter 10; water pollution can also lead to adverse

effects on aquatic and terrestrial ecosystems resulting in subsequent costs to society, and those pathways are treated mainly in Chapter 11.

Three important themes apply with equal force to the issues treated in both chapters, so we introduce them here: (1) the importance of not neglecting dispersed, chronic hazards while dealing with concentrated, acute ones; (2) the special dangers arising from time lags between the initiation of an insult and the appearance of the resulting cost; and (3) the nature of uncertainty in environmental assessment and its implications for policy-making.

It is a truism that people's attention is captured by spectacular events -- disastrous smogs, massive oil spills from blowouts or tanker wrecks, and epidemics of acute poisoning from mercury or cadmium or pesticides. Similarly, the threats most likely to be taken seriously are those to which spectacular or otherwise compelling images can be attached -- the SST, the whales as endangered species, suggestions for

putting dams in the Grand Canyon. These are all important matters, and we are grateful for the attention they have attracted to environmental concerns. But it is essential that environmentalists and environmental scientists avoid pouring all their resources into winning a few spectacular battles while losing the war. For every ton of oil spilled into the oceans in accidents, twenty tons are discharged unnoticed in routine operations. For every coal miner who dies in a cave-in, making headlines, ten people may die because of air pollution from burning coal, unheralded. For every hectare of spectacular landscape saved from despoilation in national parks, a hundred hectares of more ordinary land remain at risk. Struggles to stave off extinctions, species by species, cannot succeed if habitat throughout the world is disappearing under pavement and plow. Somehow, society must learn to recognize and combat the subtle threats as well as the spectacular ones, or it will find itself nickel-and-dimed into environmental impoverishment.

Time lags between insults to the environment and the unmistakable appearance of the consequences compound the predicament with respect to hazards both subtle and spectacular, because they postpone recognition of the need for corrective action. A variety of lags may be important: the time required for contaminants to be transported horizontally or vertically in ocean or atmosphere or over or under the land; the time it takes for such materials to find their ways up food chains; the time associated with the rates of certain chemical reactions, such as those responsible for the formation of photochemical smog; the ill-understood phenomena responsible for the latency period between many carcinogenic insults and the actual appearance of the cancers; the lag between mutagenic insults and the appearance of genetic disorders in subsequent generations. Besides these physical phenomena, there is often an analysis lag -- that is, the time it takes to understand theoretically and/or establish with measurements just what is happening. The threat posed by fluorocarbons to atmospheric ozone is a good example of lags of several kinds: the rate of diffusion of the fluorocarbons up to the stratosphere, where the ozone is, is slow; the reactions that lead to the destruction of the ozone are slow; and slowest of all was the development of scientific understanding of the existence of a threat and the details of its operation.

To the time lags already mentioned must be added the time lags of societal response: inventing solutions and getting them in place. What the lags add up to, all too often, is a situation in which corrective action is too little and too late. By the time the symptoms are unmistakable and the cause isolated, the damage may be irreversible. Species that have been eradicated cannot be restored. The radioactive debris of atmospheric bomb tests cannot be reconcentrated and isolated from the environment, nor can the chlorinated-hydrocarbon pesticides that have spread through the biosphere. Radiation exposure cannot be undone.

Clearly, if problems that are potentially irreversible are to be caught in time, society must be prepared to act on imperfect information. Tremendous gaps exist in scientific understanding of environmentally induced diseases, of the operation of ecosystems, even of the simpler nonbiological processes that govern such aspects of the environment as climate. It is customary in the scientific community, when

confronted with a possible environmental threat of one kind or another, to refer to these gaps in understanding and call for more research to reduce the uncertainties before taking any action. But the fact is that the uncertainty usually cannot be removed -- and often cannot even be reduced -- within the time in which a decision must be made. Policy-makers must accept a degree of scientific uncertainty as an irremovable component of their decision-making predicament. Given that decision-making in the face of uncertainty means some mistakes are sure to be made, the most reasonable policy is one that errs on the side of avoiding those mistakes that are irreversible. Another way of saying this is: the greater the degree of irreversibility potentially associated with a given course of action (or inaction), the heavier should be the burden of proof upon those advocating this course to show that the irreversible harm will not in fact materialize.

[This page intentionally left blank.]

CHAPTER 10
Direct Assaults on Well-Being

He will manage the cure best who forsees what is to happen from the present condition of the patient.

--

Hippocrates, ca. 460-377 B.C.

Don't drink the water and don't breathe the air.

-- Tom Lehrer, *Pollution*, 1965

In some respects the activities of humanity over the past several centuries have made the environment more hospitable. Some parts of the countryside in places as diverse as Europe and China are undoubtedly more productive, more pleasant, more varied in flora and fauna than they were in prehistoric times. In terms of freedom from epidemic disease, cities are much healthier places than they once were. But the activities of human society have also created some new threats to life and health and made some old threats worse. These threats arise from insults -- effluents, accidents, and environmental transformations -- generated by the activities of societies both industrial and agricultural.

Deaths and illnesses ascribable directly to such insults understandably have received much of the attention that the public and policy-makers have given to environmental matters. Respiratory ailments from air pollution, hepatitis from polluted water, cancer from a host of environmental contaminants -- all have a clear and compelling claim on the public consciousness. These direct threats to life and health, and corollary threats to economic goods and services, are the subject of this chapter. Many of the insults discussed here also undermine human well-being by disrupting the natural functioning of geophysical and ecological processes. These often subtle and unpublicized indirect assaults on human well-being are taken up in Chapter 11.

The term *pollution* describes the class of environmental insults with which most people are most familiar. The dictionary defines it as "a state of being impure or unclean, or the process of producing that state." [1] A *pollutant* is an agent -- for example, chemicals, noise,

[1] *Webster's Third New International Dictionary*, Springfield, Mass., G. & C. Merriam, 1966.

radiation -- that produces the state of pollution. What is meant by *impure* or *unclean* needs to be clarified, however. For the purposes of this book, we interpret impure and unclean to imply the presence of agents added to the environment by society in kinds and quantities potentially damaging to human welfare or to organisms other than people. By this definition, pollution is a man-made phenomenon. This is not to deny that agents naturally present in the environment can be harmful. Natural ionizing radiation doubtless does biological damage, a variety of plant pollens cause respiratory disease, hydrocarbons emitted by trees can contribute to the formation of photochemical smog, particulate matter from volcanoes influences climate, and so on. But we believe it useful to preserve a distinction between these nonhuman natural phenomena and pollution as a process or condition having human origins. Two further definitions are useful in this connection. We define *qualitative pollutants* as agents produced and released only by human activities and not otherwise present in nature. We define *quantitative pollutants* as contributions made by society to the environmental pools of agents that would be present even in the absence of human influences.

Within the category of quantitative pollutants, there are three distinct criteria by which a human contribution may be judged significant: (1) Humanity can perturb a natural cycle with a large amount of a substance ordinarily considered innocuous, either by overloading part of the cycle (nitrogen, Chapter 11), by destabilizing a finely tuned balance (CO_2, Chapter 11), or by swamping the natural cycle completely (heat, in the very long term, Chapter 11). (2) An amount of material that is negligible when compared to natural flows of the same thing can produce an important disruption if released in a sensitive spot, within a small area, or suddenly (oil, Chapter 11). (3) *Any* addition of a substance that is dangerous even at its natural concentrations is significant (mercury and many radioactive substances, Chapter 10).

For synthetic pollutants, of course, the situation is even more clear-cut. There can be no question of the potential for harm from biologically active substances with which organisms have had no prior evolutionary experience (synthetic organic pesticides, PCBs, and herbicides, Chapters 10 and 11).

AIR POLLUTION

"The air nimbly and sweetly recommends itself unto our gentle senses," wrote William Shakespeare in *Macbeth*. Perhaps he was referring to the air in the countryside, for even in Shakespeare's day the air in London would hardly have inspired such sentiments. It was smoky, and it stank. The nature of air pollution has changed somewhat since then, but it remains the most obvious form of pollution worldwide. It can be felt when it burns the eyes and irritates the lungs. Virtually every major metropolis of the world has serious air-pollution problems. Travelers know how often their first sight of a city can be spoiled by the pall of smog. Today, however, it is not only the air over cities that is polluted. Large regions are now afflicted to some degree. Humanity is taxing the capacity of the atmosphere to absorb, and to transport away from areas of high population density, the enormous amounts of waste exhausted into it. Air pollution is now recognized not only as a phenomenon that rots nylon stockings and windshield-wiper blades, that corrodes paint and steel, and that blackens skies and the wash on the clothesline; it is recognized as a killer of people.

Types and Sources of Air Pollutants

There are many different ways to sort and classify air pollutants: by source, by chemical composition, by types of reactions undergone, by type of effect on health, and so on. The main categories monitored nationally are sulfur oxides, nitrogen oxides, hydrocarbons, carbon monoxide, and particulate matter. Estimates of emissions of these pollutants in 1974 in the United States are given in Table 10-1. [2]

The first two source categories in Table 10-1 represent the combustion of fossil fuels. Sulfur oxides result from the presence of sulfur in coal and fuel oil as a natural contaminant. Emissions re almost entirely in the form of sulfur dioxide gas (SO^2), mixed with 1 to 3 percent sulfur

[2]Council on Environmental Quality, *Environmental Quality, 1975*. More detail on the emissions characteristics of various sources of pollutants is given in U.S. Environmental

Protection Agency (EPA), Compilation of air pollutant emission factors.

TABLE 10-1
Emissions of Air Pollutants in the U.S., by Source (million tons/yr, 1974)

Source	Sulfur oxides	Nitrogen oxides	Hydrocarbons	Carbon monoxide	Particulates
Transportation	0.8	10.7	12.8	73.5	1.3
Stationary fuel combustion	24.3	11.0	1.7	0.9	5.9
Industrial processes	6.2	0.6	3.1	12.7	11.0
Solid waste disposal	0.0	0.1	0.6	2.4	0.5
Miscellaneous [*]	0.1	0.1	12.2	5.1	0.8
	---	---	---	---	---
Total	31.4	22.5	30.4	94.6	19.5

[*]Includes oil and gasoline production.

trioxide (SO_3), also gaseous. Once in the atmosphere, SO_2 can be oxidized to SO_3; the SO_3 reacts with water vapor or dissolves in water droplets to form sulfuric acid, H_2SO_4. The sulfur dioxide can also form the weak acid H_2SO_3 directly, and the sulfate ion (SO_4-) appears in a variety of solid and liquid particulates in addition to H_2SO_4. [3] The rate at which SO_2 is oxidized to the much more dangerous sulfuric acid and other sulfates is greatly increased when significant numbers of suspended particles are present, because these provide surfaces that facilitate the reactions. Atmospheric concentrations of sulfur oxides are generally measured in parts per million (ppm) by volume of SO_2; 1 ppm of SO_2 by volume is 2.2 ppm by weight or 2.7 milligrams per cubic meter of air at sea level.

The oxides of nitrogen of interest in most air-pollution contexts are nitric oxide (NO) and nitrogen dioxide (NO_2). Emissions are usually calculated as grams or tons of NO; a concentration of 1 ppm NO by volume is also about 1 ppm by weight, or 1.2 milligrams per cubic meter. The colorless nitric oxide is slowly oxidized in air to orangish-brown NO_2, a process that is much faster in badly polluted atmospheres. Nitrogen dioxide reacts readily with water vapor to form nitric acid, HNO_3. Formation of nitric oxide from nitrogen and oxygen takes place at the high temperatures (and sometimes pressures) produced in the combustion of fossil fuels. The nitrogen comes not only from the air, but is also present as a contaminant in significant quantities in coal, oil, and natural gas. [4] This means that nitrogen-oxide pollution could not be eliminated by burning fuel in pure oxygen rather than air, as has sometimes been suggested.

A great variety of hydrocarbons are emitted in fossilfuel combustion when the fuel does not burn completely. (Complete combustion of hydrocarbon fuels would give H_2O and CO_2). Those of greatest interest are the "reactive" ones, which participate in the formation of photochemical smog, and others known or suspected to be carcinogenic (cancer-causing). The bulk of the

emissions of hydrocarbons in the United States is methane (CH_4), which falls in neither of these categories.

Another product of incomplete combustion is carbon monoxide (CO). The bulk of the emissions of this compound comes from engines used in transportation. Concentrations are usually measured in parts per million by volume; 1 ppm by volume of CO is about equal to 1 ppm by weight, or 1.2 milligrams per cubic meter.

Particulate matter in polluted air occurs in a tremendous variety of sizes and chemical compositions. Many particles contain heavy metals such as cadmium, mercury, and lead, which are either natural contaminants of the original fuel or (like lead) have been added deliberately to improve fuel performance. "Suspended particulates" are those 10 microns (thousandths of a millimeter) or smaller in aerodynamic equivalent diameter, that is, the diameter of a sphere with the same air resistance as the particle. Below the 10-micron range, the settling velocity is low enough so that atmospheric mixing tends to keep the particles suspended. Particles of a micron or less have the longest residence times in the atmosphere and are the most difficult for pollution-control equipment to remove from gaseous effluent. As already noted, some atmospheric particles are formed from substances emitted as gases or vapors.

---

[3]For an extended discussion, see P. P. Gaspar, *Sulfur in the atmosphere*, chapter 2.

[4]National Academy of Sciences, *Air quality and stationary source emission control* chapter 14.

The term photochemical smog describes a variable mixture of compounds, including ozone (O_3) and other more complex reactive chemicals formed by the action of sunlight on nitrogen oxides and hydrocarbons. Ozone and other chemicals that readily give up an oxygen atom in chemical reactions are often lumped together under the term *oxidants*. [5] The most common oxidant other than ozone is peroxyacetl nitrate (PAN).

Important sources of pollutants other than fuel combustion include the smelting of ores, petroleum refining, pulp and paper mills, chemical plants, and trash burning.

Impacts on Health

Death rates are above normal when and where air pollution occurs at significant concentrations. The demise of the very young, the very old, and those with respiratory ailments is accelerated. [6] Perhaps the most dramatic case ever recorded was the London smog disaster of 1952 (see Box 10-1). But such disasters have still been less significant to public health than have the less spectacular, but ultimately more far-reaching, effects that day-to-day exposure has had on people living in seriously polluted localities. In 1968, sixty faculty members of the Medical School of the University of California at Los Angeles made a recommendation to the residents of southern California's smoggy areas. Their statement read, in part: "air pollution has now become a major health hazard to most of this community during much of the year," and they advised "anyone who does not have compelling reasons to remain to move out of smoggy portions of Los

FIGURE 10-1
Air pollution is a worldwide problem. *Top*. An early morning inversion blankets the Los Angeles basin in smog, while the higher Hollywood Hills in the foreground remain clear. This picture was taken in 1949. (Photo by William A Garnett.) *Center*. Air pollution from a plant near Alvik, Norway, in July 1972. (Photo by Robert E. Van Vuren.) *Bottom*. [5]A good introductory discussion is D. A. Lynn, *Air pollution: Threat and response*, chapter 3.
[6]An excellent introduction to the impacts of pollutants on health and the methods used to discover these impacts in large populations is Samuel S. Epstein and Dale Hattis, *Pollution and human health*. For a discussion of air pollution's effects on children, who are more susceptible than adults because of their size and relatively high levels of metabolism and activity, see Dorothy Noyes Kane, *Bad air for children*.

Box 10-1 Air Pollution Disasters

Donora, Pennsylvania, is a small town in the steep valley of the Monongahela River; in 1948 it had a population of 12,300. Because of the steepnesss of the surrounding hills, it tends to be even smokier than other mill towns. In the autumn, fog is often added to the smoke, making the mixture smog (smog equals smoke plus fog in the strict sense of the word, but air pollution not involving fog, such as that found in Los Angeles, is now commonly called smog). On Tuesday, October 26, 1948, a thermal inversion (a layer of warm air above a layer of cold air; see Figure 10-3) trapped fog and smoke producing a lethal situation. The red, black, and yellow smoke from Donora's huge wire factory, zinc and sulfuric acid plants, and steel factory lingered for days over the grimy town, and the upper layer of fog absorbed the sun's heat, creating more warm air above the cold and intensifying the inversion. The smog persisted through Sunday, and 6,000 people, nearly half the people in the area, were made ill as a result. Fifteen men and five women died, and the lives of many others may have been shortened.

A similar smog occured in London in 1952; the combination of fog and thermal inversion was accompanied by severe cold weather. London's homes were heated by coal, and the cold greatly increased fuel consumption and the production of smoke. The atmospheric content of sulfur dioxide rose to double its usual level. The episode started on Friday, December 5, and by Sunday the smog had reduced visibility to only one yard in parts of London, and created multitudes of incredible situations. For example, so much smog seeped into theaters that only people in the first four rows could see the cinema screen. People inadvertently walked off of quays along the names and fell into the river. A pilot trying to taxi to the terminal at London Airport after an instrument landing got lost, as did the party sent to search for him. The consensus was that about 4,000 deaths were directly attributable to the London smog. [*]

There have, of course, been other smog disasters, as well as many close calls. Two often-cited cases occurred in the Meuse Valley of Belgium in 1930 and at Poza Rica Near Mexico City in 1950. When the next smog "disaster" will come, no one knows. But in August 1969 citizens of both Los Angeles and St. Louis were warned by doctors not to play golf, jog, or do anything that involved deep breathing because of the airpollution hazards that prevailed. The activities of school children in the Los Angeles basin are curtailed on doctors' orders with increasing frequency, and attrition of the health of asthmatics and others with respiratory or cardiovascular problems continues.

Angeles, San Bernardino, and Riverside counties to avoid chronic respiratory diseases like bronchitis and emphysema." [7]

What are the general effects of individual air pollutants on health?

Carbon monoxide combines with the pigment hemoglobin in blood more efficiently and more tightly than oxygen does, displacing the oxygen that hemoglobin normally transports. Thus carbon monoxide tends to cause suffocation by occupying the high-speed transport system that in

the human organism normally guarantees a steady renewal of the supply of oxygen necessary to maintain metabolism in the cells. When oxygen supply to the cells is reduced, the heart must work harder, as must the respiratory mechanism. These effects may produce a critical strain in people with heart and lung diseases. When a person lives for eight hours in an atmosphere containing 80 parts per million (ppm) of carbon monoxide, the oxygen-carrying capacity of the circulatory system is diminished by about 15 percent. (That is, the "saturation" of oxygen-transport sites with carbon monoxide--the carboxyhemoglobin level--is 15 percent.) This has about the same effect as the loss of more than a pint of blood. Observable effects on human performance appear to set in at around 3 percent carboxyhemoglobin in the blood. [8]

---

[8]Lynn, *Air pollution* chapter 4; G. Wright et al., *Carbon monoxide in the urban atmosphere*.

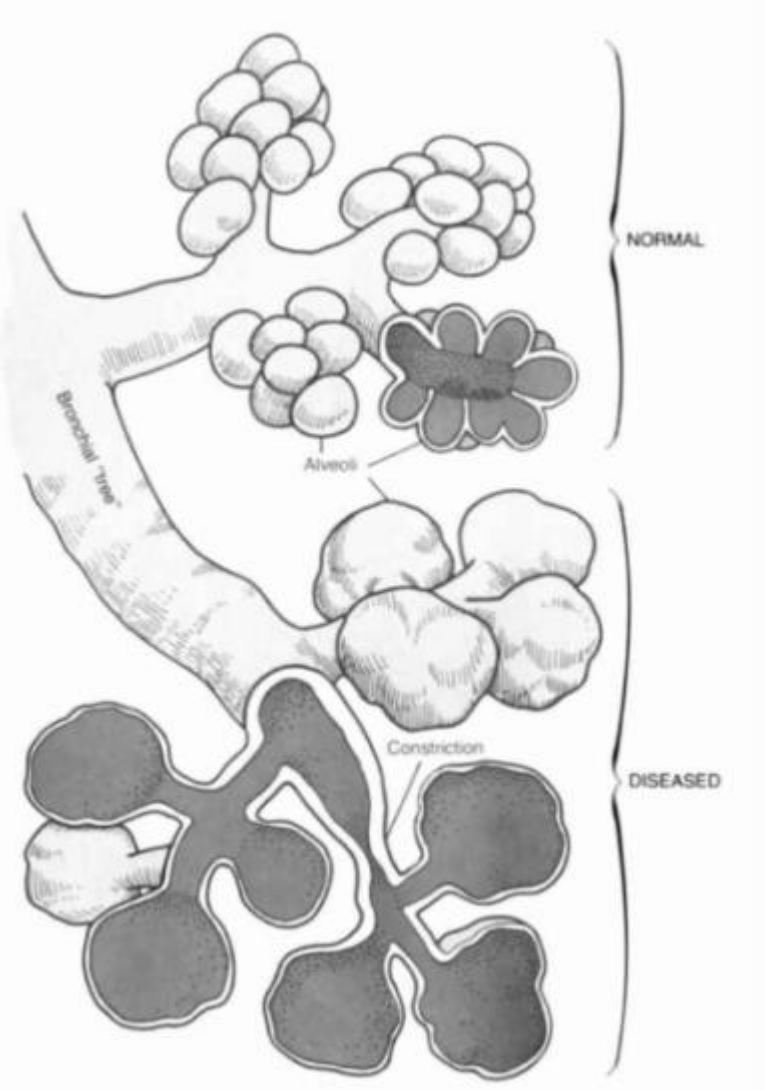

FIGURE 10-2 Bronchitis-emphysema, a disease caused or aggravated by air pollution. In the normal lung the bronchial tubes branch into millions of tiny chambers (alveoli), where transfer of oxygen to blood takes place. In the diseased lung the alveoli coalesce, reducing the amount of surface available for oxygen transfer. Furthermore, the "twigs" of the bronchial tree are constricted, reducing the rate at which air is exchanged. (After McDermott, 1961.)

When traffic is badly snarled, the carbon-monoxide content of the air may approach 400 ppm. Symptoms of acute poisoning, often experienced by people in traffic jams and on freeways, include headache, loss of vision, decreased muscular coordination, nausea, and abdominal pain. If exposure to concentrations in the hundreds of ppm is prolonged, unconsciousness, convulsions, and death follow. Cases of chronic carbon-monoxide poisoning have been reported, and an association between high concentrations of atmospheric carbon monoxide with higher mortality in Los Angeles County has been demonstrated for the years 1962 to 1965. [9]

Sulfur oxides have been implicated in the increased rates of acute and chronic asthma, bronchitis, and emphysema observed in people exposed to concentrations encountered in many cities in the U.S. [10] Indirect and limited evidence suggests there may also be some association between sulfur oxides and lung cancer. [11]

Asthma is an allergic supersensitivity of the bronchial tree, the set of branching tubes that carry air from the trachea to the lungs. An asthmatic attack causes the muscles that encircle the "twigs" of the bronchial tree to contract and narrow the tubes. The victim is able to inhale air, but is unable to exhale with sufficient force to clear the lungs. The result is a distension of the lungs: input exceeds output. Carbon dioxide builds up in the lungs, and the victim also suffers oxygen deprivation. Asthma attacks kill several hundred Americans a year; even attacks that are not lethal often last for long periods, and may lead to more or less permanent changes in the breathing apparatus.

Bronchitis, inflammation of the bronchial tree, leads to difficulty in expelling foreign matter from the lungs by coughing. The muscles surrounding the bronchial tubes weaken, and mucus accumulates. There is a progressive loss of breathing ability. Bronchitis is often accompanied by emphysema, a disease of the air sacs in the lungs (Figure 10-2). These air sacs tend to fuse, essentially coalescing from clusters of small pouches to form larger

[10] An exceedingly useful review is National Academy of Sciences (NAS), *Air quality*, chapter 4, Health effects of sulfur oxides; see also J. French et al., *The effect of sulfur dioxide and suspended sulfates on acute respiratory disease*; L. Lave and E. Seskin, *Air pollution and human health*; D. P. Rall, *Review of health effects of sulfur oxides*.

[11] NAS, *Air quality*.

[9] A. C. Hexter and J. R. Goldsmith, *Carbon monoxide: Association of community air pollution with mortality*.

ones. This is accompanied by a narrowing of the finer branches of the bronchial tree. The combined results are a reduction of total surface area for the exchange of oxygen between air and

blood stream and a reduction of the amount of air flow through the lungs. This process takes place gradually over a period of years, while the lungs become progressively less capable of providing oxygen for activity. The victim of fatal emphysema dies of suffocation. [12]

The available evidence suggests that sulfur dioxide alone, at concentrations commonly encountered in urban air, would not be able to cause the observed increases in bronchitis and emphysema; rather, there is a *synergism* between SO_2 and suspended particulate matter. This synergism probably involves the tendency of SO_2 adsorbed onto small particles to penetrate farther into the lung than SO_2 gas alone, and also involves the faster conversion of SO_2 into more dangerous sulfates in the presence of particles. [13]

Of the oxides of nitrogen, the most active biologically is NO_2. Its effects include reduction of the oxygencarrying capacity of the blood (like CO), bronchial and other lung damage (like SO_2), and acute pulmonary edema (accumulation of excess fluid in the lung, also caused by ozone). [14] Although atmospheric levels of NO2 rarely reach concentrations at which these direct effects can be demonstrated to occur, a major study of school children in Chattanooga, Tennessee, demonstrated an increase in respiratory infections at a concentration of NO_2 that is regularly exceeded in 85 percent of all U.S. cities of over 500,000 population. [15]

Most of the many kinds of hydrocarbons emitted into the atmosphere have not been shown by themselves to be harmful to human health at levels usually encountered in urban air (1 to 4 ppm in most cities). The lowest demonstrated effect is irritation of mucous membranes by benzene at around 100 ppm. [16] The concentration at which hydrocarbons strongly suspected to be carcinogens, such as benzpyrene, may be harmful is not known.

Much of the concern about adverse effects on health of hydrocarbons and nitrogen oxides stems from the photochemical smog these two classes of pollutants combine to produce under the influence of sunlight. The main ingredient of such smog is ozone, which kills experimental animals by damaging the respiratory tract at concentrations in the tens of parts per million, which causes similar damage (but without mortality) at 5 to 10 parts per million, and which produces symptoms of bronchitis and emphysema (again, in animals) under long-term exposure at around 1 ppm. Statistical evidence in Los Angeles, with the worst photochemical smog in the country (see below), reveals no mortality or morbidity (disease) effects, but does reveal some correlation of oxidant levels with reduced lung function in respiratory patients and with impairment of athletic performance. Constituents of photochemical smog other than ozone produce eye irritation whenever total oxidant concentrations exceed about 0. 10 ppm. [17]

The disease effects of particulates take several forms: synergistic effects with other pollutants, as discussed above; the direct effects of sulfate particulates (increasingly well-studied in recent years and also mentioned above); and causation of cancer or other ailments by specific toxic ingredients, such as cadmium, lead, mercury, beryllium, and asbestos. The latter effects are treated below.

Unfortunately, it is difficult to make definitive statue+00AD ments about the precise health effects of air pollution, for reasons explained in Box 10-2. In spite of these problems, the evidence pointing to the severity of air pollution as a definite hazard is now massive. Consider

these sample findings. Cigarette smokers from smoggy St. Louis, Missouri, have roughly 4 times the incidence of emphysema as smokers from relatively smog-free Winnipeg, Manitoba. At certain times, air pollution increases the frequency of head colds. Ten years after a smog disaster in Donora, Pennsylvania, in 1948, those residents who had reported severe effects during the smog showed the highest death rates. (This, of course, does not prove that the smog hurried them toward their graves-perhaps only previously weakened people suffered severe effects.) Pneumonia deaths are more frequent in areas of

BOX 10-2 Assaying the Hazards of Pollutants

A hint of the difficulty of relating specific adverse effects on health to specific pollutants is provided by the example of cigarette-smoking. From the analyses point of view, assaying the health hazards of smoking should be far easier than is the case for most contaminants. In smoking, the source of the pollutant is relatively uniform in character (although the number of potentially hazardous substances in tobacco smoke is large), and the intensity and duration of exposure are known with reasonable accuracy for a large number of individuals. Even with these advantages, it took many years to do the research required to demonstrate convincingly a close association between smoking and heart disease and lung cancer. (Whether the smoking public even today is convinced is arguable).The difficulties facing toxicologists and epidemiologists in most other cases are much greater. We summarize some of the most important of these difficulties here. (Some apply to the smoking problem, too, but many do not.)

Pollutants are numerous and varied, and many of them are difficult to detect. Their concentrations vary geographically. In many areas, techniques for monitoring pollutants are highly inadequate, and longterm records are unavailable. Yet long periods of study are usually needed to reveal delayed and chronic effects.

It is often impossible to determine with precision the degree of exposure of a given individual to specific pollutants.

Which pollutant among many candidates is actually responsible for the suspected damage is often unknown. In many if not most cases, the agent doing the damage is a "secondary" substance produced by the chemical or radioactive transformation of the "primary" pollutant produced by human activity.

The preceding difficulty is multiplied many times over by the importance of *synergisms*, wherein the effect of two agents acting in concert exceeds the sum of the effects to be expected if the two acted individually. One or both agents in a synergism might be secondary substances produced from pollutants, one might be a naturally occurring agent, or there might be more than two actors involved.

Persons being studied for effects of pollutants may differ in many respects besides their degree of exposure to the suspected agent--for example, in socioeconomic class, sex, age,

physiological susceptibility to certain contaminants, occupational exposure to pollutants, and smoking habits. Variation of many factors at once in the sample population makes it easy to be misled about what is causing what.

Official records of incidence of disease and causes of death are somewhat unreliable, for two main reasons: first, diagnostic procedures, nomenclature, and the knowledge of the average physician vary with time and probably, to some extent, regionally as well; second, final causes of death are often different from the malady that brought death near, and the primary maladies are often not listed on the death certificate.

Controlled experiments with laboratory animals are of limited usefulness because of differences in physiology between the experimental animals and humans. Effects with a long latency period between insult and symptoms may not appear at all in animals whose natural lifespan is short. For these reasons, the extent to which animal data can be used to infer effects of pollutants on humans is often controversial. The animals that most resemble humans physiologically--the large primates--are so expensive (and, in some cases, endangered as species) that experiments involving substantial numbers are impracticable.

Very large sample populations (of animals or people) are needed to investigate effects at low doses of pollutants, where only a small percentage of those exposed will manifest the suspected effect even if the cause-effect relationship is genuine. It cannot be assumed that the dose-response relation is linear with dose, that is, that effects occur in the same direct proportion to dose from low doses to high ones. For some agents, low doses may produce more damage per unit of exposure than high doses; for others, there may be a threshold in dose below which no ill effect occurs. It has been customary in regulation of pollution to assume that evidence obtained at high doses can be extrapolated linearly to low ones; this will be overcautious in some cases and not cautious enough in others.

high pollution. Chronic bronchitis is more serious among British postmen who work in areas of high air pollution than in those who serve in relatively smog-free areas. Emphysema death rates have skyrocketed as urban air pollution has increased (although incidence of this disease is also high in rural areas, where dust is probably the culprit). The United Kingdom has higher overall rates of air pollution than the United States, and death from lung cancer is more than twice as common among British men as it is among American men. The lungcancer death rates in the United Kingdom are correlated with the density of atmospheric smoke. The lung-cancer rate for men over 45 in the smoggiest part of Staten Island, New York, is 55 per 100,000. In a less smoggy area just a few miles away, the rate is 40 per 100,000. [18]

Some of the effects just described are still the subject of controversy within the scientific community, undoubtedly because of the sorts of difficulties described in Box 10-2. However, much of the debate resembles the cigarette-smoking-and-cancer arguments of a few years ago--the evidence is "only statistical," but to those knowledgeable in statistics, it is already persuasive and is becoming overwhelming. In short, air pollution kills. Since it usually kills slowly and unobtrusively, however, the resulting deaths are not dramatically called to the attention of the public. Estimates of the annual American financial loss resulting from air pollution's effects on health run as high as 14 to 29 billion dollars. A 1970 study put the *lower limit* on the annual savings in medical care and lost income that a 50-percent reduction in air pollution in major urban regions would provide at slightly more than 2 billion dollars. [19]

Standards

Standards imposed by federal and state agencies for permissable degrees of air pollution by major contaminants fall into two basic categories. *Ambient air-quality standards* specify the concentrations of various pollutants permitted to exist in the lower level of the atmosphere where people, other organisms, and property can be exposed to them; these standards are generally given in parts per million (by volume) or micrograms of contaminant per cubic meter of air. *Emission standards* specify what quantities of different contaminants may be released per unit of time or per unit of activity (e.g., miles driven in an automobile) by various pollutant sources.

Operationally, the setting and enforcement of emission standards are the principal tools for seeing that ambient air standards are met. It is exceedingly difficult, however, to relate emissions to concentrations in an exact quantitative way. One knows, of course, that higher emissions mean higher ambient concentrations, all else being equal; but the precise relation depends on the geographical distribution of a tremendous variety of sources (from automobiles to dry-cleaning establishments to refineries and electric-power plants), on the interaction of these with meteorological conditions that change not only from day to day but sometimes from minute to minute, and on complex chemical and photochemical reactions the pollutants undergo with each other and with other atmospheric constituents. This clearly is a case where statistical correlation of emissions and ambient air quality would be a useful approach. But this, too, is difficult because (1) there generally are not enough measuring stations to get an accurate picture of the spatial distribution of ambient air quality, and (2) it is hard to know what total emissions were in a given region on a given day. Even if one knows the emission characteristics of all sources, one must also know the intensity with which all those sources were in use on the day in question. [20]

Emission standards are set, then, partly on the basis of incomplete analytic models of the processes relating emissions to ambient air quality, partly on the basis of an incomplete body of statistical data, and partly by the outcome of competing political pressures generated by people in favor of clean air, on the one hand, and the pollution-producing industries and manufacturers of

pollution-producing devices on the other. Ambient airquality standards are supposed to be set to protect public health and property, although, again, the data and theory needed to do this properly are incomplete, and political pressures and value judgments cannot help entering into the process. As an example of the latter: should standards be set to protect the "average" member of the public or the most sensitive member of the public--the asthmatic, the very old, the very young?

Emissions standards, once set, can be enforced by spot-checking individual sources (for example, automobiles or power plants) for compliance and by fining or shutting down violators. Ambient standards as such cannot be enforced, but it is not uncommon to try to alleviate the worst conditions by requiring or encouraging reduced use of major sources (even if they meet established emission standards) on days when meteorological conditions threaten to make ambient air quality especially bad.

The ambient air-quality standards in force in the United States in 1975 are summarized in Table 10-2. "Primary standards" are designed to protect public health and "secondary standards" to protect public welfare (meaning property and aesthetics). Amendments to the *Clean Air Act* passed by Congress in 1970 set mid-1975 as the deadline for achieving the primary standards, but the deadline was not met; at the deadline, the standards were being violated for one or more pollutants in 156 of the nation's 247 air quality control regions. [21] Although it is sometimes suggested that the ambient standards incorporate large margins of safety between the specified concentrations and those at which actual adverse effects on health would be expected, major reviews by the National Academy of Sciences have affirmed repeatedly that evidence for such

margins is absent and that no scientific basis existed at the time of these reviews for revising the standards. [22] (Interestingly, there are no standards at all for indoor air quality in homes and public buildings--see Box 10-3.)

The emissions standards for automobiles that have been developed as part of the attempt to improve ambient air quality have had a complex history. *The Clean Air Act Amendments of 1970* established specific goals for reducing emissions from autos, but they also permitted the Environmental Protection Agency (EPA) considerable leeway in extending the amount of time allowed for automobile manufacturers to comply. An extension of one year was made by the administrator of EPA in April 1973 for 1975 standards, with interim standards to be enforced in place of the statutory requirements. Under the pressure of the "energy crisis" in 1974, and responding to the questionable assertion that tight emission control and good fuel economy are incompatible, Congress entered the arena once more with amendments to

[21]Council on Environmental Quality (CEQ), *Environmental quality, 1975*, pp. 299 ff.
[22]NAS, *Air quality*; NAS, *Air quality and automobile emission control*, vol. 3.

the *Clean Air Act* that extended the interim standards for hydrocarbons and carbon monoxide and replaced the statutory standard for nitrogen oxides with a new one. [23] All the while, the state of California has consistently imposed standards stricter than the federal ones. The history of automotive emission standards and their possible status through 1981 are summarized in Table 10-3.
